Foreword

The International Conference on Extending Database Technology (EDBT) is an established and renowned forum for the exchange of the latest research results and advances in data management. This year, the 22nd edition of EDBT takes place in Lisbon, Portugal, from March 26 to March 29, 2019. It is jointly organized with the International Conference on Database Theory (ICDT). In a world where increasingly many aspects of our lives and society are data-driven, data management technology continues to broaden its reach and extends its tradition of contributing models, algorithms, and architectures to novel applications adapted to new hardware and software.

As in previous years, EDBT 2019 solicited contributions both on novel research results and on experience and analysis results that focus on a comprehensive and detailed performance evaluation. For the first time, EDBT 2019 further solicited papers that describe innovative systems as part of its main research track. We also continued the recently established short paper track, offering a forum to present research in progress and visionary ideas during plenary poster sessions of the conference. To complement the scientific program, EDBT further solicited demonstrations of research prototypes, descriptions of industrial and application achievements, and proposals for tutorials.

The EDBT 2019 program committee reviewed 157 full research papers, of which 36 were accepted. For short papers, 28 papers out of 122 were selected. Among the 24 submissions to the industry and application track, 8 papers were accepted. The 21 demonstrations presented at the conference were selected among 42 demonstration proposals. Finally, we accepted 3 out of 10 tutorials. All these contributions will be presented at the conference. The program additionally features five workshops, an EDBT/ICDT joint session on research challenges, and four invited EDBT/ICDT joint keynotes.

Shaping the exciting program of EDBT 2019 is the result of a large community effort, and I take this opportunity to thank all persons involved. First, I would like to thank all authors for their high-quality submissions and contributions. I also would like to thank all reviewers who served on the EDBT 2019 program committee and the chairs responsible for our different tracks, namely Berthold Reinwald (IBM, United States) who chaired the industrial and application track, Carsten Binnig (TU Darmstadt, Germany) who served as demonstration chair, our tutorial chair Irini Fundulaki (ICS FORTH, Greece), and Paolo Papotti (EUROCOM, France) who served as workshop chair. The special session on joint EDBT/ICDT research challenges was organized by Julia Stoyanovich (NYU, USA). I also thank Laura Haas (UMass Amherst, USA) and Alon Halevy, who generously accepted to serve on the Test of Time Award Committee. Many thanks also to Paolo Atzeni (Universita' Roma Tre, Italy), Wei Wang (UNSW Sydney, Australia), and Jeffrey Xu Yu (Chinese University of Hong Kong) for serving on the Best Paper Award committee.

The conference would not have been possible without the tireless effort of the general chair Helena Galhardas (INESC-ID and IST, Universidade de Lisboa, Portugal) and the local organization team. Special thanks to the finance chair Manuel J. Fonseca (Universidade de Lisboa, Portugal), the local executive chairs José Borbinha and Luís Rodrigues, the sponsorship chairs João Garcia and Miguel Pardal, the publicity chair Paolo Romano, the student volunteers chair Hugo Nicolau (all from INESC-ID and IST, Universidade de Lisboa, Portugal), and the website chair António Higgs (INESC-ID, Portugal). These proceedings have been produced thanks to our proceedings chair Zoi Kaoudi (QCRI, Qatar). Norman Paton was most helpful in advising and coordinating with the EDBT Executive Board.

I really look forward to an interesting program and exciting conference on March 26–29, 2019 and to meeting you in Lisbon.

Test-of-Time Award

Established in 2014, the Test-of-Time Award awarded by the Extended Database Technology (EDBT) Conference recognizes papers presented at EDBT Conferences that have had the most impact in terms of research, methodology, conceptual contribution, or transfer to practice over the past ten years.

The 2019 Test-of-Time Award committee was formed by Laura Haas (University of Massachusetts, USA), Alon Halevy, and Melanie Herschel, the EDBT 2019 PC chair. The committee was charged with selecting a paper from the EDBT 2009 Proceedings.

After careful consideration, the Test-of-Time Award committee decided for the following paper from the 2009 EDBT Conference held in Saint Petersburg, Russia to receive the award:

Shore-MT: a scalable storage manager for the multicore era
by Ryan Johnson, Ippokratis Pandis, Nikos Hardavellas, Anastasia Ailamaki, and Babak Falsafi
published in the EDBT 2009 Proceedings, pp. 24–35, DOI: 10.1145/1516360.1516365.

The committee members agreed that this paper clearly stands out in terms of methodology, impact, and influence. It has catalyzed and enabled substantial follow-up research and has demonstrated its high relevance to industry.

Abstract:

Historically, database engines focused on the ability to efficiently overlap many requests over a small number processor cores, with I/O latencies and scalability as the main design driver. However, the advent of increasingly multicore hardware circa 2000 brought new challenges because concurrent transactions begin to stress the limits of the storage manager's thread scalability by accessing its internal structures simultaneously and in large numbers. This EDBT 2009 paper shows the results of experiments running benchmarks on four (then and still) popular open-source storage managers (Shore, BerkeleyDB, MySQL, and PostgreSQL) on a multicore machine. The results show that all systems suffer from scalability bottlenecks at the storage engine level. From that research emerged Shore-MT, an open-source multithreaded and highly scalable storage manager, built with Shore as a base. We learned that designers should favor scalability over single-thread performance, and we identified several other key principles for architecting scalable storage engines.

Ten years later, Shore-MT work has concluded, although the system still serves as a research platform in the space. Meanwhile, research on transaction processing scalability continues to mature, the move to main-memory transaction processing and their higher TPS increased the need for scalable storage managers, while the popular open-source systems, such as MySQL and PostgreSQL, significantly improved their scalability. In particular, a significant amount of research and industrial developments in the ten years since the Shore-MT paper focused on improving the scalability of individual components of a storage manager, such as latches, the logging subsystem and access methods. This research was partly carried out by our research group as follow-on work, but other research groups and database vendors have made important contributions as well. Another significant amount of effort has focused on scalable concurrency control protocols, again both within and outside our research group. The knowledge that we have gained from building Shore-MT has been invaluable in maintaining scalability in this new, multi-dimensional ecosystem.

The EDBT Test-of-Time award for 2019 will be presented during the EDBT/ICDT 2019 Conference as part of the Awards session on Wednesday, March 27, 2019, by Anastasia Ailamaki (EPFL, Switzerland).

ABSTRACT

The rising demands of real-time analytics have emphasized the need for Hybrid Transactional and Analytical Processing (HTAP) systems, which can handle both fast transactions and analytics concurrently. Wildfire is such a large-scale HTAP system prototyped at IBM Research - Almaden, with many techniques developed in this project incorporated into the IBM's HTAP product offering. To support both workloads efficiently, Wildfire organizes data differently across multiple *zones*, with more recent data in a more transaction-friendly zone and older data in a more analytics-friendly zone. Data *evolve* from one zone to another, as they age. In fact, many other HTAP systems have also employed the multi-zone design, including SAP HANA, MemSQL, and SnappyData. Providing a *unified* index on the large volumes of data across multiple zones is crucial to enable fast point queries and range queries, for both transaction processing and real-time analytics. However, due to the scale and evolving nature of the data, this is a highly challenging task. In this paper, we present Umzi, the *multi-version* and *multi-zone* LSM-like indexing method in the Wildfire HTAP system. To the best of our knowledge, Umzi is the first indexing method to support evolving data across multiple zones in an HTAP system, providing a consistent and unified indexing view on the data, despite the constantly on-going changes underneath. Umzi employs a flexible index structure that combines hash and sort techniques together to support both equality and range queries. Moreover, it fully exploits the storage hierarchy in a distributed cluster environment (memory, SSD, and distributed shared storage) for index efficiency. Finally, all index maintenance operations in Umzi are designed to be non-blocking and lock-free for queries to achieve maximum concurrency, while only minimum locking overhead is incurred for concurrent index modifications.

1 INTRODUCTION

The popularity of real-time analytics, e.g., risk analysis, online recommendations, and fraud detection etc., demands data management systems to handle both fast concurrent transactions (OLTP) and large-scale analytical queries (OLAP) over fresh data. These applications ingest data at high-speed, persist them into disks or shared storage, and run analytical queries simultaneously over newly ingested data to derive insights promptly.

The necessity of real-time analytics prompts the emergence of Hybrid Transactional and Analytical Processing (HTAP) systems, e.g., MemSQL [7], SnappyData [28], SAP HANA [21], and among others. HTAP systems support both OLTP and OLAP queries in a single system, thus allowing real-time analytics over freshly ingested data. Wildfire [15] is a large-scale HTAP system, prototyped at IBM research - Almaden. Many of the techniques developed in this research project have been incorporated into the IBM Db2 Event Store offering [4]. Wildfire leverages the Spark ecosystem [10] to enable large-scale data processing with different types of complex analytical requests (SQL, machine learning, graph analysis, etc), and compensates Spark with an underlying engine that supports fast transactions with snapshot isolation and accelerated analytics queries. Furthermore, it stores data in open format (Parquet [8]) on shared storage, so that other big data systems can access consistent snapshots of data in Wildfire. The back-end shared storage that Wildfire supports includes distributed file systems like Hadoop Distributed File System (HDFS) and GlusterFS [2], as well as object-based storage on cloud like Amazon S3 and IBM Cloud Object Storage.

To support efficient point lookups and range queries for high-speed transactional processing and real-time analytics, fine-grained indexing is mandatory in a large-scale HTAP system like Wildfire. However, indexing large volumes of data in an HTAP system is highly non-trivial due to the following challenges.

Challenges due to shared storage. First of all, for large-scale HTAP, memory-only solutions are not enough. As a result, most HTAP systems, including Wildfire, persist data in highly-available fault-tolerant shared storage, like HDFS and Amazon S3, etc. However, most of these shared storage options are not good at random access and in-place update. For example, HDFS only supports append-only operations and optimizes for block-level transfers, and object storage on cloud allows neither random access inside an object nor update to an object. To accommodate the unique characteristics of shared storage, index operations, e.g., insert, update and delete, have to leverage sequential I/Os without in-place updates. Naturally, LSM-like index structures are more appealing.

Furthermore, a typical shared storage prefer a small number of large files to a large number of small files. This is not only because of the overhead in metadata management, e.g., the maximum number of files supported by an HDFS cluster is determined by how much memory is available in the namenode, but more importantly because of the reduced seek time overhead when accessing larger files.

Finally, accessing remote shared storage through networks for index lookups is costly. Thus, indexing methods on HTAP must fully exploit the storage hierarchy in a distributed cluster environment for efficiency. Particularly, nowadays, we can take advantage of large memories and SSDs in modern hardware. Due to the large scale of data in HTAP systems, however, only the most frequently accessed portions of indexes can be cached locally,

*†Work done while at IBM Research - Almaden.

Series ISSN: 2367-2005

10.5441/002/edbt.2019.02

while leaving cold entries in shared storage. Effective caching mechanisms must be developed to facilitate index lookup.

Challenge due to evolving nature of data. Since HTAP systems have to support both transactional and analytical workloads efficiently, many of them [7, 14, 21, 23, 28] store data in different organizations, typically one organization good for transactions on the more recent data and one organization good for analytics on the older data. We call the different data organizations *zones*. As data age in the system, they evolve from the transaction-friendly zone to the analytics-friendly zone. In Wildfire, transactions first append writes into a transaction log, which is then groomed into columnar data blocks. The groomed data is further periodically post-groomed to a more analytics-friendly organization that is optimal for queries by creating data versions, data partitioning, and larger data blocks. SAP HANA organizes data into a read-optimized main store and a write-optimized delta store. Writes are first buffered into the row-major delta store, which is further transformed into the columnar main store to facilitate analytical queries. Some loosely-coupled HTAP solutions employ NoSQL stores, like HBase [3] or Cassandra [1], for operational workloads, and periodically copy data from the NoSQL stores into files in columnar format like Parquet or ORC-File on the shared storage, so that SQL-on-Hadoop engines, like Hive [35] or SparkSQL [13], can efficiently query them. The data evolution across different zones in these HTAP systems/solutions is constantly on-going, posing a significant challenge to building and maintaining indexes.

Existing indexing solutions on multi-zone HTAP systems either support index on the transaction-friendly zone only, like in SnappyData [28] and the loosely coupled HTAP solutions, or support separate indexes on different zones, like in MemSQL [7]. First of all, being able to efficiently query historical data is very important for real-time analytics, especially for analytical queries that are part of a transaction in the true HTAP scenario. As a result, the index needs to cover both recent data and historical data. Secondly, having separate indexes on different zones exposes a divided view of data. This requires queries to perform extra work to combine index query results that span multiple zones. In particular, with the constant evolving nature of HTAP data, it is non-trivial for queries to make sure that there is no duplicate or missing data in the final results. Therefore, it is highly desirable to have a consistent and unified index across the different zones in an HTAP system.

Contributions. To tackle the challenges of indexing in a large-scale HTAP system, we present Umzi, the multi-version and multi-zone LSM-like index in the context of Wildfire. Umzi provides a consistent and unified indexing view across the groomed and post-groomed zones in Wildfire. To the best of our knowledge, Umzi is the first unified multi-zone indexing method for large-scale HTAP systems.

Umzi employs an LSM-like structure with lists of sorted index runs to avoid in-place updates. A novel index-run format that combines hash and sort techniques is introduced to flexibly answer equality/range queries as well as the combination of both using the index. Runs are organized into multiple levels as in today's NoSQL systems, e.g., LevelDB [6] and RocksDB [9]. A new run is added into the lowest level, i.e., level 0, and runs are periodically merged into higher levels within a zone. However, when data evolve from one zone to another, an *index evolve* operation is introduced to build new index runs in the new zone and garbage-collect obsolete index runs from the old zone in a coordinated way, so that the entire index is always in a consistent state. To fully exploit the storage hierarchy, lower index levels can be made non-persistent to speed up frequent merges, and we dynamically adjust cached index runs from memory and SSD to speed-up index lookups and transactional processing. In Umzi, all operations are carefully designed to be non-blocking such that readers, i.e., index queries, are always lock-free while only negligible locking overhead is incurred for index maintenance.

Paper organization. Section 2 provides the background on Wildfire. Section 3 describes an overview of the Umzi index. Section 4 presents the internal structure of Umzi components. Section 5 describes index maintenance operations in Umzi. Section 6 discusses some design decisions of Umzi to exploit the storage hierarchy. Section 7 introduces methods for processing index queries, i.e., range scans and point lookups. Section 8 reports the experimental evaluation of Umzi. Section 9 surveys related work. Finally, Section 10 concludes this paper.

2 BACKGROUND

2.1 Wildfire

Wildfire [15] is a distributed multi-master HTAP system consisting of two major pieces: Spark and the Wildfire engine. Spark serves as the main entry point for the applications that Wildfire targets, and provides a scalable and integrated ecosystem for various types of analytics on big data, while the Wildfire engine adds the support for high-speed transactions, accelerates the processing of application requests, and enables analytics on newly-ingested data. All inserts, updates, and deletes in Wildfire are treated as *upserts* based on the user-defined primary key. Wildfire adopts last-writer-wins semantics for concurrent updates to the same key, and snapshot isolation of quorum-readable content for queries, without having to read the data from a quorum of replicas to satisfy a query.

A table in Wildfire is defined with a *primary key*, a *sharding key*, and optionally a *partition key*. Sharding key is a subset of the primary key, and it is primarily used for load balancing of transaction processing in Wildfire. Inserted records are routed by the sharding key to different shards. A table shard is replicated into multiple nodes, where one replica serves as the shard-leader while the rest are slaves. Any replica of a shard can ingest data. A table shard is the basic unit of a lot of processes in Wildfire, including grooming, post-grooming, and indexing (details later). In contrast, the partition key is for organizing data in a way that benefits the analytics queries. Typically, the sharding key is very different from the partition key. For example, an IoT application handling large volumes of sensor readings could use the device ID as the sharding key, but the date column as the partition key to speed up time-based analytical queries.

Wildfire adds the following three hidden columns to every table to keep track of the life of each record and support snapshot isolation as well as time travel. The column beginTS (begin timestamp) indicates when the record is first ingested in Wildfire; endTS (end timestamp) is the time when the record is replaced by a new record with the same primary key; prevRID (previous record ID) holds the RID (record ID) of the previous record with the same key.

In order to support both OLTP and OLAP workloads efficiently within the same system, Wildfire divides data into multiple zones where transactions first append their updates to the OLTP-friendly zone, which are gradually migrated to the OLAP-friendly zone. Figure 1 depicts the data lifecycle in Wildfire across multiple zones.

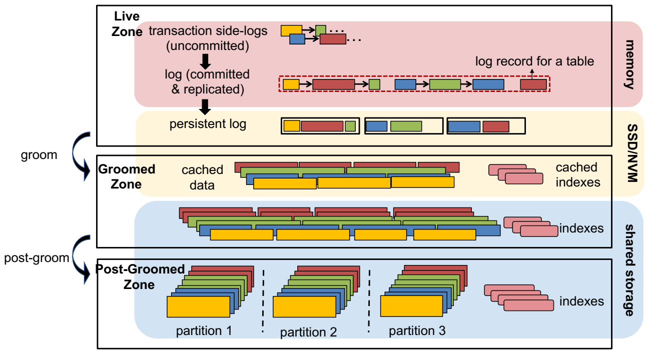

Figure 1: Data Lifecycle in Wildfire

Live Zone. A transaction in Wildfire first appends uncommitted changes in a transaction local side-log. Upon commit, the transaction tentatively sets beginTS for each record using the local wall clock time (beginTS is reset later in the groomed zone), and appends its side-log to the committed transaction log, which is also replicated for high-availability. The committed log is kept in memory for fast access, and also persisted on the local SSDs using the Parquet columnar-format. Since this zone has the latest ingested/updated data, it is called the *live zone*.

Groomed Zone. To bound the growth of the committed log and resolve conflicts from different replicas, each shard in Wildfire has a designated *groomer* which periodically (e.g., every second) invokes a *groom* operation to migrate data from the live zone to the groomed zone.

The groom operation merges, in the time order, transaction logs from shard replicas, resolves conflicts by setting the monotonic increasing beginTS for each record, and creates a Parquet columnar-format data file, called a *groomed block*, in the shared storage as well as the local SSD cache. Each groomed block is uniquely identified by a monotonic increasing ID called *groomed block ID*. Note that the beginTS set by the groomer is composed of two parts. The higher order part is based on the groomer's timestamp, while the lower order part is the transaction commit time in the shard replica. Thus, the commit time of transactions in Wildfire is effectively postponed to the groom time. The groomer also builds indexes over the groomed data.

Post-Groomed Zone. The groomer only sets the beginTS for each record. EndTS and prevRID still need to be set to support snapshot isolation and time travel. In addition, up to the groomed zone, data is still organized according to the sharding key, and they need yet to be re-organized based on the more analytics-friendly partition key. To achieve these tasks, another separate process, called *post-groomer*, periodically (e.g., every 10 minutes) performs *post-groom* operations to evolve the newly groomed data to the post-groomed zone.

The post-groom operation first utilizes the post-groomed portion of the indexes to collect the RIDs of the already post-groomed records that will be replaced by the new records from the groomed zone. Then, it scans the newly groomed blocks to set the prevRID fields using the RIDs collected from the index, and re-organizes the data into post-groomed blocks on the shared storage according to the OLAP-friendly partition key. The post-groomer also uses the same set of RIDs from the index to directly locate the to-be-replaced records and sets their endTS fields. Since the post-groomer is carried out less frequently than the groomer, it usually generates much larger blocks, which results in better access performance on shared storage. At the end, the post-groomer also notifies the indexer process to build indexes on the newly post-groomed blocks.

