**ABSTRACT**

In the last decade, many business applications have moved into the cloud. In particular, the “database-as-a-service” paradigm has become mainstream. While existing multi-tenant data management systems focus on single-tenant query processing, we believe that it is time to rethink how queries can be processed across multiple tenants in such a way that we do not only gain more valuable insights, but also at minimal cost. As we will argue in this paper, standard SQL semantics are insufficient to process cross-tenant queries in an unambiguous way, which is why existing systems use other, expensive means like ETL or data integration instead. We first propose MTSQL, an extension to standard SQL, which fixes the ambiguity problem. Next, we present MTBase, a query processing middleware that efficiently processes MTSQL on top of SQL. As we will see, there is a canonical, provably correct, rewrite algorithm from MTSQL to SQL, which may however result in poor query execution performance, even on high-performance database products. We further show that with carefully-designed optimizations, execution times can be reduced in such ways that the difference to single-tenant queries becomes marginal.

1 INTRODUCTION

Indisputably, cloud computing is one of the fastest growing businesses related to the field of computer science. Cloud providers promise good elasticity, high availability and a fair pay-as-you-go pricing model to their tenants. Moreover, corporations are no longer required to rely on on-premise infrastructure which is typically costly to acquire and maintain. While it is still an open research question whether and how these good promises can be kept with regard to databases [19, 32], all the big players, like Google [30], Amazon [8], Microsoft [34] and recently Oracle [38], have launched their own Database-as-a-Service (DaaS) cloud products.

All these products host massive amounts of data from multiple clients and are therefore multi-tenant. However, as pointed out by Chong et al. [17], the term multi-tenant database is ambiguous and can refer to a variety of DaaS schemes with different degrees of logical data sharing between tenants. On the other hand, as argued by Aulbach et al. [11], multi-tenant databases not only differ in the way how tenants logically share information, but also how information is physically separated. We conclude that the multi-tenancy spectrum consists of four different schemes: First, there are DaaS products that offer each tenant her proper database while relying on shared resources (SR), i.e. hardware (e.g. CPU, network, storage) and/or software (e.g. buffer pools, system tables, system users, etc.). Examples include SAP HANA [42], SqlVM [36], RelationalCloud [35], Snowflake [18] and Oracle’s multitenant container database (CDB) [40]. Next, there are systems that share databases (SD), but each tenant gets her own set of tables within such a database, as for instance Azure SQL DB [20].

Finally, there are the two schemes where tenants not only share a database, but also the table layout (schema). Either, as for example in Apache Phoenix [9], tenants still have their private tables, but these tables share the same (logical) schema (SS), or the data of different tenants is consolidated into shared tables (ST) which is hence the layout with the highest degree of physical and logical sharing. Prominent examples for ST include Oracle’s Virtual Private Database [3] as well as different Microsoft Azure DaaS offerings [33, 34], SS and ST layouts are not only used in DaaS, but also in Software-as-a-Service (SaaS) platforms, as for example in Salesforce [44]. The main reason why all these commercial systems prefer ST over SS is cost [11]. Moreover, if the number of tenants exceeds the number of tables a database can hold, which is typically a number in the range of ten thousands, SS becomes prohibitive. Conversely, ST databases can easily accommodate hundred thousands to even millions of tenants.

An important feature of multi-tenant databases, which, to the best of our knowledge, no DaaS or SaaS natively supports today, is cross-tenant query processing, i.e. combining data of different tenants and query this unified data set as if it was single-tenant, using SQL. In order to illustrate that cross-tenant query processing is indeed a highly relevant requirement, let us have a look at one of the many initiatives to democratize the use of personal data, the Health Data Cooperative (HDC) [27]. In HDC, all patient data is stored in a single, multi-tenant SaaS database, each patient being a tenant managing her own data. For clinical studies, however, it is essential to be able to run queries over a cohort of patients who give their consent, or, in other words enable cross-tenant query processing. Clearly, the health data use case has also another big challenge, which is data privacy. This aspect, despite being out of the scope of this paper, is considered essential future work.

There are several existing approaches to cross-tenant query processing which are summarized in Figure 1. The first approach is data warehousing [29] where data is extracted from several data sources (tenant databases/tables), transformed into one common format and finally loaded into a new database where it can be queried by the client. This approach has high integration transparency in the sense that once the data is loaded, it is in the expected format as required by the client and she can ask any query she wants, using plain SQL. Moreover, as all data is in a single place, queries can be optimized. On the down-side of this approach – well-known and argued by many [10, 14, 37] – are costs in terms of both, developing and maintaining such ETL
Figure 1: Cross-tenant query processing systems

pipelines, as well as maintaining a separate copy of the data. Another disadvantage is data staleness in the presence of frequent updates.

Federated Databases [26, 31] reduce some of these costs by integrating data on demand, i.e. there is no data copying. However, maintenance costs are still significant as for every new data source, a new integrator/wrapper has to be developed. As data resides in different places (and different formats), queries can only be optimized to a very small extent (if at all), which is why the degree of integration transparency is considered sub-optimal. Finally, systems like SAP HANA [42] and Salesforce [44], which are mainly tailored towards single-tenant queries, offer some degree of cross-tenant query processing, but only through their application logic, not natively. This means that the set of queries that can be asked is limited, accounting for low integration transparency.

We believe that the reason why none of these previous works uses a native approach, i.e. SQL plus transparent rewriting, for cross-tenant query processing is that there is an ambiguity problem. Consider, for instance, the ST database in Figure 2, which we are going to use as a running example throughout the paper. Further assume that we would like to query the joint dataset of tenants 0 and 1: As shown on the left, we might want to join Employees with Roles. Joining on role_id alone is not enough as this would also join Alice with executive, which does not correspond to the expected output because Alice is a professor, and only a professor. In this case, a rewrite algorithm would have to add the tenant-ID ttid to the join predicate. On the other hand, joining the Employees table with itself on E1.age = E2.age, as illustrated on the right, does not require ttid to be present in the join predicate because it actually makes sense to include results like (Alice, Ed) because they are indeed the same age.