While both groomed and post-groomed blocks reside in the shared storage, based on the access patterns of a node, they are also cached in the local SSDs of that node, similarly to the indexes.

2.2 LSM-tree

Since Umzi employs an LSM-like structure, here we brief introduce the background of LSM-trees. Interested readers can refer to [27] for a survey of recent research on LSM-trees. The Log-Structured Merge-tree (LSM-tree) is a write-optimized persistent index structure. It first appends all writes into a memory table. When the memory table is full, it is flushed into disk as a sorted run using sequential I/Os. A query over an LSM-tree has to look up all runs to perform reconciliation, i.e., to find the latest version of each key.

As runs accumulate, query performance tends to degrade. To address this, runs are periodically merged together to improve query performance and reclaim disk spaced occupied by obsolete entries. Two LSM merge policies are commonly used in practice, i.e., leveling and tiering [27]. In both merge policies, runs are organized into levels, where a run at level $L + 1$ is T times larger than the run at level L. The leveling policy optimizes for queries by limiting only one run per level. A run is merged with the one at the higher level when its size reaches a threshold. In contrast, the tiering policy optimizes for write amplification by allowing multiple runs at each level. Multiple runs at level L are merged together into a new run at level $L + 1$.

3 UMZI OVERVIEW

In Wildfire, depending on the freshness requirement, a query may need to access data in the live zone, groomed zone, and/or the post-groomed zone. We choose to build indexes over the groomed zone and the post-groomed zone. Indexing does not cover the live zone for a few reasons. First, since groomer runs very frequently, data in the live zone is typically small, which alleviates the need for indexing. Secondly, to support fast data ingestion, we cannot afford maintaining the index on a record basis.

In a nutshell, Umzi employs an LSM-like [31] structure with multiple runs. Each groom operation produces a new index run, and runs are merged over time to improve query performance. Even though Umzi is structurally similar to LSM, it has significant differences from existing LSM-based indexes. First, existing LSM-based indexes either store the records directly into the index itself, e.g., LevelDB [6] and RocksDB [9], or store the records separately with the assumption that each record has a fixed RID, e.g., WiscKey [25] [1]. However, both approaches do not work well in Wildfire. Storing records into the LSM-tree incurs too much write amplification during merges, significantly affecting ingestion performance. While for the second approach, as data evolve from one zone to another, RIDs also change.[2] To accommodate the multi-zone design and the evolving nature, Umzi divides index runs into multiple zones accordingly. Runs in each zone are chained and merged, as in LSM indexes. When data evolve from one zone to another, Umzi performs the evolve operation

[1] The same assumption is generally held by non-LSM-based indexes as well

[2] In Wildfire, an RID is identified by the combination of zone, block ID, and record offset.

to migrate affected index entries to the target zone accordingly. Since data evolution in Wildfire is accomplished by a number of loosely-coupled distributed processes, it is critical for index evolve operations to require minimum coordination among distributed processes and incur negligible overhead for queries.

Furthermore, Umzi targets at multi-tier storage hierarchies in distributed environment, including memory, SSD and shared storage. Index runs are persisted on shared storage for durability, while Umzi aggressively exploits local memory and SSD as a caching layer to speed up index queries. Umzi dynamically adjusts cached index runs based on the space utilization and the age of the data, even without ongoing queries. To improve merge performance and avoid frequent rewrites on shared storage, Umzi allows certain lower levels to be non-persisted, i.e., their runs are only stored in local memory and optionally SSD.

Even though we present Umzi with two zones, i.e., groomed zone and post-groomed zone, this structure does not limits the applicability of Umzi to other systems. It is straightforward to extend Umzi to support other HTAP systems with arbitrary number of zones. To this end, one needs to structure Umzi with multiple run lists, each of which corresponds to one zone of data. When data evolves from one zone to another, the indexing process should be notified to trigger an index evolve operation to migrate index entries accordingly.

As mentioned in Section 2, a table shard is the basic unit of groomer and post-groomer processes in Wildfire. This is also the case for indexing. In the distributed setting of Wildfire, each Umzi index structure instance serves a single table shard. There are a number of indexer daemons running in the cluster. Each runs independently, and is responsible for building and maintaining index for one or more index structure instances. As a result, this paper describes the Umzi index design from the perspective of one table shard.

The following four sections describe the detailed design of Umzi and its index maintenance operations. Without loss of generality, we assume Umzi is used as a primary index throughout the paper.

4 INDEX STRUCTURE

This section details the internal structure of Umzi. We first describe the index definition of Umzi, followed by the singe-run storage format and multi-run structure respectively.

4.1 Index Definition

Umzi is designed for supporting both equality queries and range queries, as well as facilitating index-only access plans if possible. Index definitions in Umzi reflect these design goals. An index is defined with key columns plus optionally included columns. Index key columns can be a composition of equality columns (for equality predicates) and sort columns (for range predicates). Included columns are extra columns to enable efficient index-only queries. If equality columns are specified, we also store the hash value of equality column values to speed-up index queries, which makes Umzi a combination of hash and range index. In an example IoT application, the user can define the deviceID as the equality column, while the message number as the sort column. As a special case, the user could leave out the equality column(s), which makes Umzi a complete range index. Similarly, omitting the sort columns would turn Umzi into a hash index. The flexibility of this index structure helps Umzi to answer equality queries, range queries, and combinations of the two, with one index.

	hash	device	msg	beginTS	RID
0	0000 0101	1	1	100	...
1	0010 0011	8	2	101	...
2	1001 0001	4	1	97	...
3	1001 0001	4	1	94	...
4	1001 0001	4	2	102	...
5	1001 0001	5	1	97	...
6	1110 0000	3	0	103	...
7	1110 0000	3	1	104	...

(c) Physical Layout of An Index Run

Figure 2: Example Index Run: *device* is the equality column, *msg* is the sort column, and there is no included columns. For simplicity, we assume the hash value takes only one byte.

4.2 Run Format

Each run in Umzi can be logically viewed as a sorted table containing the hash column, index key columns, included columns, beginTS and RID. As mentioned before, the hash column stores the hash value of equality columns (if any) to speed up queries with equality predicates. The beginTS column indicates the timestamp when the indexed record is inserted, which is generated by groomers in Wildfire (Section 2). The RID column defines the exact location of the indexed record. Index entries are ordered by the hash column, equality columns, sort columns, and descending order of beginTS. We sort the beginTS column in descending order to facilitate the access of more recent versions. All ordering columns, i.e., the hash column, equality columns, sort columns and beginTS, are stored in lexicographically comparable formats, similar to LevelDB [6], so that keys can be compared by simply using memory compare operations when processing index queries. Figure 2 shows an example index run, where *device* is the equality column and *msg* is the sort column. There is no included columns in this example, and we assume the hash value takes only one byte. Figure 2a shows the index rows in this run, where the hash value is shown in the binary format.

An index run is physically stored as a header block plus one or more fixed-size data blocks. The header block contains the metadata information of the index run, such as the number of data blocks, the merge level this run belongs to (Section 5), and the range of groomed block IDs to which this run corresponds.

To prune irrelevant runs during index queries, we also store a synopsis in the header block. The synopsis contains the range (min/max values) of each key column stored in this run. A run can be skipped by an index query if the input value of some key column does not overlap with the range specified by the synopsis. Figure 2c shows an example index run layout which contains one header block and two data blocks.

When equality columns are specified in the index definition, we store in the header block an offset array of 2^n integers to facilitate index queries. The offset array maps the value of the most significant n bits of hash values to the offset in the index run. When processing index queries, the offset array can be used to provide a more compact start and end offset for binary search. For example, Figure 2b shows the offset array with the most significant 3 bits of hash values from Figure 2a.

4.3 Multi-Run Structure

An example multi-run structure of Umzi is shown in Figure 3. Similar to LSM indexes, Umzi contains multiple runs. A groom operation produces a new run to level 0, and runs from lower levels are gradually merged into higher levels to improve query performance. Each run is further labeled with the range of groomed block IDs, where larger IDs correspond to newer groomed blocks.

In this meanwhile, to accommodate the multi-zone design and data evolving nature of the HTAP systems, Umzi divides index runs in multiple zones accordingly. For concurrency control purpose, runs in each zone are chained together based on their recency into a list, where the header points to the most recent run. We will further discuss concurrency control of Umzi in Section 5.1. Based on this multi-zone design, Umzi only merges runs within the same zone. When data evolves from one zone to another, an index evolve operation is triggered to migrate index entries to the target zone accordingly.

The assignment of levels to zones are configurable in Umzi. For example in Figure 3, levels 0 to 5 are configured as the groomed zone, while levels 6 to 9 are configured as the post-groomed zone.

5 INDEX MAINTENANCE

In this section we describe index maintenance operations in Umzi, including index build, merge, and evolve. Before presenting the details of index maintenance operations, we first discuss concurrency control in Umzi since index maintenance is performed concurrently with queries. Finally, we also briefly discuss how recovery is performed in Umzi.

5.1 Concurrency Control

Umzi aims at providing non-blocking and lock-free access for queries. To this end, Umzi relies on atomic pointers and chains runs in each zone together into a linked list, where the header points to the most recent run. All maintenance operations are carefully designed so that each index modification, i.e., a pointer modification, always results in a valid state of the index. As a result, queries can always traverse run lists sequentially without locking to get correct results. To minimize contentions caused by concurrent index maintenance operations, each level is assigned a dedicated index maintenance thread. A short duration lock is acquired when modifying the run list to prevent concurrent modifications. Note that the locking overhead is negligible since locks are only used to prevent concurrent modifications to the run list, which happens infrequently. Moreover, these locks never block any index queries.

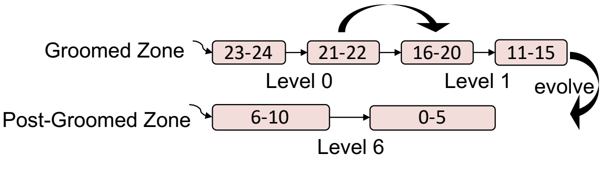

Figure 3: Multi-Run Structure in Umzi

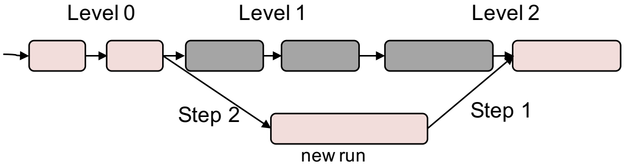

Figure 4: Index Merge Example

5.2 Index Build

After a groom operation is completed, Umzi builds an index run over the newly groomed data block. This is done by simply scanning the data block and sorting index entries in ascending order of hash values, sort columns, equality columns and descending order of beginTS. Along with writing sorted index entries back to data blocks, the offset array can be computed on-the-fly. Finally, the new run becomes the new header of the run list for the groomed zone. Note that the order of pointer modifications is important to guarantee the correctness for concurrent queries, where the new run must be set to point to the header before the header pointer is modified.

5.3 Index Merge

In order to easily trade-off write amplification and query performance, Umzi employs a hybrid merge policy similar to [20]. This policy is controlled by two parameters K, the maximum number of runs per level, and T, the size ratio between runs in adjacent levels. Each level L maintains the first run as an active run, while the remaining runs are inactive. Incoming runs from level $L-1$ are always merged into the active run of level L. When the active run in level L is full, i.e., its size is T times larger than an inactive run in level $L-1$, it is marked inactive and a new active run is created. Finally, when level L contains K inactive runs, they are merged together with the active run in level $L+1$.

After a merge, the new run replaces old runs in the run list. As shown in Figure 4, this is done by first setting the new run point to the next run of the last merged run, and then set the previous run before the first merged run point to the new run. A lock over the run list is acquired during the replacement, since otherwise pointers could be concurrently modified by other maintenance threads. There is no need for a query to acquire any locks when traversing the list; it sees correct results no matter whether the old runs or the new run are accessed.

5.4 Index Evolve

In Wildfire, the post-groomer periodically moves groomed data blocks to the post-groomed zone. After a post-groom operation, groomed data blocks are marked deprecated and eventually deleted to reclaim storage space. As a result, index entries in Umzi must be migrated as well so that deprecated groomed blocks are no longer referenced. However, index evolving in distributed HTAP systems is non-trivial due to the following problems.

First, HTAP systems like Wildfire are often composed of several loosely-coupled distributed processes. The post-groomer in Wildfire is a separate process running on a different node from the indexer process. In a distributed environment, one requirement for index evolving is to minimize the coordination among multiple processes. Second, an index evolve operation must apply multiple modifications to the index. This requires index evolve operations to be carefully designed to ensure the correctness for concurrent queries without blocking them.

To tackle the first problem, an index evolve operation in Umzi is performed asynchronously by the indexer process with minimum coordination, as shown in Figure 5. Each post-groom operation is associated with a post-groom sequence number (PSN). After a post-groom operation, the post-groomer publishes the metadata for this operation and updates the maximum PSN. In the meanwhile, the indexer keeps track of the indexed post-groom sequence number, i.e., IndexedPSN, and keeps polling the maximum PSN. If IndexedPSN is smaller than the maximum PSN, the indexer process performs an index evolve operation for IndexedPSN+1, which guarantees the index evolves in a correct order, and increments IndexedPSN when the operation is finished. Note that asynchronous index evolution has no impact on index queries since a post-groom operation only copies data from one zone to another without producing any new data. For a query, it makes no difference to access a record from the groomed zone or post-groomed zone.

For the concurrency control issue, we decompose the index evolve operation into a sequence of atomic sub-operations. Each sub-operation is guaranteed to result in a valid state of the index, ensuring that concurrent queries always see correct results when traversing the run lists. Specifically, an index evolve operation for a given PSN is performed as follows. First, the indexer builds an index run for post-groomed data blocks associated with this PSN, and adds it atomically to the post-groomed run list. Note that this run still contains the range of groomed block IDs it corresponds to. Second, the indexer atomically updates the maximum groomed blocked ID covered by the post-groomed run list, based on the newly built run. All runs in the groomed run list with end groomed block ID no larger than this value would be automatically ignored by queries since entries in these runs are already covered by the post-groomed run list. Finally, these obsolete runs are garbage collected from the groomed run list. Note that during each step, a lock over the run list is acquired when modifying a run list to prevent concurrent modifications by other maintenance threads.

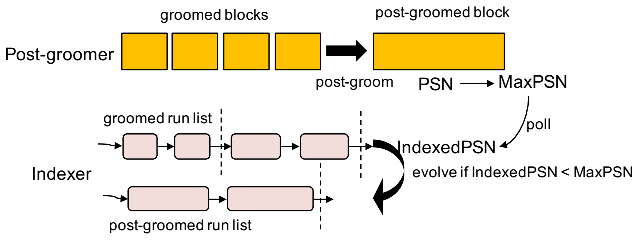

Figure 5: Interaction between Post-groomer and Indexer

We further illustrate the index evolve operation with an example depicted in Figure 6. Suppose the groomed blocks 11 to 18 have been post-groomed, and the indexer now performs an index evolve operation for this post-groom operation accordingly. First, the indexer builds a new run labeled 11-18 for the newly post-groomed data, and atomically adds it to the post-groomed run list. The indexer then atomically updates the maximum groomed blocked ID of the post-groomed run list from 10 to 18. At this moment, run 11-15 will be ignored by subsequent queries since it is fully covered by run 11-18. Finally, this obsolete run is garbage collected from the groomed list, which concludes this index evolve operation.

It is straightforward that each step of an evolve operation only makes one modification to the index, and is thus atomic. Between any two of the above three steps, the index could contain duplicates, i.e., a record with the same version could appear in both a groomed run and a post-groomed run. Moreover, even after the last step of the index evolve operation, the index may still contain duplicates since groomed blocks consumed by a post-groom operation may not align perfectly with the boundaries of index runs. However, duplicates are not harmful to index queries. Since a query only returns the most recent version of each key, duplicates are removed on-the-fly during query processing (Section 7).

5.5 Recovery

We assume runs in Umzi are persisted in shared storage. After each index evolve operation, the maximum groomed blocked ID for the post-groomed run list and IndexedPSN are also persisted. However, an indexer process could crash, losing all data structures in the local node. To recover an index, we mainly need to reconstruct run lists based on runs stored in shared storage, and cleanup merged and incomplete runs if any.

A run list can be recovered by examining all runs in shared storage. Runs are first sorted in descending order of end groomed blocked IDs, and are added to the run list one by one. If multiple runs have overlapping groomed block IDs, the one with largest range is selected, while the rest are simply deleted since they have already been merged.

6 UMZI ON MULTI-TIER STORAGE HIERARCHY

Recall that Umzi is designed for large-scale distributed HTAP systems running on multi-tier storage hierarchy, i.e., memory, SSD, and distributed shared storage. Even though shared storage provides several key advantages for distributed HTAP systems such as fault tolerance and high availability, it brings significant challenges when designing and implementing an indexing component. Shared storage generally does not support in-place

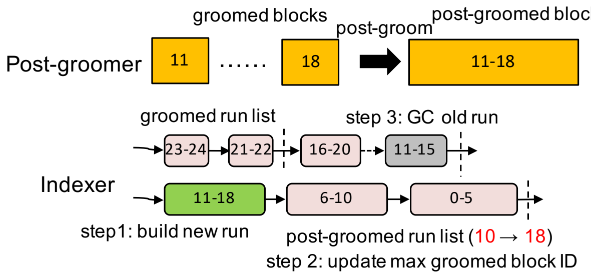

Figure 6: Index Evolve Example

updates and random I/Os, and prefers a small number of large files to reduce metadata overhead. Furthermore, accessing shared storage through networks is often costly, incurring high latency for index queries.

So far, we only discussed how Umzi eliminates random I/Os and in-place updates by adopting an LSM-like structure. In this section, we present solutions adopted by Umzi to improve storage efficiency in a multi-tier storage hierarchy.

6.1 Non-Persisted Levels

In a traditional LSM design, on-disk runs of all levels are persisted on disk equivalently. Even though this design garbage collects olds runs after a merge, it introduces a large overhead on shared storage because of writing a large number of (potentially small) files. To avoid frequently rewriting a large number of small files on shared storage, Umzi supports non-persisted levels, i.e., certain low levels of the groomed zone can be configured as non-persisted.

Runs in persisted levels are always stored in shared storage for fault tolerance and can be cached in local memory and SSD to speedup queries. However, runs in non-persisted levels are only cached in local memory and optionally spilled to SSD if memory is full, but they are not stored in shared storage for efficiency.

Introducing non-persisted levels complicates the recovery process of Umzi, since after a failure all runs in non-persisted levels could be lost. To address this, Umzi requires level 0 must be persisted to ensure that we do not need to rebuild any index runs from groomed data blocks during recovery. Moreover, if level L to K are configured as non-persisted, runs in level L-1 cannot be deleted immediately after they are merged into level L. Otherwise, if the node crashes, we would again lose index runs since the new run is not persisted in shared storage. To handle this, when merging into non-persisted levels, old runs from level L-1 are not deleted but rather recorded in the new run. When the new run is finally merged into a persisted level again, i.e., level K+1, its ancestor runs from level L-1 can be safely deleted.

6.2 Cache Management

As mentioned before, accessing shared storage through networks is often costly and incurs high latencies for index queries. To address this, Umzi aggressively caches index runs using local memory and SSD, even without ongoing queries. We assume most frequently accessed index runs fit into the local SSD cache so that shared storage is mainly used for backup. However, when the local SSD cache is full, Umzi has to remove some index runs to free up the cache space. For this purpose, we assume recent data is accessed more frequently. As the index grows, Umzi dynamically purges old runs, i.e., runs in high levels, from the SSD cache to free up the cache space. In contrast, when the local SSD is spacious, Umzi aggressively loads old runs from shared storage to speedup future queries.

To dynamically purge and load index runs, Umzi keeps track of the current cached level that separates cached and purged runs, as shown in Figure 7. When the SSD is nearly full, the index maintenance thread purges some index runs and decrements the current cached level if all runs in this level have been purged. When purging an index run, Umzi drops all data blocks from the SSD while only keeps the header block for queries to locate data blocks. On the contrary, when the SSD has free space, Umzi loads recent runs (in the reverse direction of purging) into SSD, and increments the current cached level when all runs in the current cached level have been cached. Umzi further adopts a write-through cache policy when creating new index runs during merge or evolve. That is, a new run is directly written to the SSD cache if it is below (lower than) the current cache level.

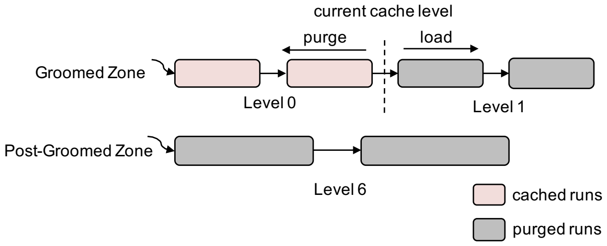

Figure 7: Cache Management in Umzi

7 INDEX QUERY

In this section, we discuss how to process index queries on Umzi. Since Umzi is a multi-version index, a query has to specify a query timestamp (queryTS), and only the most recent version for each matching key is returned, i.e., the version with largest beginTS such that beginTS ≤ queryTS. In general, two types of index queries are supported. The range scan query specifies values for all equality columns (if any) and bounds for the sort columns, and returns the most recent version of each matching key. The point lookup query specifies the entire index key (i.e., the primary key), and at most one matching record is returned.

A query first collects candidate runs by iterating the run lists and checking run synopses. A run is considered as a candidate only if all column values as specified in the query satisfy the column ranges in the synopsis. Also note that all runs are read from the SSD cache. In case that a query must access purged runs, we first transfer runs from shared storage to the SSD cache on a block-basis, i.e., the entire run data block is transferred at a time, to facilitate future accesses. After the query is finished, the cached data blocks are released, which are further dropped in case of cache replacement. Depending on the query type, the details of query processing are as follows.

7.1 Range Scan Query

For a range scan query, we first discuss how to search a single run to get matching keys. Results returned from multiple runs are further reconciled, since results from newer runs could override those from older runs, to guarantee only the most recent version is returned for each matching key.

7.1.1 Search Single Run. Searching a single run returns the most recent version for each matching key in that run. Since a run is a table of sorted rows, the query first locates the first matching key using binary search with the concatenated lower bound, i.e., the hash value, equality column values, and the lower bound of sort column values. If the offset array is available, the initial search range can be narrowed down by computing the most significant n bits of the hash value (denoted as i) and taking the i-th value in the offset array.

After the first matching key is determined, index entries are then iterated until the concatenated upper bound is reached, i.e., the concatenation of the hash value, equality column values, and the upper bound of sort column values. During the iteration, we further filter out entries failing timestamp predicate beginTS ≤ queryTS. For the remaining entries, we simply return for each key the entry with the largest beginTS, which is straightforward since entries are sorted on the index key and descending order of beginTS.

Consider again the example run in Figure 2. Recall that *device* is the equality column, while *msg* is the sort column. Consider a range scan query with *device* = 4, 1 ≤ *msg* ≤ 3, and queryTS = 100. We first take the most significant 3 bits of hash(4) = 1001 0001, i.e., 100, to obtain the initial search range from the offset array, i.e., 2 to 6. The first matching key is still entry 2 after binary search with the input lower bound (1001 0001, 4, 1). We then iterate index entries starting from entry 2. Entry 2 is returned since it is the most recent version for key (4, 1), while entry 3 is filtered out since it is an older version of entry 2. However, entry 4 is filtered out because its beginTS 102 is beyond the queryTS 100. We stop the iteration at entry 5, which is beyond the input upper bound (1001 0001, 4, 3).

7.1.2 Reconcile Multiple Runs. After searching each run independently, we have to reconcile results returned from multiple runs to ensure only the most recent version is returned for each matching key. In general, two approaches can be used for reconciliation: the set approach and the priority queue approach.

Set Approach. In the set approach, the query searches from the newest to the oldest runs sequentially, and maintains a set of keys which have already been returned to the query. If a key has not been returned before, i.e., not in the set, it is added to the set and the corresponding entry is returned to the query; otherwise, the entry is simply ignored since we have already returned a more recent version from the newer runs. The set approach mainly works well for small range queries since it requires intermediate results to be kept in memory during query processing.

Priority Queue Approach. In the priority queue approach, the query searches multiple runs together and feeds the results returned from each run into a priority queue to retain a global ordering of keys, which is similar to the merge step of merge sort. Once keys are ordered, we can then simply select the most recent version for each key and discard the rest without remembering the intermediate results.

7.2 Point Lookup Query

The point lookup query can be viewed as a special case of the range scan query, where the entire primary key is specified such that at most one entry is returned. As an optimization, one can search from newest runs to oldest runs sequentially and stop the search once a match is found. Here we can use exactly the same approach from above to search the single run, where the lower bound and upper bound of sort column values are the same.

For a batch of point lookups, we first sort the input keys by the hash value, equality column values, and sort column values, to improve search efficiency. The sorted input keys are searched against each run sequentially from newest to oldest, one run at a time, until all keys are found or all runs to be searched are exhausted. This guarantees that each run is accessed sequentially and only once.

8 EXPERIMENTAL EVALUATION

In this section, we report the experimental evaluation of Umzi. We first evaluate the index build performance, index query performance, and further study the end-to-end query performance with concurrent data ingestion. We first outline the general experiment setup, then report and discuss the experimental results.

As mentioned in Section 3, there are a distributed cluster of indexer daemons running in Wildfire, each independently responsible for building and maintaining index for one or more Umzi index structure instances (one per table shard). As a result, Umzi scales up and down nicely with more or less indexer daemons. Since the goal of our experiments is to demonstrate the performance of Umzi index structure, we focus on a single shard setting for our experiments.

Note that since all experiments were conducted inside Wildfire, which is closely tied to an IBM product, we cannot report absolute performance numbers. As a result, we report normalized performance numbers, with the normalization process explained for each experiment.

8.1 Experiment Setup

All experiments are performed against a single table shard on a single node using a dual-socket Intel Xeon E5-2680 server (2.40GHZ) with 14 cores in a socket (28 with hyper-threading) and 1.5TB of RAM. The operating system is Ubuntu 16.04.2 with Linux kernel 4.4.0-62. The node uses an Intel 750 Series SSD as the SSD cache. For end-to-end experiments, we use GlusterFS [2] as the shared storage layer.

We use a synthetic data generator to generate keys with include columns used in all experiments, where keys can be sequential or random. Note that our index only stores key and include columns instead of entire records, thus a key generator is sufficient for our experiments. Throughout the experiments, we consider three different index definitions as below:

- I1: one equality column, one sort column, and one include column
- I2: two equality columns and one include column
- I3: one equality column and one include column

Each column is a long type with 8 bytes. Unless otherwise noted, we use index definition I1 as the default case. Each of the following experiments was reported for three times, and the average number is reported.

Moreover, for the scope of this paper, we only focus on the time of index lookups, while omitting the time of retrieving records based on the fetched RIDs, since the latter depends on the record storage format and is orthogonal to the indexing method.

8.2 Index Building Performance

In the first set of experiments, we evaluate the performance of building index runs, which is the primitive operation for Umzi's index maintenance after a groom or post-groom cycle. Figure 8 shows the results for the time it takes to build an index run using the three different index definitions mentioned above as we increase the number of entries in a run. The running time is normalized against the time of building a run with 1000 tuples using I1. As the graph shows, index building almost scales linearly with the number of rows. Furthermore, the index building time for index I3 is always faster than I1 and I2, since I3 has one fewer key column. The impact of the number of indexed columns on the index building time, however, is negligible, compared to the overhead of sorting entries during index building.

8.3 Index Query Performance

Next set of experiments evaluate the performance of querying Umzi under various settings. By default, an index contains 20 runs, where each index run has 100000 entries. We execute index

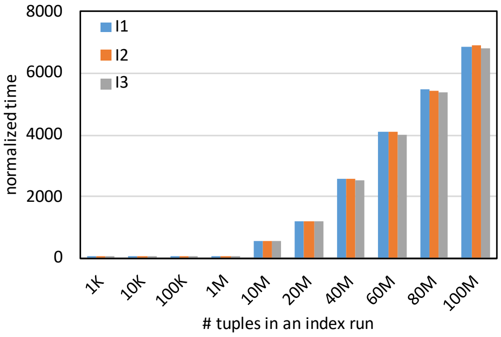

Figure 8: Index Building Performance

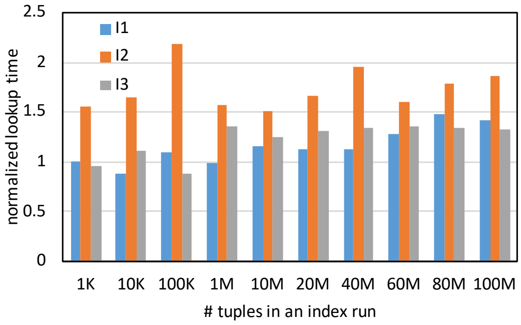
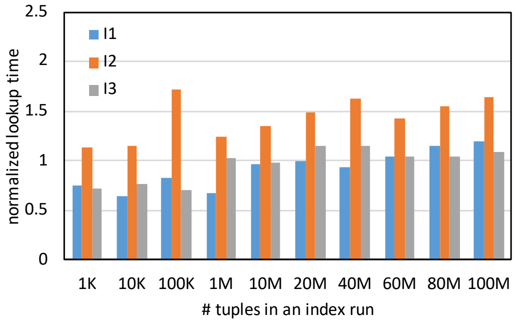


(a) Sequential queries



(b) Random queries

Figure 9: Single Run Query Performance

queries in a batch, where the default batch size is 1000. All index runs used in this set of experiments are cached in the local SSD.

We consider two kinds of entry characteristics for the following experiments, i.e., ingested with sequential keys or random keys. Sequential keys are sequentially generated by our synthetic key generator to simulate the time correlated keys, while random keys are randomly sampled from a uniform distribution without any temporal correlation. We further consider two kinds of key distribution in index queries: sequential and random. As the name suggests, sequential and random queries use sequentially and randomly generated keys in a batch, respectively.

8.3.1 Single Run. We first evaluate the index query performance against a single run. For brevity, we only report experiment results with sequentially ingested keys in this experiment. Since entries in a run are sorted on hash values, there is no difference to use sequentially or randomly ingested data. Figure 9 shows the normalized lookup time with varying run sizes and index definitions.

The time is normalized against the index lookup time of the sequential query over the run with 1000 tuples under the index definition I1. In general, the query time increases with larger index runs, since search keys spread across the run and potentially more I/Os are required to process the query batch when the run size increases. However, the impact of run size is limited because we use the hash offset array to locate the initial search range, and further use binary search to locate the exact location. Moreover, index lookup performance of index definition of I1 is comparable to that of I3, but index lookup performance of index definition I2 is generally slower since I2 contains two equality columns, making the hash offset array less effective in terms of locating the initial search range.

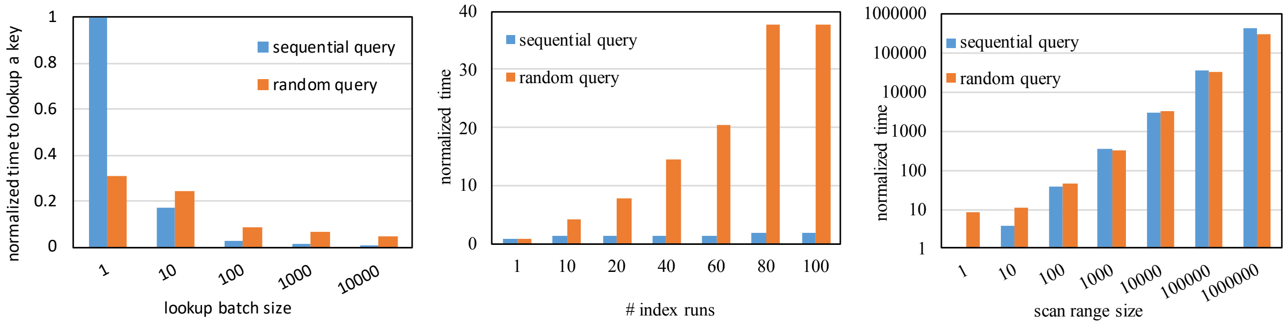
8.3.2 Multiple Runs with Sequential Keys. In this section we evaluate the index query performance against multiple index runs with sequentially ingested keys. We vary the query batch size and the number of index runs for the lookup queries, and the scan range for the range queries. The experiment results are shown in Figure 10.

Figure 10a shows the impact of the batch size on the index lookup performance. The index lookup time per key is normalized against the lookup time of the sequential query with batch size one. In general, sequential queries perform much better than random ones since the run synopsis enables pruning most of the irrelevant runs and leaving only a small fraction of the runs need to be searched (except for the case of batch size 1, where the sequential queries take longer because of some variances in the experiments). Furthermore, batching greatly improves index lookup performance, since once an index block is fetched into memory for a the lookup of a particular key, no additional I/O is required to fetch that block again for looking up other keys in the batch.

Figure 10b shows the index lookup performance with varying number of index runs. The query time is normalized against the time it takes to complete the sequential query against one run. As the result shows, the number of runs has limited impact over the sequential queries, since most irrelevant runs are simply pruned because of the run synopsis. However, the time of the random queries grows almost linearly with more runs, since more runs need to be searched to complete the batch of lookups.

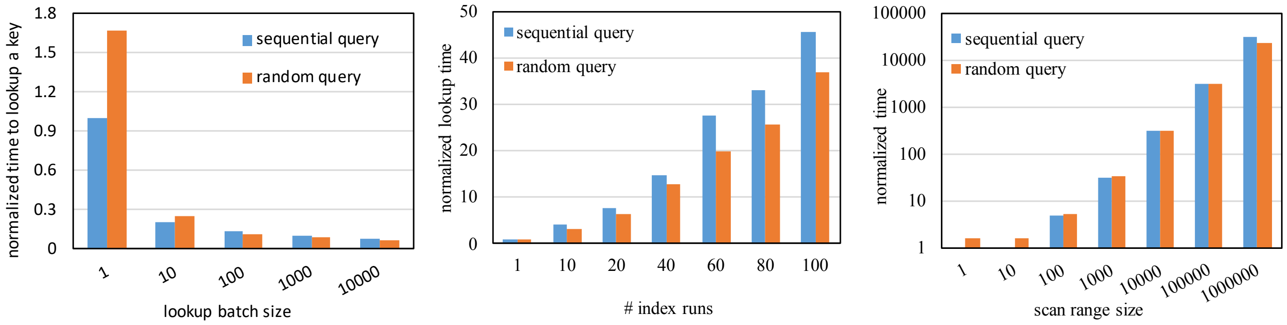
Finally, the performance of the range scan queries using the priority queue method is in Figure 10c. The time is normalized against the query time of the sequential query with range one. In general, the query time of the range scan query grows linearly with the query range, since larger ranges require more time to read index entries and output matching keys. Moreover, sequential or random ranges have little impact over the query performance, since the time of locating start position is negligible compared to scanning the index entries.

8.3.3 Multiple Runs with Random Keys. After investigating the index query time using sequentially ingested keys, this section evaluates the query performance against multiple index runs with randomly ingested keys. The results are shown in Figure 11. The numbers on the y-axes are normalized the same way as the corresponding numbers in Figure 10. In general, random keys render the run synopsis less useful, which decreases the performance of sequential queries since more runs need to be searched. However, the impact on the random queries is almost negligible,



(a) Varying batch size **(b) Varying number of runs** **(c) Varying scan ranges**

Figure 10: Query performance of multiple runs with sequentially ingested keys



(a) Varying batch size **(b) Varying number of runs** **(c) Varying scan ranges**

Figure 11: Query performance of multiple runs with randomly ingested keys

since the pruning capability of the run synopses is anyway limited when we have random keys in the query batch. As a result, the performance of sequential queries becomes similar to that of random queries.

8.4 End-to-end Experiments

The last set of experiments evaluates the end-to-end performance of Umzi in Wildfire as we perform data ingest and index lookups concurrently while Umzi's index maintenance operations are also handled in the background. By default, for each experiment, we ingest roughly 100000 random records per second. The groomer runs every second, and the post-groomer runs every 20 seconds. We also submit batches of 1000 random index lookup queries continuously. Each experiment lasts for 100 seconds.

For this set of experiments, we generate data with update rates that mimic a realistic IoT application, where the recent data are updated more frequently. The update rates are calculated based on the groom cycles: the ingested data for the latest groom cycle updates $p\%$ of data from the last groom cycle, and $0.1 \times p\%$ of data from the last 50 cycles, and $0.01 \times p\%$ of data in the last 100 cycles. By default, we set $p\% = 10\%$.

With this experimental setup, we investigate the impact of concurrent readers, percentage of updates, purged runs, and index evolve operations on index lookup time. The results are summarized and discussed below.

8.4.1 Concurrent Readers. Figure 12 shows how varying the number of concurrent readers impact the average index lookup time. Each reader thread submits batches of 1000 lookup queries continuously. For brevity, we show results for only 4, 16, 28, 40, and 52 readers, and the experiment results are normalized against the lookup time with 1 reader from the beginning of the experiment. In addition, Figure 12 zooms into a 30 second period from the middle of the overall experiment to focus on the impact of concurrency as opposed to the index behavior over time as the index grows. As one can see, more concurrent readers have small impact on the query performance, which demonstrates the advantages of Umzi's lock-free design for the readers. The varying performance of the index lookup operation in this graph (and the rest of the graphs in this section) is due to the random input keys we generate for the index lookup requests. Based on the distribution of these random keys, the search for a key can lead to reading fewer or more index runs, which impacts the performance of a point lookup as seen previously.

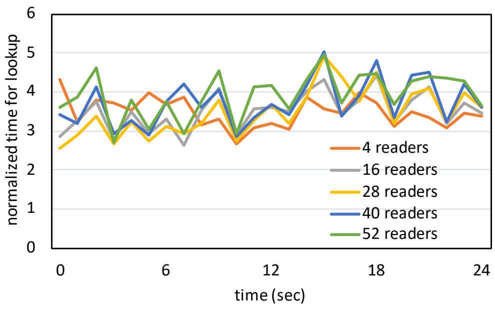


Figure 12: Performance with concurrent readers

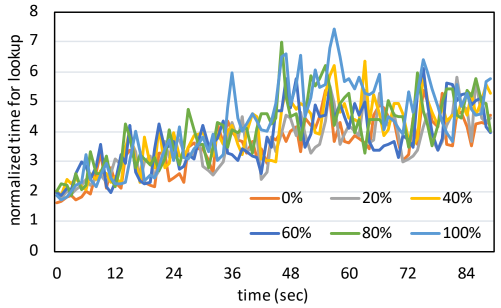

Figure 13: Varying percentage of update workloads

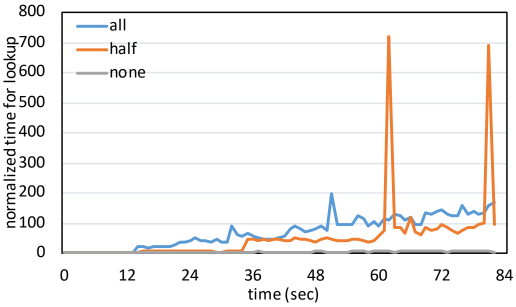

Figure 14: Performance with various purge levels

8.4.2 Updates. Figure 13 analyzes the impact of varying level of updates in a workload on the query performance. We change the update rate $p\%$ from 0% (read-only workload) to 100% (all ingested records are updates after the first groom cycle). As the graph demonstrates, updates have limited impact on the average query performance. The slightly increasing lookup time over time, which can be observed in all the experiments in this section, is due to the growing of the index run chain of Umzi.