An additional challenging fact is that different tenants might store their data in different units. In our example, tenant 0 might store her employees’ salaries in a different currency than tenant 1. If this is the case, computing the average salary across all tenants clearly involves some value conversions that should, ideally, happen without the client noticing or even worrying about.

This paper presents MTSQL as a solution to these ambiguity problems, following a native approach. MTSQL extends the SQL API and provides additional data definition syntax and corresponding semantics specifically-suited for cross-tenant query processing. It enables high integration transparency because once the schema is defined and the database connection established, any client, with any desired data format, can ask any query at any time and do so by using nothing else but plain SQL. Moreover, as data resides in a single database (SS or ST), queries can be aggressively optimized with respect to both, standard SQL semantics and additional MTSQL semantics. As MTSQL adopts the single-database layout, it is also very cost-effective, especially if used on top of ST. Also, data conversion only happens as needed, which perfectly fits the cloud’s pay-as-you-go cost model and thus makes MTSQL an attractive option to complement existing DaaS offerings.

Specifically, the paper makes the following contributions:

- It defines the syntax and semantics of MTSQL, a database language that extends SQL and solves the ambiguity problem for cross-tenant query processing.
- It presents the design and implementation of MTBase, a database middleware that executes MTSQL on top of any shared-table multi-tenant database.
- It studies MTSQL-specific optimizations for query execution in MTBase.
- It extends the well-known TPC-H benchmark in order to run and evaluate MTSQL workloads, resulting in new benchmark called MT-H.
- It evaluates the performance and the implementation correctness of MTBase with MT-H, concluding with satisfactory results.

The rest of this paper is organized as follows: Section 2 defines MTSQL, while Section 3 gives an overview on MTBase. Section 4 discusses the MTSQL-specific optimizations which are validated in Section 5. Section 6 shortly summarizes lines of related work, specifically focusing on the relation of MTSQL to data integration as well as data privacy, whereas the paper is concluded in Section 7.

2 MTSQL

In order to model the specific aspects of cross-tenant query processing in multi-tenant databases, we developed MTSQL, which will be described in this section. MTSQL extends SQL in two ways: First, it extends the SQL interface with two additional parameters, C and D. C is the tenant ID (or ttid for short) of the client who submits a statement and hence determines the format in which the result must be presented. The data set, D, is a set of ttids that refer to the tenants whose data the client wants to query. Secondly, MTSQL extends the syntax and semantics of SQL, as well as its Data Definition Language (DDL), Data Manipulation...
Language (DML) and Data Control Language (DCL, consists of GRANT and REVOKE statements).

As mentioned in the introduction, there are several ways how a multi-tenant database can be laid out: Figure 2 shows an example of the ST scheme, also referred to as basic layout in related work [11] where tenants’ data is consolidated using the same tables. Meanwhile, there also exists the SS scheme, also referred to as private table layout, where every tenant has its own set of tables. In that scheme, data ownership is defined as part of the table name (e.g. Roles_1, Roles_2, ...) while in ST, records are explicitly annotated with the tid of their data owner, using an extra meta column in the table which is invisible to the client.

As these two approaches are semantically equivalent, the MTSQL semantics that we are about to define, apply to both. In the case of the SS, applying a statement s with respect to D simply means to apply s to the logical union of all private tables owned by a tenant in D. In SS, s is applied to tables filtered according to D. In order to keep the presentation simple, the rest of this paper assumes an ST scheme, but sometimes defines semantics with respect to SS if that makes the presentation easier to understand.

2.1 MTSQL API

MTSQL needs a way to incorporate the additional parameters C and D. As C is the tid of the tenant that issues a statement, we assume it is implicitly given by the SQL connection string. tids are not only used for identification and access control, but also for data ownership. While this paper uses integers for simplicity reasons, tids can have any data type, in particular they can also be database user names.

```
LISTING 1: Simple SCOPE expression using IN

SET SCOPE = "IN (1,3,41)";
```

```
LISTING 2: Complex SCOPE expression with sub-query

D is defined using the MTSQL-specific SCOPE runtime parameter on the SQL connection. This parameter can be set in two different ways: Either, as shown in Listing 1, as simple scope with an IN list stating the set of tids that should be queried, or as in Listing 2, as a sub-query with a FROM and a WHERE clause (complex scope). The semantics of the latter is that every tenant that owns at least one record in one of the tables mentioned in the FROM clause that satisfies the WHERE clause is part of D. The SCOPE variable defaults to {C}, which means that by default a client processes only her own data. Defining a simple scope with an empty IN list, on the other hand, makes D include all the tenants present in the database.

Making C and D part of the connection allowed for a clear separation between the end users of MTSQL (for which tids do not make much sense and hence remain invisible) and administrators/programmers that manage connections (and are aware of tids).

2.2 Data Definition Language

DDL statements are issued by a special role called the data modeller. In a multi-tenant application, this would be the SaaS provider (e.g. a Salesforce administrator) or the provider of a specific application. However, the data modeller can delegate this privilege to any tenant she trusts using a GRANT statement, as will be described in Section 2.3.

There are two types of tables in MTSQL: tables that contain common knowledge shared by everybody (like the Regions table in TPC-H [43]) and those that contain data of a specific tenant (i.e. Employees and Roles in Figure 2). More formally, we define the table generality of Regions as global and the one of Employees as tenant-specific. In order to process queries across tenants, MTSQL needs a way to distinguish whether an attribute is comparable (can be directly compared against attribute values of other tenants), convertible (can be compared against attribute values of other tenants after applying a well-defined conversion function) or tenant-specific (it does semantically not make sense to compare against attribute values of other tenants).

An overview of these types of attribute comparability, together with examples from Figure 2, is shown in Table 1.