8.4.3 Purged Runs. The impact of purged runs on the query performance is shown in Figure 14, where we manually set the purge level to control the percentage of purged runs. The running time is normalized against the performance of the no-purge case in the beginning of this experiment. As expected, Figure 14 emphasizes the significance of the SSD cache on the query performance. The latency of the lookup queries is much lower when all the index runs are cached (*none*) compared to the cases where the *half* or *all* of the runs are purged. Moreover, when some runs are purged, we observe unpredictable latency spikes. The reason is that when purged runs are first accessed after being merged or evolved, they have to be fetched from the shared storage into the local SSD cache on a block by block basis as the queries require them.

8.4.4 Index Evolve Operations. Finally, we evaluate the impact of the index evolve operations on the query performance by enabling/disabling the post-groomer. The results are shown in Figure 15. The running time is normalized against the lookup time in the beginning of the experiment where the post-groomer (including index evolution), is enabled. As the graph illustrates, the index evolve operation has certain overhead over the query performance, since often the query may experience several cache misses after runs have been evolved. However, the overhead again is limited, since in the meanwhile the index evolve operation reduces the total of number of runs, which in turn improves the query performance.

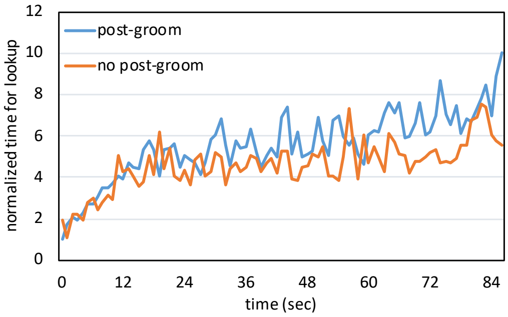

Figure 15: Impact of index evolve operations

9 RELATED WORK

In this section, we survey related work in indexing methods for HTAP systems, as well as LSM-like indexes.

Indexing in HTAP Systems. To satisfy the demand of fast transactions and analytical queries concurrently, many HTAP systems and solutions have been proposed recently. A recent survey of HTAP systems can be found in [32]. In-memory HTAP engines, e.g., SAP HANA [21], HyPer [22], Pelaton [14], Oracle TimesTen [23] and DBIM [29] take unique advantage of large main memories, e.g., random writes and in-place updates, while large-scale HTAP systems that go beyond the memory limit have to face inherently different challenges in the presence of disks and shared storage. MemSQL [7] supports skip-list or hash indexes over the in-memory row store, and LSM-like indexes over the on-disk column store. However, column store indexes cannot be combined with row indexes to provide a unified view for queries. SnappyData [28] only supports indexes over row tables, while providing no indexing support for column tables.

Another category of HTAP solutions typically glue multiple systems together to handle OLTP and OLAP queries. For example, one typical solution is to use a key-value store, such as HBase [3] or Cassandra [1], as the updatable storage layer, while resorting to SQL-on-Hadoop systems such as Spark-SQL [13] to process analytical queries with the help of data connectors. Other systems directly build upon updatable storage engines to handle both transactional and analytical queries, such as Hive [35] on HBase [3] and Impala [16] on Kudu [5]. In these solutions, indexes, if any, are exclusively managed by the storage engine to support efficient point lookups. However, none of these solutions support both fast ingestion and data scans, which is different from our system where ingested data evolves constantly to be more analytics-friendly.

LSM-like Index. The LSM-tree [31] is a persistent index structure optimized for write-heavy workloads. Instead of updating entries in place, which potentially requires a random I/O, the LSM-tree batches inserts into memory and flushes the data to disk using sequential I/O when the memory is full. It was subsequently adopted by many NoSQL systems, such as HBase [3], Cassandra [1], LevelDB [6] and RocksDB [9], for its superior write performance. Many variations of the original LSM-tree have been proposed as well. LHAM [30] is a multi-version data access method based on LSM for temporal data. FD-tree [24] is designed for SSDs by limiting random I/Os and uses fractional cascading [18] to improve search performance. bLSM [34] uses bloom filters to improve point lookup performance, and proposes a dedicated merge scheduler to bound write latencies. AsterixDB [12] proposes a general framework for using LSM-tree as secondary indexes. Ahmad and Kemme [11] present an approach to improve the merge process by offloading merge to dedicated nodes and a cache warm-up algorithm to alleviate cache misses after merge. LSM-Trie [36] organizes runs using a prefix tree-like structure to improve point lookup performance by sacrificing the ability to do range queries. WiscKey [25] reduces write amplification by only storing keys in the LSM tree while leaving values in a separate log. The work [26] presented efficient maintenance strategies for LSM-based auxiliary structures, i.e., secondary indexes and filters, to facilitate query processing. Monkey [19] is an analytical approach for automatic performance tuning of LSM trees. Dostoevsky [20] presents a lazy leveling merge policy for better trade-offs among query cost, write cost and space amplification. Accordion [17] optimizes LSM on large memories by in-memory flushes and merges. SlimDB [33] optimizes LSM-based key-value stores for managing semi-sorted data.

Different from existing work on LSM indexes, which focuses on a key-value store setting, Umzi is an end-to-end indexing solution in distributed HTAP systems. It supports the multi-zone design commonly adopted by large-scale HTAP systems, and evolves itself as data migrates without blocking queries. We further discuss how Umzi is designed to accommodate the multi-tier storage hierarchy, i.e., memory, SSD, and shared storage, to improve storage efficiency.

10 CONCLUSION

This paper describes Umzi, the first unified multi-version and multi-zone indexing method for large-scale HTAP systems in the context of Wildfire. Umzi adopts the LSM-like design to avoid random I/Os in shared storage, and supports timestamped queries for multi-version concurrency control schemes. Unlike existing LSM indexes, Umzi addresses the challenges posed by the multi-zone design of modern HTAP systems, and supports migrating index contents as data evolves from one zone to another. It also utilizes an interesting combination of hash and sort techniques to enable both equality and range queries using one index structure. Furthermore, it fully exploits the multi-level storage hierarchy of HTAP systems for index persistence and caching.

In the future, we plan to extend Umzi to build and maintain secondary indexes in HTAP systems. Then, we would like to perform more experimental evaluation on Umzi to study its performance under various workloads. Finally, we would also like to study other SSD cache management strategies, and evaluate their impact on query performance.

ABSTRACT

Answering exact shortest path distance queries is a fundamental task in graph theory. Despite a tremendous amount of research on the subject, there is still no satisfactory solution that can scale to billion-scale complex networks. Labelling-based methods are well-known for rendering fast response time to distance queries; however, existing works can only construct labelling on moderately large networks (million-scale) and cannot scale to large networks (billion-scale) due to their prohibitively large space requirements and very long preprocessing time. In this work, we present novel techniques to efficiently construct distance labelling and process exact shortest path distance queries for complex networks with billions of vertices and billions of edges. Our method is based on two ingredients: (i) a scalable labelling algorithm for constructing minimal distance labelling, and (ii) a querying framework that supports fast distance-bounded search on a sparsified graph. Thus, we first develop a novel labelling algorithm that can scale to graphs at the billion-scale. Then, we formalize a querying framework for exact distance queries, which combines our proposed highway cover distance labelling with distance-bounded searches to enable fast distance computation. To speed up the labelling construction process, we further propose a parallel labelling method that can construct labelling simultaneously for multiple landmarks. We evaluated the performance of the proposed methods on 12 real-world networks. The experiments show that the proposed methods can not only handle networks with billions of vertices, but also be up to 70 times faster in constructing labelling and save up to 90% of labelling space. In particular, our method can answer distance queries on a billion-scale network of around 8B edges in less than 1ms, on average.

1 INTRODUCTION

Finding the shortest-path distance between a pair of vertices is a fundamental task in graph theory, and has a broad range of applications [5, 11, 20, 26, 30, 31, 33]. For example, in web graphs, ranking of web pages based on their distances to recently visited web pages helps in finding the more relevant pages and is referred to as context-aware search [30]. In social network analysis, distance is used as a core measure in many problems such as centrality [11, 26] and community identification [5], which require distances to be computed for a large number of vertex pairs. However, despite extensive efforts in addressing the shortest-path distance problem for many years, there is still a high demand for scalable solutions that can be used to support analysis tasks over large and ever-growing networks.

Traditionally, one can use the Dijkstra algorithm [27] for weighted graphs or a breadth-first search (BFS) algorithm for unweighted graphs to query shortest-path distances. However, these algorithms are not scalable, i.e., for large graphs with billions of vertices and edges, they may take seconds or even longer to find the shortest-path distance between one pair of vertices, which is not acceptable for large-scale network applications where distances need to be provided in the order of milliseconds. To improve query time, a well-established approach is to precompute and store shortest-path distances between all pairs of vertices in an index, also called *distance labelling*, and then answer a *distance query* (i.e., find the distance between two vertices) in constant time with a single lookup in the index. Recent work [15] shows that such labelling-based methods are the fastest known exact distance querying methods on moderately large graphs (million-scale) having millions of edges, but still fail to scale to large graphs (billion-scale) due to quadratic space requirements and unbearable indexing construction time.

Thus, the question is still open as to how scalable solutions to answer exact distance queries in billion-scale networks can be developed. Essentially, there are three computational factors to be considered concerning the performance of algorithms for answering distance queries: construction time, index size, and query time. Much of the existing work has focused on exploring trade-offs among these computational factors [1–4, 8, 12, 14, 15, 17, 19, 22, 23, 29, 32], especially for the 2-hop cover distance labelling [3, 9]. Nonetheless, to handle large graphs, we believe that a scalable solution for answering exact distance queries needs to have the following desirable characteristics: (1) the construction time of a distance labelling is scalable with the size of a network; (2) the size of a distance labelling is minimized so as to reduce the space overhead; (3) the query time remains in the order of milliseconds, even in graphs with billions of nodes and edges.

In this work, we aim to develop a scalable solution for exact distance queries which can meet the aforementioned characteristics. Our solution is based on two ingredients: (i) a scalable labelling algorithm for constructing minimal distance labelling, and (ii) a querying framework that supports fast distance-bounded search on a sparsified graph. More specifically, we first develop a novel labelling algorithm that can scale to graphs at the billion-scale. We observed that, for a given number of landmarks, the distance entries from these landmarks to other vertices in a graph can be further minimized if the definition of 2-hop cover distance labelling is relaxed. Thus, we formulate a relaxed notion for labelling in this paper, called the *highway cover distance labelling*, and develop a simple yet scalable labelling algorithm that adds a significantly small number of distance entries into the label of each vertex. We prove that the distance labelling constructed by our labelling algorithm is minimal, and also experimentally verify that the construction process is scalable.

IS-L [12]	yes	no	no	no
PLL [3]	yes	yes	no	neighbours
HDB [16]	yes	no	no	no
HHL [2]	yes	no	no	no

Figure 1: High-level overview of the state-of-the-art methods and our proposed method (HL) for exact distance queries: (a) performance w.r.t. query time and labelling size on networks of size up to 400M, (b) scalability w.r.t. labelling construction time and network size, and (c) several important properties related to labelling methods.

Then, we formalize a querying framework for exact distance queries, which combines our proposed highway cover distance labelling with distance-bounded searches to enable fast distance computation. This querying framework is capable of balancing the trade-off between construction time, index size and query time through an offline component (i.e. the proposed highway cover distance labelling) and an online component (i.e. distance-bounded searches). The basic idea is to select a small number of highly central landmarks that allow us to efficiently compute the upper bounds of distances between all pairs of vertices using an offline distance labelling, and then conduct distance-bounded search over a sparsified graph to find exact distances efficiently. Our experimental results show that the query time of distance queries within this framework is still in millionseconds for large graphs with billions of vertices and edges.

Figure 1 summarizes the performance of the state-of-the-art methods for exact distance queries [2, 3, 8, 12, 15, 16, 21, 27], as well as our proposed method in this paper, denoted as HL. In Figure 1(a)-1(b), we can see that, labelling-based methods PLL [3], HDB [16], and HHL [2] can answer distance queries in a considerably small amount of time. However, they have very large space requirements and very long labelling construction time. On the contrary, traditional online search methods such as Dijkstra [27] and bidirectional BFS (denoted as Bi-BFS) [21] are not applicable to large-scale networks where distances need to be provided in the order of milliseconds because of their very high response time. The hybrid methods FD [12], IS-L [15] and HL (our method) combine an offline labelling and an online graph traversal technique, which can provide better trade-offs between query response time and labelling size. In Figure 1(b), we can also see that only our proposed method HL can handle networks of size 8B, and is scalable to perform distance queries on networks with billions of vertices and billions of edges.

Figure 1(c) presents a high-level overview for several important properties of labelling methods. The column Ordering dependent refers to whether a distance labelling depends on the ordering of landmarks when being constructed by a method. Only our method HL and FD are not ordering-dependent. The columns 2HC-minimal and HWC-minimal refer to whether a distance labelling constructed by a method is minimal in terms of the 2-hop cover (2HC) and highway cover (HWC) properties, respectively. PLL is 2HC-minimal, but not HWC-minimal. Our method HL is the only method that is HWC-minimal. The column Parallel refers to what kind of parallelism a method can support. FD and PLL support bit-parallelism for up to 64 neighbours of a landmark. Our method HL supports parallel computation for multiple landmarks, depending on the number of processors. Other methods did not mention any parallelism.

In summary, our contributions in this paper are as follows:

- We introduce a new labelling property, namely highway cover labelling, which relaxes the standard notion of 2-hop cover labelling. Based on this new labelling property, we propose a highly scalable labelling algorithm that can scale to construct labellings for graphs with billions of vertices and billions of edges.
- We prove that the proposed labelling algorithm can construct HWC-minimal labellings, which is independent of any ordering of landmarks. Then, due to this determinstric nature of labelling, we further develop a parallel algorithm which can run parallel BFSs from multiple landmarks to speed up labelling construction.
- We combine our novel labelling algorithm with online bounded-distance graph traversal to efficiently answer exact distance queries. This querying framework enables us to balance the trade-offs among construction time, labelling size and query time.
- We have experimentally verified the performance of our methods on 12 large-scale complex networks. The results that our methods can not only handle networks with billions of vertices, but also be up to 70 times faster in constructing labelling and save up to 90% of labelling space.

The rest of the paper is organized as follows. In Section 2, we present basic notations and definitions used in this paper. Then, we discuss a novel labelling algorithm in Section 3, formulate the querying framework in Section 4, and introduce several optimization techniques in Section 5. In Section 6 we present our experimental results and in Section 7 we discuss other works that are related to our work here. The paper is concluded in Section 8.

2 PRELIMINARIES

Let $G = (V, E)$ be a graph where V is a set of vertices and $E \subseteq V \times V$ is a set of edges. We have $n = |V|$ and $m = |E|$. Without loss of generality, we assume that the graph G is connected and undirected in this paper. Let $V' \subseteq V$ be a subset of vertices of G. Then the induced subgraph $G[V']$ is a graph whose vertex set is V' and whose edge set consists of all of the edges in E that have both endpoints in V'. Let $N_G(v) = \{u \in V | (u, v) \in E\}$ denote a set of neighbors of a vertex $v \in V$ in G.

The *distance* between two vertices s and t in G, denoted as $d_G(s, t)$, is the length of the shortest path from s to t. We consider

$d_G(s,t) = \infty$, if there does not exist a path from s to t. For any three vertices $s, u, t \in V$, the following *triangle inequalities* are satisfied:

$$d_G(s,t) \leq d_G(s,u) + d_G(u,t) \quad (1)$$

$$d_G(s,t) \geq |d_G(s,u) - d_G(u,t)| \quad (2)$$

If u belongs to one of the shortest paths from s to t, then $d_G(s,t) = d_G(s,u) + d_G(u,t)$ holds.

Given a special subset of vertices $R \subseteq V$ of G, so-called *landmarks*, a *label* $L(v)$ for each vertex $v \in V$ can be precomputed, which is a set of *distance entries* $\{(u_1, \delta_L(u_1, v)), \dots, (u_n, \delta_L(u_n, v)\}$ where $u_i \in R$ and $\delta_L(u_i, v) = d_G(u_i, v)$ for $i = 1, \dots, n$. The set of labels $L = \{L(v)\}_{v \in V}$ is called a *distance labeling* over G. The *size* of a distance labelling L is defined as size(L)=$\Sigma_{v \in V} |L(v)|$.

Using such a *distance labeling* L, we can query the distance between any pair of vertices $s, t \in V$ in graph G as follows,

$$\text{Q}(s,t,L) = \texttt{min}\{\delta_L(u,s) + \delta_L(u,t) | (u, \delta_L(u,s)) \in L(s), (u, \delta_L(u,t)) \in L(t)\} \quad (3)$$

We define $\text{Q}(s,t,L) = \infty$, if $L(s)$ and $L(t)$ do not share any landmark. If $\text{Q}(s,t,L) = d_G(s,t)$ holds for any two vertices s and t of G, L is called a *2-hop cover distance labeling* over G [2, 9].

Given a graph G and a set of landmarks $R \subseteq V$, the *distance querying problem* is to efficiently compute the shortest path distance $d_G(s,t)$ between any two vertices s and t in G, using a distance labeling L over G in which labels may contain distance entries from landmarks in R.

3 HIGHWAY COVER LABELLING

In this section, we formulate the highway cover labelling problem and propose a novel algorithm to efficiently construct the highway cover distance labelling over graphs. Then, we provide theoretical analysis of our proposed algorithm.

3.1 Highway Cover Labelling Problem

We begin with the definitions of highway and highway cover.

Definition 3.1. (*Highway*) A highway H is a pair (R, δ_H), where R is a set of landmarks and δ_H is a *distance decoding function*, i.e. $\delta_H : R \times R \to \mathbb{N}^+$, such that for any $\{r_1, r_2\} \subseteq R$ we have $\delta_H(r_1, r_2) = d_G(r_1, r_2)$.

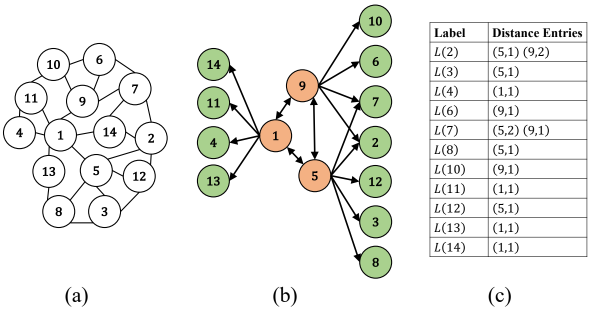
Given a landmark $r \in R$ and two vertices $s, t \in V \backslash R$ (i.e. $V \backslash R = V - R$), a *r-constrained shortest path* between s and t is a path between s and t satisfying two conditions: (1) It goes through the landmark r, and (2) It has the minimum length among all paths between s and t that go through r. We use P_{st} to denote the set of vertices in a shortest path between s and t, and P^r_{st} to denote the set of vertices in a r-constrained shortest path between s and t.

Definition 3.2. (*Highway Cover*) Let $G = (V, E)$ be a graph and $H = (R, \delta_H)$ a highway. Then for any two vertices $s, t \in V \backslash R$ and for any $r \in R$, there exist $(r_i, \delta_L(r_i, s)) \in L(s)$ and $(r_j, \delta_L(r_j, t)) \in L(t)$ such that $r_i \in P_{rs}$ and $r_j \in P_{rt}$, where r_i and r_j may equal to r.

If the label of a vertex v contains a distance entry $(r, \delta_L(r, v))$, we also say that the vertex v is *covered* by the landmark r in the distance labelling L. Intuitively, the highway cover property guarantees that, given a highway H with a set of landmarks R and $r \in R$, any r-constrained shortest path distance between two vertices s and t can be found using only the labels of these two vertices and the given highway. A distance labelling L is called a *highway cover distance labelling* if L satisfies the highway cover property.

Example 3.3. Consider the graph G depicted in Figure 2(a), the highway H has three landmarks $\{1, 5, 9\}$ as highlighted in red in Figure 2(b). Based on the graph in Figure 2(a) and the highway in Figure 2(b), we have $\langle 11, 1, 4 \rangle$ which is a shortest path between the vertices 11 and 4 constrained by the landmark 1, i.e. 1-constrained shortest path between 11 and 4. In contrast, neither of the paths $\langle 11, 10, 9, 1, 4 \rangle$ and $\langle 11, 4 \rangle$ is a 1-constrained shortest path between 11 and 4.

In Figure 2(b), the outgoing arrows from each landmark point to vertices in G that are covered by this landmark in the highway. The distance labelling in Figure 2(c) satisfies the highway cover property because for any two vertices that are not landmarks and any landmark $r \in \{1, 5, 9\}$, we can find the r-constrained shortest path distance between these two vertices using their labels and the highway.



Label	Distance Entries
$L(2)$	(5,1) (9,2)
$L(3)$	(5,1)
$L(4)$	(1,1)
$L(6)$	(9,1)
$L(7)$	(5,2) (9,1)
$L(8)$	(5,1)
$L(10)$	(9,1)
$L(11)$	(1,1)
$L(12)$	(5,1)
$L(13)$	(1,1)
$L(14)$	(1,1)

(a) (b) (c)

Figure 2: An illustration of highway cover distance labelling: (a) an example graph G, (b) a highway structure H and (c) a distance labelling that fulfills the highway cover property over (G, H).

Definition 3.4. (*Highway Cover Labelling Problem*) Given a graph G and a highway H over G, the *highway cover labelling problem* is to efficiently construct a highway cover distance labelling L.

Several choices naturally come up: (1) One is to add a distance entry for each landmark into the label of every vertex in $V - R$, as the approach proposed in [15]; (2) Another is to use the pruned landmark labelling approach [3] to add the distance entry of a landmark r into the labels of vertices in $V - R$ if the landmark has not been pruned during a BFS rooted at r; (3) Alternatively, we can also extend the pruned landmark labelling approach to construct the highway cover labeling by replacing the 2-hop cover pruning condition with the one required by the highway cover as defined in Definition 3.2 at each step of checking possible labels to be pruned.

In all these cases, the labelling construction process would not be scalable nor be suitable for large-scale complex networks with billions of vertices and edges. Moreover, these approaches would potentially lead to the construction of distance labellings with different sizes. A question arising naturally is how to construct a minimal highway cover distance labelling without redundant labels? In a nutshell, it is a challenging task to construct a highway cover distance labelling that can scale to very large networks, ideally in linear time, but also with the minimal labelling size.

3.2 A Novel Algorithm

We propose a novel algorithm for solving the highway cover labelling problem, which can construct labellings in linear time.

The key idea of our algorithm is to construct a *label* $L(v)$ for vertex $v \in V\backslash R$ such that the distance entry $(r_i, \delta_L(r_i, v))$ of each landmark $r_i \in R$ is only added into the label $L(v)$ iff there does not exist any other landmark that appears in the shortest path between r_i and v, i.e. $P_{r_i v} \cap R = \{r_i\}$. In other words, if there is another landmark $r \in R$ and r_i is in the shortest path between r and v, then $(r_i, \delta_L(r_i, v))$ is added into $L(v)$ iff r_i is the "closest" landmark to v. To compute such labels efficiently, we conduct a breadth-first search from every landmark $r_i \in R$ and add distance entries into labels of vertices that do not have any other landmark in their shortest paths from r_i.

Example 3.5. Consider vertex 7 in Figure 2(c), the label $L(7)$ contains the distance entries of landmarks $\{5, 9\}$, but no distance entry of landmark 1. This is because 5 and 9 are the closest landmarks to vertex 7 in the shortest paths $\langle 5, 7\rangle$ and $\langle 9, 7\rangle$, respectively. However, for either of two shortest paths $\langle 1, 9, 7\rangle$ and $\langle 1, 5, 7\rangle$ between 1 and 7, there is another landmark (i.e. 5 or 9) that is closer to 7 compared with 1 in these shortest paths. Thus the distance entry of landmark 1 is not added into $L(7)$.

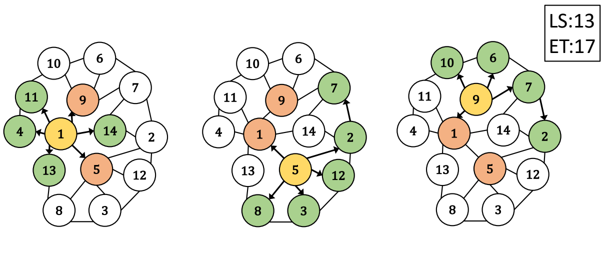
Our highway cover labelling approach is described in Algorithm 1. Given a graph G and a highway H over G, we start with an empty *highway cover distance labelling* L, where $L(v) = \emptyset$ for every $v \in V\backslash R$. Then, for each landmark $r_i \in R$, we compute the corresponding distance entries as follows. We use two queues Q_{label} and Q_{prune} to process vertices to be labeled or pruned at each level of a breadth-first search (BFS) tree, respectively. We start by processing vertices in Q_{label}. For each vertex $u \in Q_{label}$ at depth n, we examine the children of u at depth $n + 1$ that are unvisited. For each unvisited child vertex $v \in N_G(u)$ at depth $n + 1$, if $v \in R$ then we prune v, i.e., we do not add a distance entry of the current landmark r_i into $L(v)$ and we also enqueue v to the pruned queue Q_{prune} (Line 11). Otherwise, we add $(r_i, \delta_{BFS}(r_i, v))$ to the *label* of v, i.e., we add it into $L(v)$ and we also enqueue v to the labeled queue Q_{label} (Lines 13-14). Here, $\delta_{BFS}(r_i, v)$ refers to BFS decoded distance from root r_i to v. Then we process the pruned vertices in Q_{prune}. These vertices are either landmarks or have landmarks in their shortest paths from r_i, and thus do not need to be labeled. Therefore, for each vertex $v \in Q_{prune}$ at depth n, we enqueue all unvisited children of v at depth $n + 1$ to the pruned queue Q_{prune}. We keep processing these two queues, one after the other, until Q_{label} is empty.

Example 3.6. We illustrate how our algorithm conducts pruned BFSs in Figure 3. The pruned BFS from landmark 1 is depicted in Figure 3(a), which labels only four vertices $\{4, 11, 13, 14\}$ because the other vertices are either landmarks or contain other landmarks in their shortest paths to landmark 1. Similarly, in the pruned BFS from landmark 5 depicted in Figure 3(b), only vertices $\{7, 2, 12, 3, 8\}$ are labelled, and none of the vertices 4, 11, 13 and 14 is labelled because of the presence of landmark 1 in their shortest paths to landmark 5. Indeed, we can get the distance between landmark 5 to these vertices by using the highway, i.e. $\delta_H(5, 1)$, and distance entries in their labels to landmark 1. The pruned BFS from landmark 9 is depicted in Figure 3(c), which works in a similar fashion.

Note that, although a highway H is given in Algorithm 1, we can indeed compute the distances δ_H for a given set of landmarks R along with Algorithm 1.

Algorithm 1: Constructing the highway cover labelling L

```
   Input: $G = (V.E)$, $H = (R, \delta_H)$
   Output: $L$
1  $L(v) \leftarrow \emptyset, \forall v \in V\backslash R$
2  foreach $r_i \in R$ do
3      $Q_{label} \leftarrow \emptyset$
4      $Q_{prune} \leftarrow \emptyset$
5      $n \leftarrow 0$
6      Enqueue $r_i$ to $Q_{label}$ and set $r_i$ as the root of BFS
7      while $Q_{label}$ is not empty do
8          foreach $u \in Q_{label}$ at depth $n$ do
9              foreach unvisited child $v$ of $u$ at depth $n + 1$ do
10                 if $v$ is a landmark then
11                     Enqueue $v$ to $Q_{prune}$
12                 else
13                     Enqueue $v$ to $Q_{label}$
14                     Add $\{(r_i, \delta_{BFS}(r_i, v))\}$ to $L(v)$
15                 end
16             end
17         end
18         $n \leftarrow n + 1$
19         foreach $v \in Q_{prune}$ at depth $n$ do
20             Enqueue unvisited children of $v$ at depth $n + 1$
                 to $Q_{prune}$
21         end
22     end
23 end
24 return $L$
```



(a) (b) (c)

Figure 3: An illustration of the highway cover labelling algorithm: (a), (b) and (c) describe the pruned BFSs that are rooted at the landmarks 1, 5 and 9, respectively, where yellow vertices denote roots, green vertices denote those being labeled, red vertices denote landmarks, and white vertices are not labelled. LS and ET at the top right corner denote the labelling size and the number of edges traversed during the pruned BFSs, respectively.

3.3 Correctness

Here we prove the correctness of our labelling algorithm.

Lemma 3.7. *In Algorithm 1, for each pruned BFS rooted at $r_i \in R$, $(r_i, \delta_L(r_i, v))$ is added into the label of a vertex $v \in V\backslash R$ iff there is no any other landmark appearing in the shortest path between r_i and v, i.e., $P_{r_i v} \cap R = \{r_i\}$.*

Proof. Suppose that Algorithm 1 is conducting a pruned BFS rooted at r_i and v is an unvisited child of another vertex u in Q_{label} (start from $Q_{label} = \{r_i\}$) (Lines 6-9). If $v \in R$ (Line 10), then we have $(P_{r_i w} \cap R) \supseteq \{r_i, v\}$ (Lines 11, 19-21), $(r_i, \delta_L(r_i, w))$ cannot be added into the label of any child w of v, i.e., put w into Q_{prune}. Otherwise, by $v \notin R$ and v is an unvisited child of a vertex u in Q_{label} (Lines 8-9), we know that $P_{r_i v} \cap R = \{r_i\}$ and thus $(r_i, \delta_L(r_i, v))$ is added into $L(v)$ (lines 12-14). □

Then, by Lemma 3.7, we have the following corollary.

Corollary 3.8. *Let $r \in R$ be a landmark, $v \in V\backslash R$ a vertex, and L a distance labelling constructed by Algorithm 1, if $(r, \delta_L(r, v)) \notin L(v)$, then there must exist a landmark r_j such that $(r_j, \delta_L(r_j, v)) \in L(v)$ and $d_G(r, v) = \delta_L(r_j, v) + \delta_H(r, r_j)$.*

Theorem 3.9. *The highway cover distance labelling L over (G, H) constructed using Algorithm 1 satisfies the highway cover property over (G, H).*

Proof. To prove that, for any two vertices $s, t \in V\backslash R$ and for any $r \in R$, there exist $(r_i, \delta_L(r_i, s)) \in L(s)$ and $(r_j, \delta_L(r_j, t)) \in L(t)$ such that $r_i \in P_{rs}$ and $r_j \in P_{rt}$, we consider the following 4 cases: (1) If $r \in L(s)$ and $r \in L(t)$, then $r = r_i = r_j$. (2) If $r \in L(s)$ and $r \notin L(t)$, then $r_i = r$ and by Lemma 3.8, there exists another landmark r_j such that r_j is in the shortest path between t and r and $(r_j, \delta_L(r_j, t)) \in L(t)$. (3) If $r \notin L(s)$ and $r \in L(t)$, then similarly we have $r_j = r$, and by Lemma 3.8, there exists another landmark r_i such that r_i is in the shortest path between s and r and $(r_i, \delta_L(r_i, s)) \in L(s)$. (4) If $r \notin L(s)$ and $r \notin L(t)$, then by Lemma 3.8 there exist another two landmarks r_i and r_j such that r_i is in the shortest path between s and r and $(r_i, \delta_L(r_i, s)) \in L(s)$, and r_j is in the shortest path between t and r and $(r_j, \delta_L(r_j, t)) \in L(t)$. The proof is done. □

3.4 Order Independence

In previous studies [1–3, 9], given a graph G, a distance labelling algorithm builds a unique canonical distance labelling subject to a labelling order (i.e., the order of landmarks used for constructing a distance labelling). It has been well known that such a labelling order is decisive in determining the size of the constructed distance labelling [24]. For the same set of landmarks, when using different labelling orders, the sizes of the constructed distance labelling may vary significantly.

The following example shows how different labelling orders in the pruned landmark labelling approach [3] can lead to the distance labelling of different sizes.

Example 3.10. In Figure 4, the size of the distance labelling constructed using the labelling order $\langle 1, 5, 9\rangle$ in Figure 4(a)-4(c) is different from the size of the distance labelling constructed using the labelling order $\langle 9, 5, 1\rangle$ in Figure 4(d)-4(f). In both cases, the first BFS adds the distance entry of the current landmark into all the vertices in the graph. Then, the following BFSs check each visited vertex whether the shortest path distance between the current landmark and the visited vertex can be computed via the 2-hop cover property based on their labels added by the previous BFSs. A distance entry is only added into the label of a vertex if the shortest path distance cannot be computed by applying the 2-hop cover over the existing labels. Thus, the choice of the labelling order could affect the size of labels significantly. Take the vertex 11 for example, its label contains only one distance entry (1, 1) using the labelling order depicted in Figure 4(a)-4(c), but contains three distance entries (1.1), (5, 2), and (9, 2) when the labelling order depicted in Figure 4(d)-4(f) is used.

Unlike all previous approaches taken with distance labelling, our highway cover labelling algorithm is order-invariant. That is, regardless of the labelling order, the distance labellings constructed by our algorithm using different labelling orders over the same set of landmarks always have the same size. In fact, we can show that our algorithm has the following stronger property: the distance labelling constructed using our algorithm is deterministic (i.e., the same label for each vertex) for a given set of landmarks.

Lemma 3.11. *Let $G = (V, E)$ be a graph and $H = (R, \delta_H)$ a highway over G. For any two different labelling orders over R, the highway cover distance labellings L_1 and L_2 over (G, H) constructed by these two different labelling orders using Algorithm 1 satisfy $L_1(v) = L_2(v)$ for every $v \in V\backslash R$.*

Proof. Let O_{L_1} and O_{L_2} be two different labelling orders over R. For any landmark r in O_{L_1} and O_{L_2}, Algorithm 1 generates exactly the same pruned BFS tree. This implies that, for each vertex $v \in V\backslash R$, either the same distance entry $(r, \delta_{BFS}(r, v))$ is added into $L_1(v)$ and $L_2(v)$, or no distance entry is added to $L_1(v)$ and $L_2(v)$. Thus, Algorithm 1 satisfy $L_1(v) = L_2(v)$ for every $v \in V\backslash R$. □

3.5 Minimality

Here we discuss the question of minimality, i.e., whether the highway cover distance labelling constructed by our algorithm is always minimal in terms of the labelling size. We first prove the following theorem.

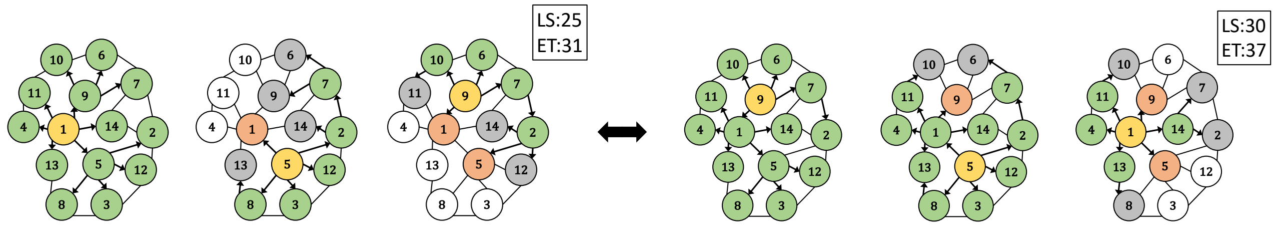
Theorem 3.12. *The highway cover distance labelling L over (G, H) constructed using Algorithm 1 is minimal, i.e., for any highway cover distance labelling L' over (G, H), $size(L') \geq size(L)$ must hold.*

Proof. We prove this by contradiction. Let us assume that there is a highway cover distance labelling L' with $size(L') < size(L)$. Then, this would imply that there must exist a vertex $v \in V\backslash R$ and a landmark $r \in R$ such that $r \in L(v)$ and $r \notin L'(v)$. By Lemma 3.7 and $r \in L(v)$, we know that there is no any other landmark in R that is in the shortest path between r and v. However, by the definition of the highway cover property (i.e. Definition 3.2) and $r \notin L'(v)$, we also know that there must exist another landmark $(r_i, \delta_L(r_i, v)) \in L(v)$ and $r_i \in P_{rv}$, which contradicts with the previous conclusion that there is no any other landmark in the shortest path between r and v. Thus, $size(L') \geq size(L)$ must hold for any highway cover distance labelling L'. □

The state-of-the-art approaches for distance labelling is primarily based on the idea of 2-hop cover [1, 3, 12]. One may ask the question: how is the highway cover labelling different from the 2-hop cover labelling, such as the pruned landmark labelling [3]? It is easy to verify the following lemma that each pruned landmark labelling satisfies the highway cover property for the same set of landmarks.

Lemma 3.13. *Let L be a pruned landmark labelling over graph G constructed using a set of landmarks R. Then L also satisfies the highway cover property over (G, H) where $H = (R, \delta_H)$.*

As the pruned landmark labelling algorithm [3] prunes labels based on the 2-hop cover property, but our highway cover labeling algorithm prunes labels based on the property described in Lemma 3.7, by Theorem 3.12, we also have the following corollary, stating that, for the same set of landmarks, the size of the



(a) (b) (c) (d) (e) (f)

Figure 4: An illustration of the pruned landmark labelling algorithm [3]: (a)-(c) show an example of constructing labels through pruned BFSs from three landmarks in the labelling order $\langle 1, 5, 9\rangle$; (d)-(f) show an example of constructing labels using the same three landmarks but in a different labelling order $\langle 9, 5, 1\rangle$. Yellow vertices denote landmarks that are the roots of pruned BFSs, green vertices denote those being labeled, grey vertices denote vertices being visited but pruned, and red vertices denote landmarks which have already been visited.

highway cover labelling is always smaller than the size of any pruned landmark labelling.

Corollary 3.14. *For a highway cover distance labelling L_1 produced by Algorithm 1 over (G, H), where $H = (R, \delta_H)$, and a pruned landmark labelling L_2 over G using any labelling order over R, we always have $|L_1| \leq |L_2|$.*

Example 3.15. Figure 4 shows the labelling size (LS) of the pruned landmark labelling at the top right corner, which is constructed using two different orderings. The first ordering $\langle 1, 5, 9\rangle$ labels 25 vertices whereas the second ordering $\langle 9, 5, 1\rangle$ labels 30 vertices. On the other hand, the LS of the highway cover distance labelling is 13 as shown in Figure 3. Note that the LS of the highway cover distance labelling does not change, irrespective of ordering. Since the highway cover distance labelling constructed by our algorithm is always minimal, the LS of the highway cover distance labelling in Figure 3 is much smaller than the LS of either pruned landmark labelling in Figure 4.