```
<table>
<thead>
<tr>
<th>type</th>
<th>description</th>
<th>examples</th>
</tr>
</thead>
<tbody>
<tr>
<td>comparable</td>
<td>can be directly compared to and aggregated with</td>
<td>E_age, R_name</td>
</tr>
<tr>
<td></td>
<td>other values</td>
<td>E_salary</td>
</tr>
<tr>
<td>convertible</td>
<td>other values need to be converted to the format of</td>
<td>E_role_id, R_role_id</td>
</tr>
<tr>
<td></td>
<td>the current tenant before comparison or aggregation</td>
<td></td>
</tr>
<tr>
<td>tenant-specific</td>
<td>values of different tenants cannot be compared to</td>
<td></td>
</tr>
<tr>
<td></td>
<td>convertible attributes of other tenants).</td>
<td></td>
</tr>
</tbody>
</table>

Table 1: Overview on attribute comparability in MTSQL
```

2.2.1 CREATE TABLE Statement. The MTSQL-specific keywords for creating (or altering) tables are GLOBAL, SPECIFIC, COMPARABLE and CONVERTIBLE. An example of how they can be used is shown in Listing 3. Note that SPECIFIC can be used for tables and attributes. Moreover, using these keywords is optional as we define that tables are global by default, attributes of tenant-specific tables default to tenant-specific and those of global tables to comparable.²

```
LISTING 3: Exemplary MTSQL CREATE TABLE statement, MT-specific keywords marked in bold

CREATE TABLE Employees SPECIFIC (
  E_emp_id INTEGER NOT NULL SPECIFIC,
  E_name VARCHAR(25) NOT NULL SPECIFIC,
  E_role_id INTEGER NOT NULL SPECIFIC,
  E_salary VARCHAR(17) NOT NULL CONVERTIBLE
);

CONVERT CONSTRAINT fk_emp PRIMARY KEY (E_emp_id),
CONVERT CONSTRAINT fk_emp FOREIGN KEY (E_role_id) REFERENCES Roles (E_role_id);
```

2.2.2 Conversion Functions. Cross-tenant query processing requires the ability to execute comparison predicates on comparable and convertible attribute. While comparable attributes can be directly compared to each other, convertible attributes, as their name indicates, have to be converted first, using conversion functions. Each tenant has a pair of conversion functions for each attribute to translate from and to a well-defined universal format. More formally, a conversion function pair is defined as follows:

Definition 2.1. (toUniversal : X × T → X, fromUniversal : X × T → X) is a valid MTSQL conversion function pair for attribute A, where T is the set of tenants in the database and X is the domain of A, if and only if:

(i) There exists a universal format for attribute A:³

```
image(toUniversal(t1)) = image(toUniversal(t2)) = ... = image(toUniversal(tn))
```

(ii) For every tenant t ∈ T, the partial functions toUniversal(.t) and fromUniversal(.t) are bijective functions.

²Global tables (shared among all tenants!) can only have comparable attributes anyway.
³image(f) denotes the mathematical image, i.e. the range of function f.
(iii) \( \text{fromUniversal} \) is the inverse of \( \text{toUniversal} \): \( \forall t \in T, x \in X : \text{fromUniversal}(\text{toUniversal}(x,t), t) = x \)

These three properties imply the following two corollaries that we are going to need later in this paper:

**Corollary 1.** \( \text{toUniversal} \) and \( \text{fromUniversal} \) are equality preserving: \( \forall t \in T : \text{toUniversal}(x,t) = \text{toUniversal}(y,t) \Leftrightarrow x = y \Rightarrow \text{fromUniversal}(x,t) = \text{fromUniversal}(y,t) \)

**Corollary 2.** Values from any tenant \( t_i \) can be converted into the representation of any other tenant \( t_j \) by first applying \( \text{toUniversal}(-, t_j) \), followed by \( \text{fromUniversal}(-, t_j) \) while equality is preserved:

\[
\forall t_i, t_j \in T : x = \text{fromUniversal}(\text{toUniversal}(x,t_i), t_j) = \text{fromUniversal}(\text{toUniversal}(x,t_j), t_i)
\]

The reason why we opted for a two-step conversion through universal format is that it allows each tenant \( t_i \) to define her share of the conversion function pair, i.e. \( \text{toUniversal}(-, t_i) \) and \( \text{fromUniversal}(-, t_i) \), individually without the need of a central authority. Moreover, this design greatly reduces the overall number of partial conversion functions as we need at most \( 2 \cdot |T| \) partial function definitions, compared to \( |T|^2 \) functions in the case where we would define a direct conversion for every pair of tenants.

---

### Listing 4: Converting a phone number to universal form (without prefix), PostgreSQL syntax

```sql
CREATE FUNCTION phoneFromUniversal (VARCHAR(17), INTEGER)
AS ' SELECT SUBSTRING($1, CHAR_LENGTH(PT_prefix)+1) FROM Tenant, PhoneTransform
WHERE T_tenant_key = $2 AND T_phone_prefix_key = PT_phone_prefix_key;'
RETURNS VARCHAR(17)
LANGUAGE SQL IMMUTABLE;
```

### Listing 5: Converting to a specific phone number format, PostgreSQL syntax

Listings 4 and 5 show an example of such a conversion function pair. These functions are used to convert phone numbers with different prefixes, like “+”, “00” or any other specific country exit code \(^4\), and the universal format is a phone number without prefix. In this example, converting phone numbers simply means to lookup the tenant’s prefix and then either prepend or remove it, depending whether we convert from or to the universal format. Note that the exemplary code also contains the keyword IMMUTABLE to state that for a specific input the function always returns the same output, which is an important hint for the query optimizer. While this keyword is PostgreSQL-specific, some other vendors, but by far not all, offer a similar syntax.

It is important to mention that the equality-preserving property as mentioned in Corollary 1 is a minimal requirement for conversion functions to make sense in terms of producing coherent query results among different clients. There are, however, conversion functions that exhibit additional properties, for example:

- order-preserving with respect to tenant \( t \):
  \[
x < y \Rightarrow \text{toUniversal}(x,t) < \text{toUniversal}(y,t)
\]

---

\(^4\)The country exit code is a sequence of digits that you have to dial in order to inform the telco system that you want to call a number abroad. A full list of country exit codes can be found on [http://www.howtocallabroad.com/codes.html](http://www.howtocallabroad.com/codes.html).

---

### Listing 6: Converting a currency to universal format (USD), PostgreSQL syntax

```sql
CREATE FUNCTION currencyToUniversal (DECIMAL(15,2), INTEGER)
AS ' SELECT CT_from_universal*$1 FROM Tenant, CurrencyTransform
WHERE T_tenant_key = $2 AND T_currency_key = CT_currency_key;'
RETURNS DECIMAL(15,2)
LANGUAGE SQL IMMUTABLE;
```

### Listing 7: Converting from USD to a specific currency, PostgreSQL syntax

The conversion function examples shown in Listings 4 to 7 assume the existence of tables holding additional conversion information (CurrencyTransform and PhoneTransform) as well as a table with references into these tables (named Tenants table). The way how a tenant can define her portion of the conversion functions is then simply to choose a specific currency and phone format as part of an initial setup procedure. However, this is only one possible implementation. MTSQL does not make any assumptions or restrictions on the implementation of conversion function pairs themselves, as long as they satisfy the properties given in Definition 2.1.

MTSQL is not the first work that talks about conversion functions. In fact, there is an entire line of work that deals with data integration and in particular with schema mapping techniques \([11, 23, 25]\). These works mention and take into account conversion functions, like for example a multiplication or a division by a constant. More complex conversion functions, including regular-expression-based substitutions and other arithmetic operations, can be found in Potter’s Wheel \([41]\) where conversion is referred to as value translation. All these different conversion functions can potentially also be used in MTSQL which is, to the best of our knowledge, the first work that formally defines and categorizes conversion functions according to their properties.

#### 2.2.3 Integrity Constraints

MTSQL allows for global integrity constraints that every tenant has to adhere to (with respect to the entirety of her data) as well as tenant-specific integrity constraints (that tenants can additionally impose on their own data). These general ideas of this paper also apply to temporal databases.
data). An example of a global referential integrity constraint is shown in the end of Listing 3. This constraint means that for every tenant, for each entry of E_role_id, a corresponding entry R_role_id has to exist in Roles and must be owned by that same tenant. Consider for example employee John with R_role_id 0. The constraint implies that their must be a role 0 owned by tenant 0, which in that case is PhD student. If the constraint were only tenant-specific for tenant 1, John would not link to roles and E_role_id 0 would just be an arbitrary numerical value. In order to differentiate global from tenant-specific constraints, the scope is used.6

2.2.4 Other DDL Statements. CREATE VIEW statements look the same as in plain SQL. As for the other DDL statements, anyone with the necessary privilege can define global views on global and tenant-specific tables. Tenants are allowed to create their own, tenant-specific views (using the default scope). The selected data has to be presented in universal format if it is a global view and in the tenant-specific format otherwise. DROP VIEW, DROP TABLE and ALTER TABLE work the same way as in plain SQL.

2.3 Data Control Language
Let us have a look at the MTSQL GRANT statement:

```
GRANT <privileges> ON <database|table> TO <ttid>;
```

Listing 8: MTSQL GRANT syntax

As in plain SQL, this grants some set of access privileges (READ, INSERT, UPDATE and/or DELETE) to the tenant identified by ttid. In the context of MTSQL, however, this means that the privileges are granted with respect to C. Consider the following statement:

```
GRANT READ ON Employees TO 42;
```

Listing 9: Example of an MTSQL GRANT statement

In the private table layout, if C is 0, then this would grant tenant 42 read access to Employees_0, but if C is 1, tenant 42 would get read access to Employees_1 instead. If a grant statement grants to ALL, then the grant semantics also depend on D, more concretely if D = {0, 1}, tenant 42 would be granted to tenants 7, 11 and 15.

By default, a new tenant that joins an MTSQL system is granted the following privileges: READ access to global tables, READ, INSERT, UPDATE, DELETE, GRANT and REVOKE on his own instances of tenant-specific tables. In our example, this means that a new tenant 111 can read and modify data in Employees_111 and Roles_111. Next, a tenant can start asking around to get privileges on other tenants’ tables or also on global tables. The REVOKE statement, as in plain SQL, simply revokes privileges that were granted with GRANT.

2.4 Query Language
Just as in FlexScheme [11, 12], queries themselves are written in plain SQL and have to be filtered according to D. Whereas in FlexScheme D always equals |C| (a tenant can only query her own data), MTSQL allows cross-tenant query processing, which means that the data set can include other tenants than C and can in particular contain more than one element. As mentioned in the introduction, this creates some new challenges that have to be handled with special care.

2.4.1 Client Presentation. As soon as tenants can query other tenants’ data, the MTSQL engine has to be make sure to deliver results in the proper format. For instance, looking again at Figure 2, if tenant 0 queries the average salary of all employees of tenant 1, then this should be presented in USD because tenant 0 stores her own data in USD and expects other data to be in USD as well. Consequently, if tenant 1 would ask that same query, the result would be returned as is, namely in EUR.

2.4.2 Comparisons. Consider a join of Roles and Employees on role_id. As long as the dataset size is only one, such a join query has the same semantics as in plain SQL (or FlexScheme). However, as soon as tenant 1, for instance, asks this query with D = {0, 1}, the join has to take the ttids into account. The reason for this is that role_id is a tenant-specific attribute and should hence only be joined within the same tenant in order to prevent semantically wrong results like John being an intern (although tenant 0 does not have such a role) or Nancy being a professor (despite the fact that tenant 1 only has roles intern, researcher and executive).

Comparison or join predicates containing comparable and convertible attributes, on the other hand, just have to make sure that all data is brought into universal format before being compared. For instance, if tenant 0 wants to get the list of all employees (of both tenants) that earn more than 100K USD, all employee salaries have to be converted to USD before executing the comparison.

Finally, MTSQL does not allow to compare tenant-specific with other attributes. For instance, we see no way how it could make sense to compare E_role_id to something like E_age or E_salary.

2.5 Data Manipulation Language
MTSQL DML works the same way as in FlexScheme [11, 12] if D = |C|. Otherwise, if D ≠ |C|, the semantics of a DML statement are defined such that it is applied to each tenant in D separately. Constants, WHERE clauses and sub-queries are interpreted with respect to C, exactly the same way as for queries (c.f. Section 2.4). This implies that executing UPDATE or INSERT statements might involve value conversion to the proper tenant format(s).

3 MTBASE
Based on the concepts described in the previous section, we implemented MTBase, an open-source MTSQL engine [1]. As shown in Figure 3, the basic building block of MTBase is an MTSQL-to-SQL translation middleware sitting between a traditional DBMS and the client. In fact, as it communicates to the DBMS (and to the client) by the means of pure SQL, MTBase works in conjunction with any off-the-shelf DBMS. For performance reasons, the proxy maintains a cache of MT-specific meta data, which is persisted in the DBMS along with the actual user data. Conversion functions are implemented as UDFs that might involve additional meta tables, both of which are also persisted in the DBMS. MTBase implements the basic data layout, which means that data ownership is implemented as an additional (meta) ttid column in each tenant-specific table as illustrated in Figure 2. There are some dedicated meta tables: Tenant stores each tenant’s privileges and conversion information and Schema stores information about table and attribute comparability. Additional

---

6Remembering that an empty IN list refers all tenants, this is exactly what is used to indicate a global constraint. Additionally, all constraints created as part of a CREATE TABLE statement are global as well.
meta tables can (but do not have to) be used to implement conversion function pairs, as for example CurrencyTransform and PhoneTransform shown in Listings 4 to 7.

While the rewrite module was implemented in Haskell and compiled with GHC [6], the connection handling and the meta data cache maintenance was written in Python (and run with the Python2 interpreter) [4]. Haskell is handy because we can make full use of pattern matching and additive data types to implement the rewrite algorithm in a quick and easy-to-verify way, but any other functional language, like e.g. Scala [5], would also do the job. Likewise, there is nothing fundamental in using Python, any other framework that has a good-enough abstraction of SQL connections, e.g. JDBC [7], could be used.

Upon opening a connection at the middleware, the client’s ttid, C, is derived from the connection string and used throughout the entire lifetime of that connection. Whenever a client sends a MTSQL statement s, first if the current scope is complex, a SQL query q_s is derived from this scope and evaluated at the DBMS in order to determine the relevant dataset D. After that, D is compared against privileges of C in the Tenant table and ttids in D without the corresponding privilege are pruned, resulting in D’. Next, C, D’ and s are input into the rewrite algorithm which produces a rewritten SQL statement s’ which is then sent to the DBMS before relaying the result back to the client. Note that in order to guarantee correctness in the presence of updates, q_s and s’ have to be executed within the same transaction and with a consistency level at least repeatable-read [13] (even if the client does not impose any transactional guarantees). If s is a DDL statement, the middleware also updates the MT-Specific meta information in the DBMS and the cache.

The rest of this section explains the MTSQL-to-SQL rewrite algorithm in its canonical form and proves its correctness with respect to Section 2.4, while Section 4 shows how to optimize the rewritten queries such that they can be run on the DBMS with reasonable performance.

3.1 Canonical Query Rewrite Algorithm

Our proposed canonical MTSQL-to-SQL rewrite algorithm works top-down, starting with the outer-most SQL query and recursively rewriting sub-queries as they come along. For each sub-query, the SQL clauses are rewritten one-by-one. The algorithm makes sure that for each sub-query the following invariant holds: the result of the sub-query is filtered according to D’ and presented in the format required by C. Note that this invariant also helps to formally prove the correctness of the rewrite algorithm as we will show in Section 3.2.

The pseudo code of the general rewrite algorithm for rewriting a (sub-) query is shown in Algorithm 1. Note that FROM, GROUP BY, ORDER BY and HAVING clause can be rewritten without any additional context while SELECT and WHERE need the whole query as an input because they might need to check the FROM for additional information, for instance they must know to which original tables certain attributes belong.

Algorithm 1: Canonical Query Rewrite Algorithm

In the following, we will look at the rewrite functions for the different SQL clauses. Because of space constraints, we only provide the high-level ideas and illustrate them with suitable minimal examples. However, we strongly encourage the interested reader to check-out the Haskell code [2] which in fact almost reads like a mathematical definition of the rewrite algorithm.

SELECT The rewritten SELECT clause has to present every attribute a in C’s format, which, if a is a convertible, is achieved by two calls to the conversion function pair of a as can be seen in the examples of Listing 10 where -> simply denotes rewriting. If a is part of compound expression (as in line 6), it has to be converted before the functions (in that case AVG) are applied. Note that in order to make a potential super-query work correctly, we also rename the result of the conversion, either by the new name that it got anyway (as in line 6) or by the name that it had before (as in line 3). Rewriting a star expression (line 9) in the uppermost query also needs special attention, in order not to provide the client with confusing information, like ttids which should stay invisible.

Listing 10: Examples for Rewriting SELECT clause

WHERE There are essentially three steps that the algorithm has to perform in order to create a correctly rewritten WHERE clause (as shown in Listing 11). First, conversion functions have to be
added to each convertible attribute in each predicate in order make
sure that comparisons are executed in the correct (client) format
(lines 2 to 6). This happens the same way as for a SELECT clause.
Notably, all constants are always in C’s format because it is C
who asks the query. Second, for every predicate involving two or
more tenant-specific attributes, additional predicates on ttid have to be added (line 9), unless if the attributes are part of
the same table, which means they are owned by the same tenant
anyway. Predicates that contain tenant-specific together with other attributes cause the entire query to be rejected as was
required in Section 2.4.2. Last, but not least, for every base table in
the FROM clause, a so-called D-filter has to be added to the WHERE
clause (line 12). This filter makes sure that only the relevant data
(data that is owned by a tenant in D) gets processed.