4 BOUNDED DISTANCE QUERYING

In this section, we describe a bounded distance querying framework that allows us to efficiently compute exact shortest-path distances between two arbitrary vertices in a massive network.

4.1 Querying Framework

We start with presenting a high-level overview of our querying framework. To compute the shortest path distance between two vertices s and t in graph G, our querying framework proceeds in two steps: (1) an upper bound of the shortest path distance between s to t is computed using the highway cover distance labelling; (2) the exact shortest path distance between s to t is computed using a distance-bounded shortest-path search over a sparsified graph from G.

Given a graph G and a highway $H = (R, \delta_H)$ over G, we can precompute a highway cover distance labelling L using the landmarks in R, which enables us to efficiently compute the length of any r-constrained shortest path between two vertices in $V \backslash R$. The length of such a r-constrained shortest path must be greater than or equal to the exact shortest path distance between these two vertices and can thus serve as an upper bound in Step (1). On the other hand, since the length of such a r-constrained shortest path between two vertices in $V \backslash R$ can always be efficiently computed by the highway cover distance labelling L, the distance-bounded shortest-path search only needs to be conducted over a sparsified graph G' by removing all landmarks in R from G, i.e. $G' = G[V \backslash R]$.

More precisely, we define the bounded distance querying problem in the following.

Definition 4.1. (*Bounded Distance Querying Problem*) Given a sparsified graph $G' = (V', E')$, a pair of vertices $\{s, t\} \in V'$, and an upper (distance) bound $d^{\top}_{st}$, the *bounded distance querying problem* is to efficiently compute the shortest path distance d_{st} between s and t over G' under the upper bound $d^{\top}_{st}$ such that,

$$d_{st} = \begin{cases} d_{G'}(s,t), & \text{if } d_{G'}(s,t) \leq d^{\top}_{st} \\ d^{\top}_{st}, & \text{otherwise} \end{cases}$$

In the following, we discuss the two steps of this framework in detail.

4.2 Computing Upper Bounds

Given any two vertices s and t, we can use a *highway cover distance labelling* L to compute an upper bound $d^{\top}_{st}$ for the shortest path distance between s and t as follows,

$$\begin{aligned} d^{\top}_{st} = \mathtt{min}\{\delta_L(r_i, s) + \delta_H(r_i, r_j) + \delta_L(r_j, t) | \\ (r_i, \delta_L(r_i, s)) \in L(s), \\ (r_j, \delta_L(r_j, t)) \in L(t)\} \end{aligned} \quad (4)$$

This corresponds to the length of a shortest path from s to t passing through landmarks r_i and r_j, where $\delta_L(r_i, s)$ is the shortest path distance from r_i to s in $L(s)$, $\delta_H(r_i, r_j)$ is the shortest path distance from r_i to r_j through highway H, and $\delta_L(r_j, t)$ is the shortest path distance from r_j to t in $L(t)$.

Example 4.2. Consider the graph in Figure 2(a), we may use the labels $L(2)$ and $L(11)$ to compute the upper bound for the shortest path distance between two vertices 2 and 11. There are two cases: (1) for the path $\langle 2, 5, 1, 11\rangle$ that goes through landmarks 5 and 1, we have $\delta_L(5, 2) + \delta_H(5, 1) + \delta_L(1, 11) = 1 + 1 + 1 = 3$, and (2) for the path $\langle 2, 9, 1, 11\rangle$ that goes through landmarks 9 and 1, we have $\delta_L(9, 2) + \delta_H(9, 1) + \delta_L(1, 11) = 2 + 1 + 1 = 4$. Thus, we take the minimum of these two distances as the upper bound, which is 3 in this case.

4.3 Distance-Bounded Shortest Path Search

We conduct a bidirectional search on the sparsified graph $G[V \backslash R]$ which is bounded by the upper bound $d^{\top}_{st}$ from the highway cover distance labelling. For a pair of vertices $\{s, t\} \subseteq V \backslash R$, we run breadth-first search algorithm from s and t, simultaneously [15]. Algorithm 2 shows the pseudo-code of our distance-bounded shortest path search algorithm. We use two sets of vertices $\mathcal{P}_s$ and $\mathcal{P}_t$ to keep track of visited vertices from s and t. We use two queues Q_s and Q_t to conduct both a forward search from s and a reverse search from t. Furthermore, we use two integers d_s and d_t to maintain the current distances from s and t, respectively.

During initialization, we set $\mathcal{P}_s$ and $\mathcal{P}_t$ to $\{s\}$ and $\{t\}$, and enqueue s and t into Q_s and Q_t, respectively. In each iteration, we increment d_s or d_t and expand $\mathcal{P}_s$ or $\mathcal{P}_t$ by running either a forward search (FS) or a reverse search (RS) as long as $\mathcal{P}_s$ and $\mathcal{P}_t$ have no any common vertex or $d_s + d_t$ is equal to the upper bound $d^{\top}_{st}$, and Q_s and Q_t are not empty. In the forward search from s, we examine the neighbors $N_{G[V\backslash R]}(v)$ of each vertex $v \in Q_s$. Suppose we are visiting a vertex $w \in N_{G[V\backslash R]}(v)$, if w is included in vertex set $\mathcal{P}_t$, then it means that we find a shortest path to vertex t of length $d_s + 1 + d_t$, because the reverse search from t had already visited w with distance d_t. At this stage, we return $d_s + 1 + d_t$ as the answer since we already know $d_s + d_t + 1 \leq d_G(s,t) \leq d^{\top}_{st}$. Otherwise, we add vertex w to $\mathcal{P}_s$ and enqueue w into a new queue Q_{new}. When we could not find the shortest distance in the iteration, we replace Q_s with Q_{new} and increase d_s by 1, and check if $d_s + d_t = d^{\top}_{st}$. If it holds, then we return $d^{\top}_{st}$ since $d^{\top}_{st} \leq d_G(s,t) \leq d_s + d_t + 1$.

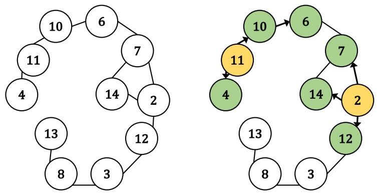
Algorithm 2: Distance-Bounded Shortest Path Search

```
Input: $G[V\backslash R]$, $s$, $t$, $d^{\top}_{st}$
Output: $d_{G[V\backslash R]}(s,t)$
$\mathcal{P}_s \leftarrow \{s\}, \mathcal{P}_t \leftarrow \{t\}, d_s \leftarrow 0, d_t \leftarrow 0$
Enqueue $s$ to $Q_s$, $t$ to $Q_t$
while $Q_s$ and $Q_t$ are not empty do
    if $|\mathcal{P}_s| \leq |\mathcal{P}_t|$ then
        $found \leftarrow \mathsf{FS}(Q_s)$
    else
        $found \leftarrow \mathsf{RS}(Q_t)$
    end
    if $found = true$ then
        return $d_s + 1 + d_t$
    else if $d_s + d_t = d^{\top}_{st}$ then
        return $d^{\top}_{st}$
    end
end
return $\infty$
```

Example 4.3. In Figure 5(b), the upper distance bound between vertices 2 and 11 is 3, as computed in Example 4.2. Suppose that we run BFSs from vertices 2 and 11 respectively. First, a forward search from 2 enqueues its neighbors 7, 12 and 14 into Q_2 and increases d_2 by 1. Then a reverse search from 11 enqueues 4 and 10 into Q_{11} and also sets d_{11} to 1. At this stage, we have not found any common vertex between Q_2 and Q_{11}, and $d_2 + d_{11} = 2$ which is less the upper bound 3. Therefore, we continue to start a search from the vertices in Q_{11}, which enqueues 5 into Q_{11} and increments d_{11} to 2. Now, we have $d_2 + d_{11} == 3$ reaching the upper bound, hence we do not need to continue our search.

4.4 Correctness

The correctness of our querying framework can be proven based on the following two lemmas. More specifically, Lemma 4.4 can be derived by the highway cover property and the definition of $d^{\top}_{st}$. Lemma 4.5 can also be proven by the property of shortest path and the definition of the sparsified graph $G[V\backslash R]$.



(a) (b)

Figure 5: An illustration of the distance-bounded shortest path search algorithm [15]: (a) shows the sparsified graph after removing three landmarks $\{1,5,9\}$ from the graph in Figure 2(a); (b) shows an example of computing the bounded distance between vertices 2 and 11 as highlighted in yellow, and green vertices denote the visited vertices in the forward and reverse searches.

Lemma 4.4. *For a highway cover distance labelling L over (G, H), we have $d^{\top}_{st} \geq d_G(s,t)$ for any two vertices s and t of G, where $d^{\top}_{st}$ is computed using L and H.*

Lemma 4.5. *For any two vertices $\{s,t\} \subseteq V\backslash R$, if there is a shortest path between s and t in G that does not include any vertex in R, then $d_G(s,t) = d_{G[V\backslash R]}(s,t)$ holds.*

Thus, the following theorem holds:

Theorem 4.6. *Let $G = (V, E)$ be a graph, H a highway over G and L a highway cover distance labelling. Then, for any two vertices $\{s,t\} \subseteq V$, the querying framework over (G, H, L) yields $d_G(s,t)$.*

Proof. We consider two cases: (1) P_{st} contains at least one landmark. In this case, By Lemma 4.4 and the definition of the highway cover property, we have $d^{\top}_{st} = d_G(s,t)$. (2) P_{st} does not contain any landmark. By Lemma 4.5, we have $d_{G[V\backslash R]}(s,t) = d_G(s,t)$. □

5 OPTIMIZATION TECHNIQUES

In this section, we discuss optimization techniques for label construction, label compression, and query processing.

5.1 Label Construction

A technique called Bit-Parallelism (BP) has been previously used in several methods [3, 15] to speed up the label construction process. The key idea of BP is to perform BFSs from a given landmark r and up to 64 of its neighbors simultaneously, and encode the relative distances (-1, 0 or 1) of these neighbors w.r.t. the shortest paths between r and each vertex v into a 64-bit unsigned integer. In the work [3], BP was applied to construct bit-parallel labels from initial vertices without pruning, which aimed to leverage the information from these bit-parallel labels to cover more shortest paths between vertices. Then, both bit-parallel labels and normal labels are constructed in the pruned BFSs. The work in [15] also used BP to construct thousands of bit-parallel shortest-path trees (SPTs) because it is very costly to construct thousands of normal SPTs in memory owing to their prohibitively large space requirements and very long construction time.

In our work, we develop a simple yet rigorous parallel algorithm (HL-P) which can run parallel BFSs from multiple landmarks (depending on the number of processors) to construct

Table 1: Datasets, where $|G|$ denotes the size of a graph G with each edge appearing in the forward and reverse adjacency lists and being represented by 8 bytes.

labelling in an extremely efficient way for massive networks, with much less time as will be demonstrated in our experiments.

5.2 Label Compression

The choice of the data structure for labels may significantly affect the performance of index size and memory usage. As noted in [19], some works [2, 10] did not elaborate on what data structure they have used for representing labels. Nonetheless, for the works that are most relevant to ours, such as FD [15] and PLL [3], they used 32-bit integers to represent vertices and 8-bit integers to represent distances for normal labels. In addition to this, they also used 64-bits to encode the distances from a landmark to up to 64 of its neighbors in their shortest paths to other vertices. Since our approach only selects a very small number of landmarks to construct the highway cover labelling (usually no more than 100 landmarks), we may use 8 bits to represent landmarks and another 8 bits to store distances for labels. In order to fairly compare methods from different aspects, we have implemented our methods using both 32 bits and 8 bits for representing vertices in labels. However, different from the BP technique that uses 64-bits to encode the distance information of up to 64 neighbours of a landmark, our parallel algorithm (HL-P) does not use a different data structure for labels constructed in parallel BFSs.

5.3 Query Processing

We show that computing the upper bound $d^{\top}_{st}$ can be optimized based on the observation, captured by the following lemma.

Lemma 5.1. *For a highway cover distance labelling L over (G, H), where $G = (V, E)$ and $H = (R, \delta_H)$, and any $\{s, t\} \subseteq V \backslash R$, if a landmark r appears in both $L(s)$ and $L(t)$, then $\delta_L(r, s) + \delta_L(r, t) \leq \delta_L(r, s) + \delta_H(r, r') + \delta_L(r', t)$ holds for any other $r' \in R$.*

Proof. By the definition of the highway cover property, we know that r is not in the shortest path between r' and t. Then by triangle inequality in Equation 1, this lemma can be proven. □

Thus, in order to efficiently compute the upper bound $d^{\top}_{st}$, for any landmarks that appear in both $L(s)$ and $L(t)$, we compute the r-constrained shortest path distance between s and t using Equation 2, while for a landmark r' that only appear in one of $L(s)$ and $L(t)$, we use Equation 4 to calculate the r'-constrained shortest path distance between s and t. This would lead to more efficient computations for queries when the landmarks appear in both labels of two vertices.

6 EXPERIMENTS

To compare the proposed method with baseline approaches, we have implemented our method in C++11 using STL libraries and compiled using gcc 5.5.0 with the -O3 option. We performed all the experiments using a single thread on a Linux server (having 64 AMD Opteron(tm) Processors 6376 with 2.30GHz and 512GB of main memory) for sequential version of the proposed method and up to 64 threads for parallel version of the proposed method.

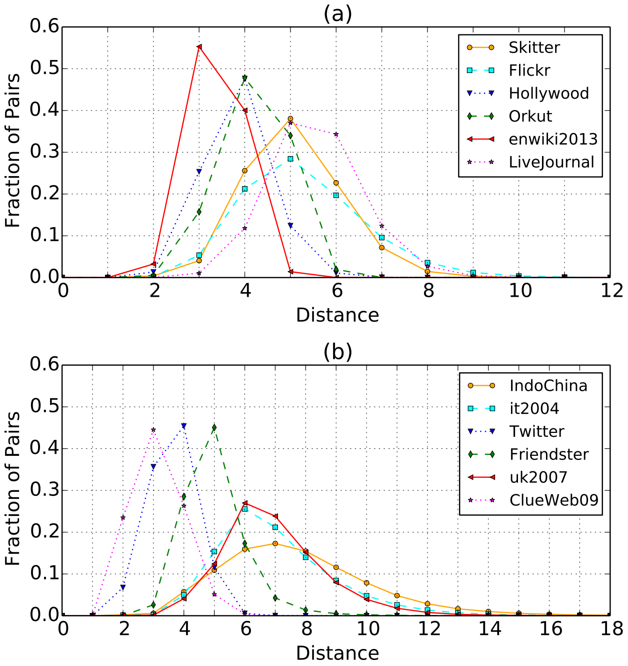

Figure 6: Distance distribution of 100,000 random pairs of vertices on all the datasets.

6.1 Datasets

In our experiments, we used 12 large-scale real-world complex networks, which are detailed in Table 1. These networks have vertices and edges ranging from millions to billions. Among them, the largest network is ClueWeb09 which has 2 billions of vertices and 8 billions of edges. We included this network in our experiments for the purpose of evaluating the robustness and

scalability of the proposed method. In previous works, the largest dataset that has been reported is uk2007 which has only around 100 millions of vertices and 3.7 billions of edges. For all these networks, we treated them as undirected and unweighted graphs.

To investigate the query time of finding the distance between two vertices, we randomly sampled 100,000 pairs of vertices from all pairs of vertices in each network, i.e., $V \times V$. The distance distribution of these 100,000 randomly sampled pairs of vertices are shown in Figure 6(a)-6(b), from which we can confirm that most of pairs of vertices in these networks have a small distance ranging from 2 to 8.

6.2 Baseline Methods

We compared our proposed method with three state-of-the-art methods. Two of these methods, namely fully dynamic (FD) [15] and IS-L [12], combine a distance labelling algorithm with a graph traversal algorithm for distance queries on complex networks. The third one is pruned landmark labelling (PLL) [3] which is completely based on distance labelling to answer distance queries. Besides these, there are a number of other methods for answering distance queries, such as HDB [16], RXL and CRXL [10], HCL [17], HHL [2] and TEDI [32]. However, since the experimental results of the previous works [3, 15] have shown that FD outperforms HDB, RXL and CRXL, and PLL outperforms HCL, HHL and TEDI, we omit the comparison with these methods.

In our experiments, the implementations of the baseline methods FD, IS-L and PLL were provided by their authors, which were all implemented in C++. We used the same parametric settings for running these methods as suggested by their authors. For instance, the number of landmarks is chosen to 20 for FD [15], the number of bit-parallel BFSs is set to 50 for PLL [3], and k is 6 for graphs larger than 1 million vertices for IS-L [12].

6.3 Comparison with Baseline Methods

To evaluate the performance of our proposed approach, we compared our approach with the baseline methods in terms of the construction time of labelling, the size of labelling, and querying time. The experimental results are presented in Tables 2 and 3, where DNF denotes that a method did not finish in one day or ran out of memory. In order to make a consistent comparison with the baseline methods [3, 12, 15], we chose top 20 vertices as landmarks after sorting based on decreasing order of their degrees, and also used 32-bit integers to represent vertices and 8-bit integers to represent distances.

6.3.1 Construction Time. As shown in Table 2, our proposed method (HL) has successfully constructed the distance labelling on all the datasets for a significantly less amount of time than the state-of-the-art methods. As compared to FD, our method is on average 5 times faster and have results on all the datasets. In contrast to this, FD failed to construct labelling for the largest dataset ClueWeb09. PLL failed for 7 out of 12 datasets, including the datasets Orkut and LiveJournal which have less than 120 millions of edges, due to its prohibitively high preprocessing time and memory requirements for building labelling. IS-L failed to construct labelling for all the datasets that have edges more than 100 million due to its very high cost for computing independent sets on massive networks, i.e. failed for 9 out of 12 datasets. We can also see from Table 2 that the parallel version of our method (HL-P) is much faster than the sequential version (HL). Compared with FD, HL-P is more than 50-70 times faster for the two large datasets Friendster and uk2007. This confirms that our method can construct labelling very efficiently and is scalable on large networks with billions of vertices and edges.