```sql
1. SELECT ttid FROM Employees WHERE currencyFromUniversal(currencyToUniversal(E1.E_salary, ttid),C) > 180K;
2. SELECT ttid FROM Employees WHERE currencyFromUniversal{ currencyToUniversal(E_salary,ttid),C } > 180K;
```

Listing 12: Rewriting a complex SCOPE expression

### 3.2 Algorithm Correctness

**Proof.** We prove the correctness of the canonical rewrite algo-

```sql
1. SELECT ttid FROM Employees WHERE E_salary > 50K; -->
2. WHERE currencyFromUniversal{ currencyToUniversal(E_salary,ttid),C } > 50K;
```

```sql
3. WHERE currencyFromUniversal{ currencyToUniversal(E_salary,ttid),C } > 50K;
```

### 3.3 Rewriting DDL and DML Statements

Rewriting DDL and DML statements is very similar to rewriting
queries, in fact, predicates are rewritten in exactly the same way.

### 4 OPTIMIZATIONS

As we have seen, there is a canonical rewrite algorithm that
correctly rewrites MTSQL to SQL. However, we will show in Sec-
tion 5 that the rewritten queries often execute very slowly on the
underlying DBMS. The main reason for this is that the pure rewritten
queries call two conversion functions on every transformable
attribute of every record that is processed, which is extremely
expensive. Luckily, the execution costs can be reduced dramati-
cally when applying the optimization passes that we describe in
this section. As we assume the underlying DBMS to optimize
query execution anyway, we focus on optimizations that a DBMS
query optimizer cannot do (because it needs MT-specific context)
or does not do (because an optimization is not frequent enough
outside the context of MTBase). We differentiate between sen-
tic optimizations, which are always applied because they never

```sql
Input: C, ttid, D: set of ttids.
1. FROM Clause: MTSQL FROM clause
2. Output: SQL FROM clause
3. function RewriteFrom(C, D, FromClause)
4. res ← extractBaseTables (FromClause)
5. for all q ∈ extractSubQueries (FromClause) do
6. res ← res U { rewriteQuery (C, D, q)}
7. for all (q1, q2, cond) ∈ extractJoins (FromClause) do
8. q1′ ← rewriteQuery (C, D, q1)
9. q2′ ← rewriteQuery (C, D, q2)
10. cond′ ← rewriteWhere (C, D, cond)
11. return res
```

Algorithm 2: Rewriter Algorithm for FROM clause

GROUP-BY, ORDER-BY and HAVING clauses are basically rewritten the same way as the expressions in the SELECT clause. Some DBMSs might throw a

warning stating that grouping by a comparable attribute a is am-
biguous because the way we rewrite a in the WHERE clause and
rename it back to a, we could actually group by the original or
by the converted attribute a. However, the SQL standard clearly says
that in such a case, the result should be grouped by the outer-more
expression, which is exactly what we need. ORDER-BY clauses
need not be rewritten at all.

**SET SCOPE** Simple scopes do not have to be rewritten at all.
The FROM and WHERE clause of a complex scope are rewritten
the same way as in a sub-query. In order to make it a valid SQL
query, the rewrite algorithm adds a SELECT clause that projects
on the respective ttids as shown in Listing 12.
make a query slower and cost-based optimizations which are only applied if the predicted costs are smaller than in the original query.

There are a couple of special cases for $C$ and $D$ that allow to save conversion function calls, join predicates and/or D-filters. First, if $D$ includes all tenants, that means that we want to query all data and hence D-filters are no longer required as shown in line 5 of Listing 13. Second, as shown in line 6, if $|D| = 1$, we know that all data is from the same tenant, which means that including $ttid$ in the join predicate is no longer necessary. Last, if we know that a client queries her own data, i.e. $D = \{C\}$ corresponds to the default scope, we know that even convertible attributes are already in the correct format and can hence remove the conversion function calls (line 9).

There are a couple of other semantic optimizations that can be applied to rewritten queries. While client presentation push-up and conversion push-up minimize the number of conversions by delaying conversion to the latest possible moment, aggregation distribution takes into account specific properties of conversion functions (as mentioned in Section 2.2.2). If conversion functions are UDFs written in SQL it is also possible to inline them. This typically gives queries an additional speed up.

There are many analytical queries that contain aggregation functions, some of which aggregate on convertible attributes. The idea of aggregation distribution is to aggregate in two steps: First, aggregate per tenant in that specific tenant format (requires no conversion) and second, convert intermediary results to universal (one conversion per tenant), aggregate those and convert the final result to client format (one additional conversion). This simple idea reduces the number of conversion function calls for $N$ records and $T$ different data owners of these records from $(2N^2)$ to $(T + 1)$. This is significant because $T$ is typically much smaller than $N$ (and cannot be greater).

We would like to extend the notion of Gray et al. [24] and define the distributability of an aggregation function $a$ with respect to a conversion function pair $(f, t)$.
of all, we want to state that, as all conversion functions have scalar values as input and output, they are always fully-order-preserving, which means that COUNT can be distributed over all sorts of conversion functions. Next, we observe that all order-preserving functions preserve the minimum and the maximum of a given set of numbers, which is why MIN and MAX distribute over the first three categories of conversion functions displayed in Table 2. We further notice that if t to (and consequently also from) is a multiplication with a constant (first column of Table 2), t0 is fully-MIN-, fully-MAX- and fully-SUM-preserving, which is why these aggregation functions distribute. As SUM and COUNT distribute, AVG, an algebraic function, distributes as well.

Finally looking at the second column of Table 2, we see that even linear functions are SUM- and AVG-preserving. To see why, we can think about computing the average over all tenants as a weighted average of partial (per-tenant) averages for AVG and multiply these partial averages with the partial counts to reconstruct the total sum [15, Appendix B].

### Table 2: Distributability of different aggregation functions over different categories of conversion functions

<table>
<thead>
<tr>
<th>Function</th>

<td></td>
</tr>
</tbody>
</table>

Listing 16: Example for conversion function distribution

We conclude this subsection by observing that the conversion function pair for phone format (c.f. Listings 4 and 5) is not even order-preserving and does therefore not distribute while the pair for currency format (c.f. Listings 6 and 7) distributes over all standard SQL aggregation functions. An example of how this can be used is shown in Listing 16.

Listing 17: Example for function inlining

4.2.3 Function Inlining. As explained in Section 2.2.2, there are several ways how to define conversion functions. However, if they are defined as a SQL statement (potentially including lookups into meta tables), they can be directly inlined into the rewritten query in order to save calls to UDFs. Function inlining typically also enables the query optimizer of the underlying DBMS to optimize much more aggressively. In WHERE clauses, conversion functions could simply be inlined as sub-queries, which, however often results in sub-optimal performance as calling a sub-query on each conversion is not much cheaper than calling the corresponding UDF. For SELECT clauses, the SQL standard does anyway not allow to inline as a sub-query as this can result in attributes not being contained neither in an aggregate function nor in the GROUP BY clause, which is why most commercial DBMS reject such queries (while PostgreSQL, for instance executes them anyway). This is why the proper way to inline functions is by using a join as shown in Listing 17. Our results in Section 5 suggest that function inlining, though producing complex-looking SQL queries, results in very good query execution performance.

It is important to mention that function inlining should only happen after the other semantic optimization passes because these other passes are able to reduce the number of required UDF calls, while function inlining can only make a UDF call faster. Furthermore, it is important to understand that, while some clever query optimizers do indeed inline UDF calls already, none of the query optimizers that we looked at seems to perform client presentation and conversion push-up, let alone aggregation distribution, despite the fact that the foundation for these transformations [24, 28] have been established already more than 20 years ago.

### 5 EXPERIMENTS AND RESULTS

This section presents the evaluation of MTBase using an extension from the well-known TPC-H benchmark [43], called MT-H [15]. We first evaluated the benefits of different optimization steps from Section 4 and found that the combination of all of these steps brings the biggest benefit. Second, we analyzed how MTBase scales with an increasing number of tenants. With all optimizations applied and for a dataset of 100 GB on a single machine, MTBase scales up to thousands of tenants with very little overhead. We also validated result correctness as explained in Section 5.1 and can report only positive results.

5.1 MT-H Benchmark

MT-H uses the same database schema as TPC-H, but considers the Customer, Order, and Lineitem tables tenant-specific and the remaining tables global. Attributes $C\_acctbal$, $O\_totalprice$, and $L\_extendedprice$ are considered convertible with respect to the conversion functions of Listings 6 and 7 and C_phone with respect to Listings 4 and 5. While C_custkey, O_orderkey, O_custkey, L_orderkey are tenant-specific, all remaining attributes are comparable. A detailed description on this benchmark, including the validation of query results, can be found in our technical report [15].

### 5.2 Setup

In our experiments, we used the following two setups: The first setup is a PostgreSQL 9.6 Beta installation, running on Debian Linux 4.1.12 on a 4x16 Core AMD Opteron 6174 processor with 256 GB of main memory. The second installation runs a commercial database (which we will call System C) on a commercial operating system and on the same processor with 512 GB of main memory. Although both machines have enough secondary storage capacity available, we decided to configure both database management systems to use in-memory backed files in order to achieve the best performance possible. Moreover, we configured the systems to use all available threads, which enabled intra-query parallelism.

### 5.3 Workload and Methodology

As the MT-H benchmark has a lot of parameters and in order to make things more concrete, we worked with the following two scenarios: Scenario 1 handles the data of a business alliance of a couple of small to mid-sized enterprises, which means there are 10 tenants with $s_f = 1$ and each of them owns more or less
the same amount of data (\(p=\text{uniform}\)). Scenario 2 simulates the HDC use case [27] and hence needs to be a huge database (\(s_f=100\)) of medical records coming from thousands of tenants, like hospitals and private practices. Some of these institutions have vast amounts of data while others only handle a couple of patients (\(p=\text{zipf}\)). A research institution wants to query the entire database (\(D=1,2,...,T\)) in order to gather new insights for the development of a new treatment. We looked at this scenario for different numbers of \(T\).

In order to evaluate the overhead of cross-tenant query processing in MTBase compared to single-tenant query processing, we also measured the standard TPC-H queries with different scaling factors. When \(D\) was set to all tenants, we compared to TPC-H with the same scaling factor as MT-H. For the cases where \(D\) had only one tenant (out of ten), we compared with TPC-H with a scaling factor ten times smaller.