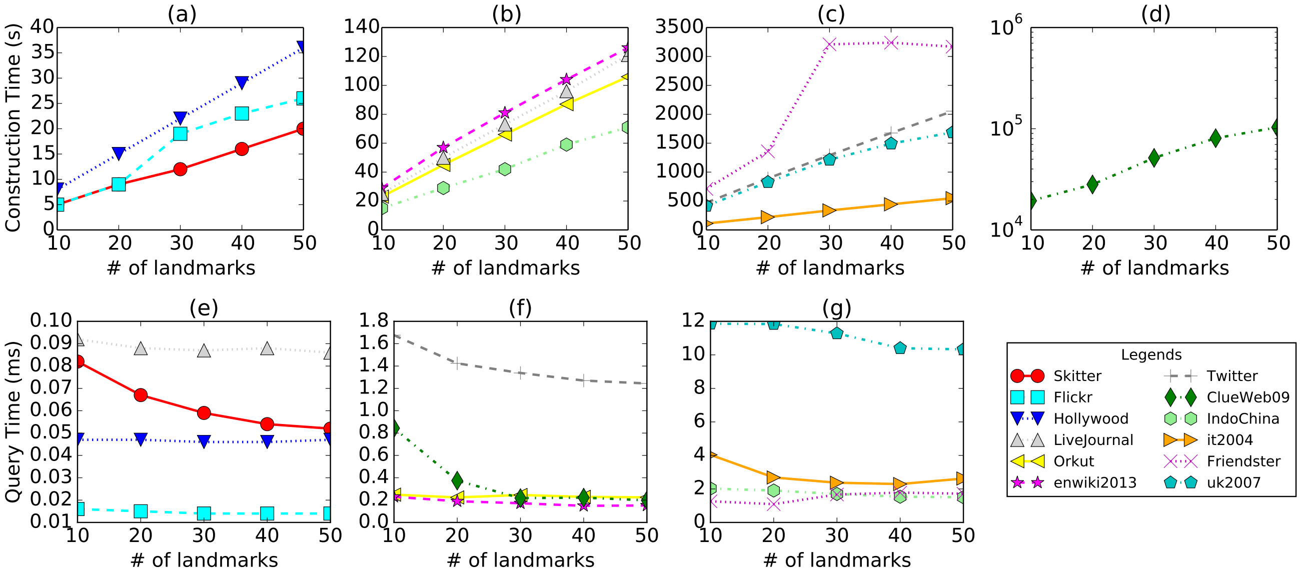

Figure 7: (a)-(d) Construction times using our method HL under 10-50 landmarks on all the datasets; (e)-(g) Query times using our method HL under 10-50 landmarks on all the datasets.

6.3.2 Labelling Size. As we can see from Table 3 that the labelling sizes of all the datasets constructed by the proposed method are significantly smaller than the labelling sizes of FD and much smaller than PLL and IS-Label. Specifically, our labelling sizes using 32-bits representation of vertices (HL) are 2-5 times smaller than FD except for ClueWeb09 (as discussed before, FD failed to construct labelling for ClueWeb09), 7 times smaller than IS-Label on Skitter, Flickr and LiveJournal and more than 60 times smaller than PLL for Skitter, Flickr, Hollywood, enwiki2013 and Indochina. The compressed version of our method that uses 8-bits representation of vertices (i.e. HL(8)) produces further smaller index sizes as compared to uncompressed version (HL). Here, It is important to note that the labelling sizes of almost all the datasets are also significantly smaller than the original sizes of the datasets shown in Table 1. This also shows that our method is highly scalable on large networks in terms of the labellng sizes.

6.3.3 Query Time. The average query times of our method (HL) are comparable with FD and PLL and faster than IS-L. Particularly, the average query time of our method on Hollywood is even faster than FD and PLL. This is due to a very small average labelling size (i.e., 12) as compared with FD and PLL (i.e., 20+64 and 2206+50, respectively) and a very small average distance. The average query time of HL on Twitter is 3 times slower than FD. This may be due to a large portion of covered pairs by FD as shown in Figure 9 which contributes towards an effective bounded traversal on the sparsified network since the landmarks of Twitter have very high degrees and the average distance is also very small. Moreover, the average query times of HL and FD on Indochina, it2004, Friendster and uk2007 are more than 1ms due to comparatively large average distances than other datasets as shown in Figure 6(b). Note that all the baseline methods are not scalable enough to have results for ClueWeb09 and the average query time on ClueWeb09 of our method HL is small because of a very large portion of covered pairs and a small average label size. We also reported the average query time for online bidirectional BFS algorithm (Bi-BFS) using randomly selected 1000 pairs of vertices in Table 2. As we can see that Bi-BFS has considerably long query times, which are not practicable in applications for performing distance queries in real time.

6.4 Performance under Varying Landmarks

We have also evaluated the performance of our method (HL) by varying the number of landmarks between 10 and 50, which are again selected based on highest degrees.

6.4.1 Construction Time. The construction times of our method HL against different numbers of landmarks (from 10 to 50) are shown in Figure 7(a)-7(d). We can see that the construction times are linear in terms of the number of landmarks, which confirms the scalability of our method. In Figure 7(a)-7(b), our method is able to construct labelling for 7 datasets under 50 landmarks from 20 seconds to 2 minutes, which is not possible with any state-of-the-art methods. In Figure 7(c), the construction time using 50 landmarks of Friendster is 3 times faster and the construction time of uk2007 is 4 times faster than FD using only 20 landmarks as shown in Table 2. Figure 7(d) shows the construction time for ClueWeb09 which has 2 billion vertices and 8 billion edges. The significant improvement in construction time allows us to compute labelling for a large number of landmarks, leading to better pair coverage ratios to tighten upper distance bounds (will be further discussed in Section 6.4.4).

6.4.2 Labelling Size. Figure 8 shows the labelling sizes of HL using 10, 20, 30, 40 and 50 landmarks on all the dataset, and of FD using only 20 landmarks on all the datasets except for ClueWeb09 (as discussed before, FD failed to construct labeling for ClueWeb09). It can be seen that the labelling sizes of HL increase linearly with the increased number of landmarks, and even the labelling sizes of HL using 50 landmarks are almost always smaller than the labelling sizes constructed by FD using only 20 landmarks. This reduction in labelling sizes enables us to save space and memory, thus makes our method scalable on large networks.

6.4.3 Query Time. Figure 7 shows the impact of using different numbers of landmarks between 10 and 50 on average query

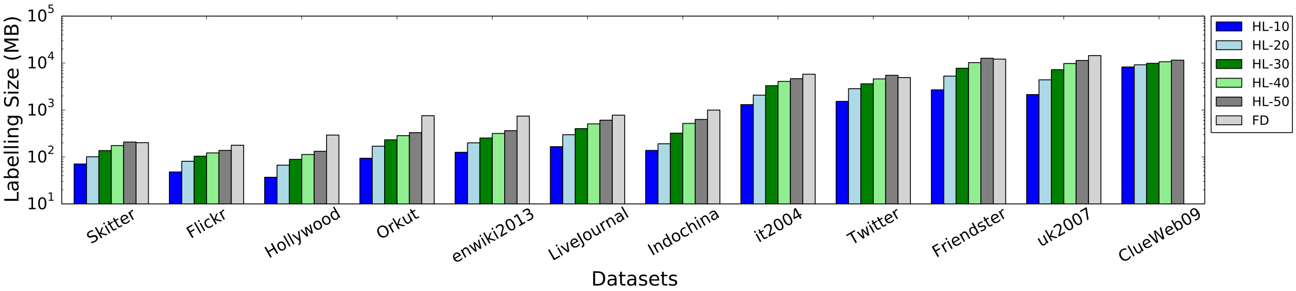

Figure 8: Labelling sizes using our method HL under 10-50 landmarks and using FD on all the datasets.

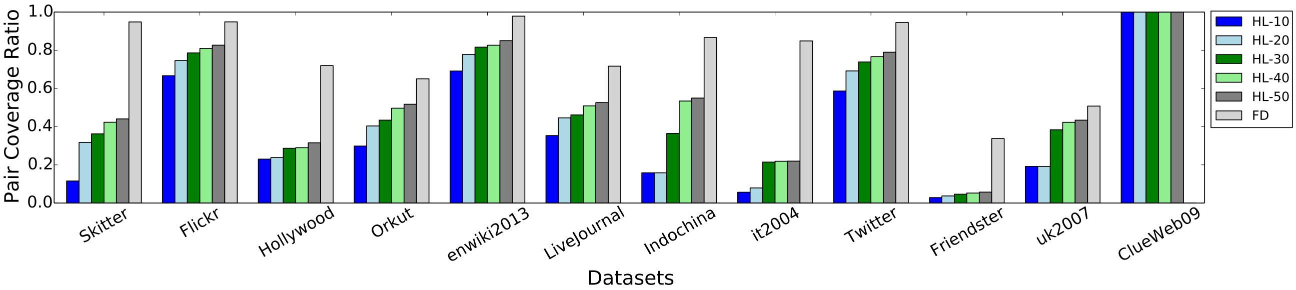

Figure 9: Pair coverage ratios using our method HL under 10-50 landmarks and using FD on all the dataset.

time of our method. The average query times either decrease or remain the same when the number of landmarks increases, except for Orkut when using 30 landmarks and for Friendster when using landmarks greater than 20. In particular, on Friendster, labelling sizes are very large as shown in Figure 8 and the fraction of covered pairs (i.e., pair coverage ratio) is very small as shown in Figure 9, which may have slowed down our query processing due to a longer time for computing upper distance bounds and ineffective use of bounded-distance traversal.

6.4.4 Pair Coverage. Figure 9 presents the ratios of pairs of vertices covered by at least one landmark (i.e., pair coverage ratios) in HL using 10-50 landmarks and in FD using 20 landmarks. As we can observe that the pair coverage ratios for HL increase when the number of landmarks increases and 40 turns out to be the better choice on the number of landmarks for most of the datasets. Specifically, pair coverage ratios on Orkut, enwiki2013, Indochina and uk2007 with 40 landmarks are good, resulting in better query times than using 20 landmarks, as shown in Figure 7. On datasets such as Hollywood and it2004, 30 landmarks are a better option than 40 landmarks because they only slightly differ in the pair coverage ratios and query times w.r.t. using 40 landmarks, but with reduced labelling sizes. The pair coverage ratios by FD are greater than HL on all the datasets except for ClueWeb09, which may be the reason behind its better query times for some datasets as shown in Table 2. Note that, on ClueWeb09, we obtain almost hundred percentage for pair coverage due to its very high degree landmarks.

7 RELATED WORK

A naive solution for exact shortest-path distance computation is to run the Dijkstra search for weighted graphs or BFS for unweighted graphs, from a source vertex to a destination vertex [27]. To improve search efficiency, a bidirectional scheme can be used to run two such searches: one from the source vertex and the other from the destination vertex [21]. Later on, Goldberg et al. [13] combined the bidirectional search technique with the A* algorithm to further improve the search performance. In their method, they precomputed labeling based on landmarks to estimate the lower bounds, and used that estimate with a bidirectional A* search for efficient computation of shortest-path distances. However, this method is known to work only for road networks and do not scale well on complex networks [15].

To efficiently answer exact shortest-path distance queries on graphs, labelling-based methods have been developed with great success [1–3, 12, 17, 19]. Most of them construct a labeling based on the idea of 2-hop cover [9]. It has also been shown that computing a minimal 2-hop cover labeling is NP-hard [2, 9]. In [1], the authors proposed a hub-based labeling algorithm (HL) which constructs hub labelling by processing contraction hierarchies (CH) and is among the fastest known algorithms for distance queries in road networks. However, the method is not feasible for complex networks as reported by the same authors and they thus proposed a hierarchical hub-labeling (HHL) algorithm for complex networks in [2]. In this work, a top-down method was used to maintain a shortest-path tree for every vertex in order to indicate all uncovered shortest-paths at each vertex. Due to very high storage and computation requirements, the method is also not scalable for handling large graphs. Another method called Highway Centric Labeling (HCL) was proposed by Jin et al. [17] which exploits highway structure of a graph. This method aimed to find a spanning tree which can assist in optimal distance labelling and used that spanning tree as a highway to compute a highway-based 2-hop labelling for fast distance computation. After that, in [3], Akiba et al. proposed the pruned landmark labeling (PLL) method which precomputes a distance-aware 2-hop cover index by performing a pruned breadth-first search (BFS) from every vertex. The idea is to prune vertices whose distance information can be obtained using a partially available 2-hop index constructed via previous BFSs. This work helps to achieve low construction cost and smaller index size due to reduced search space on million-scale networks. It has been shown that PLL outperforms other state-of-the-art methods available at the time of publication, including HHL [2], HCL [17] and TEDI [32]. However, PLL is still not feasible for constructing 2-hop cover indices for billion-scale networks due to a very high memory requirement for labelling construction.

Fu et al. [12] proposed IS-Label (IS-L) which gained significant scalability in precomputing 2-hop cover distance labellings for large graphs with hundreds of millions of vertices and edges. IS-L uses the notion of an independent set of vertices in a graph. First, it computes an independent set of vertices from a graph, then it constructs a graph by removing the independent set of vertices from the previous graph recursively and augments edges that preserve distance information after the removal of the independent set of vertices. All the vertices in the remaining graph preserve their distance information to/from each other. Generally, IS-L is regarded as a hybrid method that combines distance labelling with graph traversal for complex networks [19]. Following the same line of thought, very recently, Akiba et al. [15] proposed a method to accelerate shortest-path distances computation on large-scale complex networks. To the best of our knowledge, this work is most closely related to our work presented in this paper. The key idea of the method in [15] is to select a small set of landmarks R and precompute shortest-path trees (SPTs) rooted at each $r \in R$. Given any two vertices s and t, it first computes the upper bound by taking the minimum length among the paths that pass through R. Then a bidirectional BFS from s to t is conducted on the subgraph $G\backslash R$ to compute the shortest-path distances that do not pass through R and take the minimum of these two results as the answer to an exact distance query. The experiments in [15] showed that this method can scale to graphs with millions of vertices and billions of edges, and outperforms the state-of-the-art exact methods PLL [3], HDB [16], RXL and CRXL [10] with significantly reduced construction time and index size, while the query times are higher but still remain among 0.01-0.06 for most of graphs with less than 5M vertices.

Although the method proposed in [15] has been tested on a large network with millions of vertices and billions of edges, it still fails to construct labelling on billion-scale networks in general, particularly with billions of vertices. In contrast, our proposed method not only constructs labellings linearly with the number of landmarks in large networks with billions of vertices, but also enables the sizes of labellings to be significantly smaller than the original network sizes. In addition to these, the deterministic nature of labelling allows us to achieve further gains in computational efficiency using parallel BFSs over multiple landmarks, which is highly scalable for handling billion-scale networks.

8 CONCLUSION

We have presented a scalable solution for answering exact shortest path distance queries on very large (billion-scale) complex networks. The proposed method is based on a novel labelling algorithm that can scale to graphs at the billion-scale, and a querying framework that combines a highway cover distance labelling with distance-bounded searches to enable fast distance computation. We have proven that the proposed labelling algorithm can construct HWC-minimal labellings that are independent of the ordering of landmarks, and have further developed a parallel labelling method to speed up the labelling construction process by conducting BFSs simultaneously for multiple landmarks. The experimental results showed that the proposed methods significantly outperform the state-of-the-art methods. For future work, we plan to investigate landmark selection strategies for further improving the performance of labelling methods.

ABSTRACT

Stratified random sampling (SRS) is a widely used sampling technique for approximate query processing. We consider SRS on continuously arriving data streams, and make the following contributions. We present a lower bound that shows that any streaming algorithm for SRS must have (in the worst case) a variance that is $\Omega(r)$ factor away from the optimal, where r is the number of strata. We present S-VOILA, a streaming algorithm for SRS that is *locally variance-optimal*. Results from experiments on real and synthetic data show that S-VOILA results in a variance that is typically close to an optimal offline algorithm, which was given the entire input beforehand. We also present a variance-optimal offline algorithm VOILA for stratified random sampling. VOILA is a strict generalization of the well-known *Neyman allocation*, which is optimal only under the assumption that each stratum is abundant, i.e. has a large number of data points to choose from. Experiments show that VOILA can have significantly smaller variance (1.4x to 50x) than Neyman allocation on real-world data.

1 INTRODUCTION

Random sampling is a widely-used method for data analysis, and features prominently in the toolbox of virtually every approximate query processing system. The power of random sampling lies in its generality. For many important classes of queries, an approximate answer whose error is small in a statistical sense can be efficiently obtained through executing the query over an appropriately derived random sample. Sampling operators are part of all major database products, *e.g.,* Oracle, Microsoft SQL Server, and IBM Db2. The simplest method for random sampling is uniform random sampling, where each element from the entire data (the "population") is chosen with the same probability. Uniform random sampling may however lead to a high variance in estimation. For instance, consider a population $D = \{1, 2, 4, 2, 1, 1050, 1000, 1200, 1300\}$, and suppose we wanted to estimate the population mean. A uniform random sample of size two leads to an estimate with a variance of approximately 1.6×10^5.

An alternative sampling method is *stratified random sampling* (SRS), where the population is partitioned into subgroups called "strata". From within each stratum, uniform random sampling is used to select a per-stratum sample. All per-stratum samples are combined to derive the "stratified random sample". Suppose that the population is divided into two strata, one with elements $\{1, 2, 4, 2, 1\}$ and the other with elements $\{1000, 1050, 1200, 1300\}$. A stratified random sample of size two that chooses one element from each stratum yields an estimate with variance 2.47×10^3, much smaller than a uniform random sample of the same size.

SRS provides the flexibility to emphasize some strata over others through controlling the allocation of sample sizes; for instance, a stratum with a high standard deviation can be given a larger allocation than another stratum with a smaller standard deviation. In the above example, if we desire a stratified sample of size three, it is best to allocate a smaller sample of size one to the first stratum and a larger sample size of two to the second stratum, since the standard deviation of the second stratum is higher. Doing so, the variance of estimate of the population mean further reduces to approximately 1.23×10^3. The strength of SRS is that a stratified random sample can be used to answer queries not only for aggregates such as the mean, and sum of the entire population, but also of subsets of the population defined by selection predicates that are provided at query time. SRS has been used widely in database systems for approximate query processing [1–3, 8, 14, 30, 31].

A problem with handling large streaming data is that current methods for SRS are predominantly offline methods that assume all data is available before sampling starts. As a result, systems that rely on SRS (*e.g.,* [3, 14, 31]) cannot easily adapt to new data and have to recompute stratified random samples from scratch, as more data arrives. With the advent of streaming data warehouses such as Tidalrace [29], it is imperative to have methods for SRS that work on dynamic data streams, and maintain stratified random samples in an incremental manner.

We address the shortcoming of current methods through a study of SRS on streaming data. The difficulty of SRS on streaming data is that there are two logical processes simultaneously at work. One is sample size allocation, which allocates samples among the different strata in a manner that minimizes the variance of an estimate. The second is the actual sampling of elements from within each stratum. While each of these two steps, sample size allocation and sampling, can be done individually in a streaming fashion, it is far more challenging to do them simultaneously. We present lower bounds as well as algorithms for the task of maintaining a stratified random sample on a data stream. The quality of a stratified random sample is measured using the variance of an estimate of a population statistic, computed using the sample.

1.1 Our Contributions

– **Streaming Lower Bound:** We present a lower bound showing that in the worst case, any streaming algorithm for SRS that uses a memory of M records must have a variance that is $\Omega(r)$ away from the variance of the optimal offline algorithm that uses the same memory of M records, where r is the number of strata. We show that this lower bound is tight, by construction.

– **Practical Streaming Algorithm for SRS:** We present S-VOILA (Streaming Variance OptImaL Allocation) a streaming algorithm for SRS that is locally variance-optimal. Upon receiving new elements, it (re-)allocates sample sizes among strata so as to obtain the smallest variance among all possible re-allocations. S-VOILA can also deal with the case when a minibatch of multiple data

10.5441/002/edbt.2019.04

items is seen at a time, as in systems such as Spark streaming [42]. Re-allocations made by S-VOILA are locally optimal with respect to the entire minibatch, and the quality of re-allocations improve as the minibatch size increases. Since S-VOILA can deal with minibatches of varying sizes, it is well-suited to real-world streams that may have bursty arrivals.

– **Variance-Optimal Sample Size Reduction:** The streaming algorithm (S-VOILA) re-allocates sample sizes based on a novel method for reducing the size of an existing stratified random sample down to a desired target size in a variance-optimal manner. This novel technique for sample size reduction may be of independent interest in other tasks, e.g., sub-sampling from a given stratified random sample.