Every query run was repeated three times in order to ensure stable results. We noticed that three runs are needed for the response times to converge (within 2\%). Thus we always report the last measured response time for each query with two significant digits.

All experiments were executed with both setups (PostgreSQL and System C). Whereas the major findings were the same on both systems, PostgreSQL optimizes conversion functions (UDFs) much better by caching their results. System C, on the other hand does not allow UDFs to be defined as deterministic and hence cannot cache conversion results. This eliminates the effect of conversion push-up when applied to comparison predicates where we cannot cache conversion results. This eliminates the effect of conversion push-up when applied to comparison predicates where we cannot cache conversion results.

### 5.4 Benefit of Optimizations

In order to test the benefit of the different combinations of optimizations applied, we tested Scenario 1 with different optimization levels as shown in Table 6. From \(o1\) to \(o4\) we added optimizations incrementally, while the last optimization level (\(\text{inl-only}\)) only applied trivial optimizations and function inlining in order to test whether the other optimizations are useful at all.

Table 3 shows the MT-H queries for different optimization levels and Scenario 1 (\(s_f=1, T=10\)) where client 1 queries her own data. As we can see, in that case, applying trivial optimizations in \(o1\) is enough because these already eliminate all conversion functions and joins and only the D-filters remain. Executing these filters seems to be very inexpensive because most response times of the optimized queries are close to the baseline. TPC-H with \(s_f=0.1\). Queries 2, 11 and 16 however, take roughly ten times longer than the baseline. This is not surprising when taken into account that these queries only operate on shared tables which have ten times more data than in TPC-H. The same effect can be observed in Q09 where a significant part of the joined tables are shared.

Table 4 shows similar results, but for \(D = 2\), which means that now conversion functions can no longer be optimized away.
While most of the queries show a similar behaviour than in the previous experiment, for the ones that involve a lot of conversion functions (i.e. queries 1, 6 and 22), we see how the performance becomes better with each optimization pass added. We also notice that while function inlining is very beneficial in general, it is even more so when combined with the other optimizations.

Finally, Table 5 shows the results where we query all data, i.e. \( D = \{ 1, 2, \ldots, 10 \} \). This experiment involves even more conversion functions from all the different tenant formats into universal. In particular, when looking again at queries 1, 6 and 22, we observe the great benefit of conversion function distribution (added with optimization level \( o3 \)), which, in turn, only works as great in conjunction with client and conversion function push-up because aggregation typically happens in the outermost query while conversion happens in the sub-queries. Overall, \( o4 \), which contains all optimization passes that MTBase offers, is the clear winner.

### 5.5 Cross-Tenant Query Processing at Large

In our final experiment, we evaluated the cost of cross-tenant query processing up to thousands of tenants. More concretely, we measured the response time of conversion-intensive MT-H queries (queries 1, 6 and 22) for a varying number of tenants between 1 and 100,000, for a large dataset where \( sf = 100 \) and for the best optimization level (\( o4 \)) as well as for inlining-only. The obtained results were then compared to plain TPC-H with \( sf = 100 \), as shown in Figure 4. First of all, we notice that the cost overhead compared to single-tenant query-processing (TPC-H) stays below a factor of 2 and in general increases very moderately with the number of tenants. An interesting artifact can be observed for query 22 where MT-H for one tenant executes faster than plain TPC-H. The reason for this is a sub-optimal optimization decision in PostgreSQL: one of the most expensive parts of query 22, namely to find customers with a specific country code, is executed with a parallel scan in MT-H while no parallelism is used in the case of TPC-H.

## 6 RELATED WORK

MTBase builds heavily on and extends a lot of related work. This section gives a brief summary of the most prominent lines of work that influenced our design.

**Data Integration** Data integration (DI) is generally about finding schema and data mappings between the original schemas of different data sources and a target schema specified by the client application [23, 25, 41]. As such, DI techniques are applicable to the entire spectrum of multi-tenant databases because even if tenants use different schemas or databases, these techniques can identify correlations and hence extract useful information. Our work embraces and builds on top of the latest DI work, solving the DI problem very efficiently for a specific case (SS and ST). More concretely, we automatically determine join predicates from schema meta data and optimize conversion functions similar to those used in DI by thoroughly analyzing and exploiting their algebraic properties. In addition, instead of translating data into a specific client format (and update periodically), we convert it to any required client format efficiently and just-in-time.

**Database Federation** DI is often combined with database federation [26, 31], which means that there exist small program modules (called integrators, mediators or simply wrappers) to map data from different sources (possibly not all of them SQL databases) into one common format. While data federation generalizes well across the entire spectrum of multi-tenant databases, maintaining such wrapper architectures is expensive, both in terms of code maintenance and update processing. Conversely, MTSQL enables cross-tenant query processing in a more efficient and flexible way in the context of SS and ST databases.

**Data Warehousing** Another approach how data integration can happen is during extract-transform-load (ETL) operations from different (OLTP) databases into a data warehouse [29]. Data warehouses have the well-known drawbacks that there are costly to maintain and that the data is possibly outdated [10, 14, 37]. Meanwhile, MTBase was specifically designed to work well in the context of integrated OLTP/OLAP systems, also known as hybrid transaction-analytical processing (HTAP) systems, and could therefore be advocated as in-situ or just-in-time data integration. Another interesting approach to just-in-time, respectively on-demand data integration, are lenses [45] which allow to speed up ETL processes by lowering the result accuracy to the specific level required by the application.

**Shared-resources (SR) systems** In related work, this approach is also often called database virtualization or database as a service (DaaS) when it is used in the cloud context. Important lines of work in this domain include (but are not limited to) SqlVM/Azure SQL DB [20, 36], RelationalCloud [35], SAP-HANA [42], Snowflake [18] and Oracle’s multitenant container database (CDB) [40], most of which is well summarized in [22]. MTBase complements these systems by providing a platform that can accommodate more, but typically smaller tenants.

**Shared-databases (SD) systems** This approach, while appearing in the spectrum of multi-tenant databases by Chong et al. [17], is rare in practice. Sql/Azure DB [20] seems to be the only product that has an implementation of this approach. However, even Microsoft strongly advises against using SD and instead recommends to either use SR or ST [34].
Shared-tables (ST) systems: Work in that area includes Sales-force [44], Apache Phoenix [9], FlexScheme [11, 12] and Azure SQL Database [34]. Their common idea, as in MSQL, is to use an invisible tenant identifier to identify which records belong to which tenant and rewire SQL queries in order to include filters on this ttid. MSQL extends these systems by providing the necessary features for cross-tenant query processing.

Privacy/Confidentiality: Clearly, cross-tenant query processing almost immediately raises the question of data confidentiality. In the case of the HDC, for instance, patients might consent to their data being used in aggregated analytics, but they most certainly would not want sensitive, personal information, like their social security number, to appear in any report. While it is out of the scope of this paper to thoroughly discuss data confidentiality in a multi-tenant system, this work establishes proper syntax and semantics for cross-tenant query processing, which lays the ground for building appropriate encryption mechanisms [16, 21] atop as is sketched in our technical report [15].

UDFs and Complex Expressions: Oracle MLE [39] is a system that allows for highly-optimized execution of user-defined functions, which makes it a promising candidate to further investigate optimization of conversion functions. For instance, we would like to look at optimizing complex expressions, containing several nested user-defined function calls, as a whole.

7 CONCLUSION

This paper presented MSQL, a new language to address cross-tenant query processing in multi-tenant databases. MSQL extends SQL with multi-tenant-aware syntax and semantics, which allows to efficiently optimize and execute cross-tenant queries in MMBase. MMBase is an open-source system that implements MSQL. At its core, it is an MSQL-to-SQL rewrite middleware sitting between a client and any multi-tenant DBMS of choice. The performance evaluation with a benchmark adapted from TPC-H showed that MMBase (on top of PostgreSQL) can scale to thousands of tenants at very low overhead and that our proposed optimizations to cross-tenant queries are highly effective.

In the future, we plan to further analyze the interplay between the MMBase query optimizer and its counter-part in the DBMS execution engine in order to assess the potential of cost-based optimizations. We also want to study conversion functions that vary over time and investigate how MSQL can be extended to temporal databases. Moreover, we would like to look more into the privacy issues of multi-tenant databases, in particular how to enable cross-tenant query processing if data is encrypted.