– **Sampling from a Sliding Window of a Stream:** We present an algorithm for sampling from a sliding window of the most recent elements in a stream. This algorithm uses memory much smaller than the size of the window, and results in a sample whose variance is close to that obtained by an optimal offline algorithm that is allowed multiple passes through data in the window.

– **Variance Optimal Offline SRS:** We present the first offline algorithm for variance-optimal SRS. Our algorithm VOILA computes an allocation with provably optimal variance among all possible allocations of sample sizes to strata. The well known **Neyman Allocation** [36] (NeyAlloc), which originated from the statistics literature, assumes that each stratum has an abundance of data to choose from. However, this assumption may not hold in databases, since each stratum is a subset of a database table, and the size of a stratum may be small. VOILA does not make such assumptions, and computes a variance optimal allocation no matter how large/small the sizes of the strata. Hence, VOILA is a strict generalization of NeyAlloc. In addition, VOILA does not make any assumption on how data is stratified.

– **Experimental Evaluation:** We present a detailed experimental evaluation using real and synthetic data, considering both the quality of sample and accuracy of query answers using the sample. In our experimental study, we found that (a) the variance of S-VOILA is typically close to that of the optimal offline algorithm VOILA, and the allocation of S-VOILA also closely tracks that of VOILA. S-VOILA also improves significantly upon prior work [5]. The variance of S-VOILA improves as the size of the minibatch increases, and a minibatch of size 100 provides most of the benefits of S-VOILA. (b) Samples produced using S-VOILA yield accurate answers to a range of queries that involve a selection followed by aggregation, where the selection predicate is provided at query time, and the aggregation function can be one of sum, average, and standard deviation[1]. (c) In the offline setting, VOILA can have significantly smaller variance than NeyAlloc.

1.2 Related Work

Sampling has been widely used in approximate query processing on both static and streaming data [17, 28, 33, 38, 39]. The reservoir sampling [34, 41] algorithm for uniform sampling from a stream has been known for decades, and many variants and generalizations have been considered, such as weight-based sampling [11, 22], insertion and deletion of elements [25], distinct sampling [26], sampling from a sliding window [9, 12, 23], time-decayed sampling [19, 20], and distributed streaming sampling [15, 16, 18, 40].

SRS in the online setting can be viewed as weight-based reservoir sampling where the weight of each stream element depends on the stratum it belongs to. Since the weight of a stream element changes dynamically (even after it has been observed) prior work on weighted reservoir sampling [22] does not apply, since it assumes that the weight of an element is known at the time of observation and does not change henceforth. Meng [35] considered streaming SRS using population-based allocation. Al-Kateb *et al.* [4, 5] considered streaming SRS using power allocation, based on their prior work on adaptive reservoir sampling [6]. Lang *et al.* [32] consider machine learning methods for determining the per-item probability of inclusion in a sample. This work is meant for static data, and can be viewed as a version of weighted random sampling where the weights are learnt using a query workload. Prior work on streaming SRS neither considers provable guarantees on the quality of the resulting samples, nor lower bounds for streaming SRS, like we do here.

A majority of prior work on using SRS in approximate query processing [1–3, 8, 14, 30, 31] has assumed static data. With the emergence of data stream processing systems [7] and data stream warehousing systems [29], it is important to devise methods for streaming SRS with quality guarantees.

2 PRELIMINARIES

Stratified sampling can be viewed as being composed of three parts – stratification, sample allocation, and sampling. Stratification is a partitioning of the universe into a number of disjoint strata. Equivalently, it is the assignment of each data element to a unique stratum. In database applications, stratification is usually a pre-defined function of one or more attributes of the data [17]. For example, the works of Chaudhuri et al. [14] and Agarwal et al. [3] on approximate query answering stratify tuples in a database table based on the set of selection predicates in the query workload that the tuple satisfies, and the work of Kandula et al. [31] on approximate query answering stratify rows of a table using the group ids derived from a group-by query. Note that our methods do not assume that stratification is performed in any specific manner, and work regardless of the method used to stratify data.

Our work considers sample allocation, the partitioning of the available memory budget of M samples among the different strata. In streaming SRS, the allocation needs to be continuously readjusted as more data arrives, and the characteristics of different strata change. In offline sampling, allocation needs to be done only once, after knowing the data in its entirety.

The final sampling step considers each stratum and chooses the assigned number of samples uniformly at random. In offline stratified sampling, the sampling step can be performed in a second pass through the data using reservoir sampling on the subset of elements belonging to each stratum, after a first pass has determined the sample size allocation. In the case of streaming sampling, the sampling step needs to occur simultaneously with sample (re-)allocation, which may change allocations to different strata over time.

Variance-Optimal Allocation. The quality of a stratified random sample is measured through the variance of an estimate that is derived using the sample. Consider a data stream

[1] Note that a query for the variance or standard deviation of data is distinct from the variance or standard deviation of an estimate.

$R = \{v_1, v_2, \ldots, v_n\}$ of current size n, whose elements are stratified into r strata, numbered $1, 2, \ldots, r$. Let n_i denote the number of elements in stratum i. For each $i = 1 \ldots r$, let S_i be a uniform random sample of size s_i drawn without replacement from stratum i. Let $\mathbb{S} = \{S_1, S_2, \ldots, S_n\}$ denote the stratified random sample. The sample mean of each per-stratum sample S_i is: $\bar{y}_i = \frac{\sum_{v \in S_i} v}{s_i}$. The population mean of R, μ_R can be estimated as: $\bar{y} = \frac{\sum_{i=1}^{r} n_i \bar{y}_i}{n}$. It can be shown that the expectation of $\bar{y}$ equals μ_R. Given a memory budget of $M \leq n$ elements to store all the samples, so that $\sum_i s_i = M$, the following question of *variance-optimal allocation* of sample sizes has been considered in prior work [36]: *How to split the memory budget M among the s_is to minimize the variance of $\bar{y}$?* The variance of $\bar{y}$ can be computed as follows (e.g. see Theorem 5.3 in [17]):

$$V = V(\bar{y}) = \frac{1}{n^2} \sum_{i=1}^{r} n_i (n_i - s_i) \frac{\sigma_i^2}{s_i} = \frac{1}{n^2} \sum_{i=1}^{r} \frac{n_i^2 \sigma_i^2}{s_i} - \frac{1}{n^2} \sum_{i=1}^{r} n_i \sigma_i^2 \tag{1}$$

While the theory around SRS in both statistics and database communities has used the variance of the population mean as a minimization metric, variance-optimal SRS is useful for other types of queries as well, including predicate-based selection queries, sum queries across a subset of the strata, queries for the variance, and combinations of such queries [3, 14] – also see our experiments section.

`NeyAlloc` for Abundant Strata. Prior studies on variance-optimal allocation have primarily considered static data. Additionally, they assume that every stratum has a very large volume of data, so that there is no restriction on the size of a sample that can be chosen from this stratum. This may not be true for the scenario of databases. Especially in a streaming context, each stratum starts out with very little data. Given a collection of data elements R, we say that a stratum i is *abundant* if $n_i \geq M \cdot (n_i \sigma_i) / \left(\sum_{j=1}^{r} n_j \sigma_j \right)$. Otherwise, the stratum i is said to be *bounded*. Under the assumption that each stratum is abundant, the popularly used "Neyman Allocation" `NeyAlloc` [17, 36] minimizes the variance V, and allocates a sample size for stratum i as $M \cdot (n_i \sigma_i) / \left(\sum_{j=1}^{r} n_j \sigma_j \right)$. We note that `NeyAlloc` is no longer optimal if one or more strata are bounded. Our methods of sample size reduction and online (`S-VOILA`) and offline (`VOILA`) algorithms do not have this restriction and work under the general case whether or not strata are bounded.

Our solution to streaming SRS consists of two parts – sample size re-allocation, and per-stratum random sampling. Both parts execute continuously and in an interleaved manner. Sample size re-allocation is achieved using a reduction to a "sample size reduction" in a variance-optimal manner. Given a stratified random sample $\mathbb{S}_1$ of size larger than a target M, sample size reduction seeks to find a stratified sample $\mathbb{S}_2$ of size M that is a subset of $\mathbb{S}_1$ such that the variance of $\mathbb{S}_2$ is as small as possible.

Roadmap: In Section 3, we consider streaming SRS, and present a tight lower bound for any streaming algorithm, followed by `S-VOILA` an algorithm for streaming SRS. This uses as a subroutine a variance-optimal sample size reduction method that we describe in Section 4. We start with `SingleElementSSR` for reducing the size of the sample by one element, followed by a general algorithm `SSR` for reducing the size by $\beta \geq 1$ elements. We then present an algorithm `MultiElementSSR` with a faster runtime. We then consider the case of sliding windows in Section 5, followed by the optimal offline algorithm in Section 6. We present an experimental study of our algorithms in Section 7.

3 STREAMING SRS

We now consider SRS from a data stream, whose elements are arriving continuously. As more elements are seen, the allocations as well as samples need to be dynamically adjusted. We first note there is a simple two-pass streaming algorithm with optimal variance that uses $O(k + r)$ space, where k is the desired sample size and r the number of strata. In the first pass, the size, mean, and standard deviations of each stratum are computed using $O(r)$ space, constant space for each stratum. At the end of the first pass, the allocations to different strata are computed using an optimal offline algorithm, say `VOILA`. In the second pass, since the desired sample sizes are known for each stratum, samples are computed using reservoir sampling within the substream of elements belonging to each stratum. The above two-pass algorithm *cannot be* converted into a one-pass algorithm. The difficulty is that as more elements are seen, allocations to different strata may change, and the sampling rate within a stratum cannot in general be (immediately) dynamically adjusted in order to satisfy variance optimality. We first show a lower bound that it is in general not possible for any streaming algorithm to have optimal variance compared with an offline algorithm that is given the same memory.

3.1 A Lower Bound for Streaming SRS

Given a data stream $\mathcal{R}$ with elements belonging to r strata, and a memory budget of M elements, let V^* denote the optimal sample variance that can be achieved by an offline algorithm for SRS that may make multiple passes through data. Clearly, the sample produced by any streaming algorithm must have variance that is either V^* or greater. Suppose a stratified random sample R is computed by a streaming algorithm using memory of M elements. Let $V(R)$ denote the variance of this sample. For $\alpha \geq 1$, we say R *is an SRS with multiplicative error of α, if: (1) the sample within each stratum in R is chosen uniformly from all elements in the stratum, and (2) $V(R) \leq \alpha \cdot V^*$.*

Theorem 3.1. *Any streaming algorithm for maintaining an SRS over a stream with r strata using a memory of M elements must, in the worst case, result in a stratified random sample with a multiplicative error $\Omega(r)$.*

The idea in the proof is to construct an input stream with r strata where the variance of different strata are the same until a certain point in time, at which the variance of a single stratum starts increasing to a high value – a variance-optimal SRS will respond by increasing the allocation to this stratum. However, we show that a streaming algorithm is unable to do so quickly. Though a streaming algorithm may compute the variance-optimal allocation to different strata in an online manner, it cannot actually maintain these dynamically sized samples using limited memory.

Proof. Consider an input stream where for each $i = 1 \ldots r$, the ith stratum consists of elements in the range $[i, i + 1)$. The stream so far has the following elements. For each i, $1 \leq i \leq r$, there are $(\alpha - 1)$ copies of element i and one copy of $(i + \varepsilon)$ where $\varepsilon = 1/(r - 1)$ and $\alpha \geq 3$. After observing these elements, for stratum i we have $n_i = \alpha$, $\mu_i = \left(i + \frac{\varepsilon}{\alpha}\right)$, and it can be verified that $\sigma_i = \frac{\sqrt{\alpha - 1}}{\alpha} \varepsilon$.

Since the total memory budget is M, at least one stratum (say, Stratum 1) has a sample size no more than M/r. Suppose an element of value $(2 - \varepsilon)$ arrives next. This element belongs to stratum 1. Let n'_1, μ'_1, and σ'_1 denote the new size, mean, and standard deviation of stratum 1 after this element arrives. We have $n'_1 = \alpha + 1$ and $\mu'_1 = 1 + \frac{1}{\alpha+1}$. It can be verified that $\sigma'_1 = \sqrt{\frac{\varepsilon^2+(1-\varepsilon)^2-\frac{1}{\alpha+1}}{\alpha+1}}$. It follows that:

$$(\alpha + 1)\sqrt{\frac{\frac{1}{2} - \frac{1}{\alpha+1}}{\alpha + 1}} \leq n'_1\sigma'_1 \leq (\alpha + 1)\sqrt{\frac{1 - \frac{1}{\alpha+1}}{\alpha + 1}} \tag{2}$$

$$\Longrightarrow \frac{\sqrt{\alpha}}{2} \leq n'_1\sigma'_1 \leq \sqrt{\alpha} \qquad \text{(Note: } \alpha > 2\text{)} \tag{3}$$

In 2, the left inequality stands when $\varepsilon = 1/2$ and the right inequality stands when $\varepsilon = 0$ or 1. We also have: $\sum_{i=2}^{r} n_i\sigma_i = (r-1)\alpha\frac{\sqrt{\alpha-1}}{\alpha}\varepsilon = \sqrt{\alpha - 1}$, where we have used $\varepsilon = \frac{1}{r-1}$. Thus,

$$\frac{\sqrt{\alpha}}{2} \leq \sum_{i=2}^{r} n_i\sigma_i \leq \sqrt{\alpha} \qquad \text{(Note: } \alpha > 2\text{)} \tag{4}$$

Let V denote the sample variance of $\mathcal{A}$ after observing the stream of $(r\alpha + 1)$ elements. Let V^* denote the smallest sample possible with a stratified random sample of size M on this data. Let $\Delta = \left(n'_1\sigma'^2_1 + \sum_{i=2}^{r} n_i\sigma_i^2\right)/n^2$.

We observe that after processing these $(r\alpha + 1)$ elements, the sample size $s_1 \leq M/r + 1$. Using this fact and the definition of sample variance in Eq 1:

$$V = \frac{1}{n^2}\left(\frac{n'^2_1\sigma'^2_1}{s_1} + \sum_{i=2}^{r}\frac{n_i^2\sigma_i^2}{s_i}\right) - \Delta \geq \frac{1}{n^2}\left(\frac{n'^2_1\sigma'^2_1}{\frac{M}{r}+1} + \sum_{i=2}^{r}\frac{n_i^2\sigma_i^2}{\frac{M}{r-1}}\right) - \Delta$$

$$\geq \frac{1}{n^2}\left(\frac{\alpha/4}{\frac{M}{r}+1} + \sum_{i=2}^{r}\frac{(\alpha-1)\varepsilon^2}{M/(r-1)}\right) - \Delta = \frac{1}{n^2}\left(\frac{\alpha/4}{\frac{M}{r}+1} + \frac{\alpha - 1}{M}\right) - \Delta$$

On the other hand, the smallest sample variance V^* is achieved by using Neyman allocation. By Inequalities 3 and 4, we know that if Neyman allocation is for the current stream of $r\alpha + 1$ elements, stratum 1 uses at least $M/3$ memory space, whereas all other strata equally share at least $M/3$ elements since all $n_i\sigma_i$ are equal for $i = 2, 3, \ldots, r$. Using these observations into Equation 1:

$$V^* \leq \frac{1}{n^2}\left(\frac{n'^2_1\sigma'^2_1}{M/3} + \sum_{i=2}^{r}\frac{n_i^2\sigma_i^2}{M/(3(r-1))}\right) - \Delta$$

$$\leq \frac{1}{n^2}\left(\frac{\alpha}{M/3} + \sum_{i=2}^{r}\frac{(\alpha-1)\varepsilon^2}{M/(3(r-1))}\right) - \Delta = \left(\frac{1}{n^2}\frac{6\alpha - 3}{M}\right) - \Delta$$

Since $\Delta \geq 0$ and $M > r$, we have: $\frac{V}{V^*} \geq \frac{V+\Delta}{V^*+\Delta} = \Omega(r)$. □

We note that the above lower bound is tight (up to constant factors). Consider the algorithm which always allocates M/r memory to each of r strata that have been observed so far. It can be verified that this algorithm has a variance within an $O(r)$ multiplicative factor of the optimal. While theoretically such an algorithm (which we call the "senate" algorithm due to allocating every stratum the same resources) meets the worst case lower bound, it performs poorly in practice, since it treats all strata equally, irrespective of their volume or variance (see the experiments section).

3.2 S-VOILA: Streaming Algorithm for SRS

We now present a streaming algorithm S-VOILA that can maintain a stratified random sample on a stream with a good (though not optimal) variance. Given a memory budget of M items, S-VOILA maintains a SRS of size M with the following properties: (1) the samples within each stratum are chosen uniformly from all the stream elements seen in the stratum so far, (2) the sizes of samples allocated to different strata adapt to new stream elements by making "locally optimal" decisions that lead to the best allocations given the new stream elements. S-VOILA conceptually has to solve two problems. One is sample size re-allocation among strata, and the second is uniform sampling within each stratum. Let $\mathcal{R}$ denote the stream observed so far, and $\mathcal{R}_i$ the elements in $\mathcal{R}$ that belong to stratum i.

We first consider sample size re-allocation. Suppose due to the addition of new elements, the stream went from $\mathcal{R}^1$ to $\mathcal{R}^2$, and suppose that the stratified random sample at $\mathcal{R}^1$ allocated sample sizes to strata in a specific manner, S^1. Due to the new elements, the sizes and variances of different strata change, and as a result, the optimal allocation of samples in $\mathcal{R}^2$ may be different from the previous allocation S^1. Our approach is to first add new elements to the sample, and then re-allocate sample sizes using a "variance-optimal sample size reduction" optimization framework. *Given a current allocation of sample sizes to different strata, suppose new elements are added to the sample, causing it to exceed a memory threshold M. What is a way to reduce the current sample to a sample of size M such that the variance of the new sample is as small as possible?* In the following section (Section 4), we present algorithms for sample size reduction.

The second issue is to maintain a uniform random sample S_i of $\mathcal{R}_i$ when s_i, the size of the sample is changing. A decrease in an allocation to s_i can be handled easily, through discarding elements from the current sample S_i until the desired sample size is reached. What if we need to increase the allocation to stratum i? If we simply start sampling new elements according to the higher allocation to S_i, then recent elements in the stream will be favored over the older ones, and the sample within stratum i is no longer uniformly chosen. In order to ensure that S_i is always chosen uniformly at random from $\mathcal{R}_i$, newly arriving elements in $\mathcal{R}_i$ need to be held to the same sampling threshold as older elements, even if the allotted sample size s_i increases. S-VOILA resolves this issue in the following manner. An arriving element from $\mathcal{R}_i$ is assigned a random "key" drawn uniformly from the interval $(0, 1)$. The sample is maintained using the following invariant: *S_i is the set of s_i elements with the smallest keys among all elements so far in $\mathcal{R}_i$*. It is easy to verify that this is indeed a uniform sample drawn without replacement from $\mathcal{R}_i$. The consequence of this strategy is that if we desire to increase the allocation to stratum i, it may not be accomplished immediately, since a newly arriving element in $\mathcal{R}_i$ may not be assigned a key that meets this sampling threshold. Instead, the algorithm has to wait until it receives an element in $\mathcal{R}_i$ whose assigned key is small enough. To ensure the above invariant, the algorithm maintains for each stratum i a variable d_i that tracks the smallest key of an element in $\mathcal{R}_i$ that is not currently included in S_i. If an arriving element in $\mathcal{R}_i$ has a key that is smaller than or equal to d_i, it is included within S_i; otherwise, it is not.

Algorithms 1 and 2 respectively describe the initialization and insertion of a minibatch of elements. S-VOILA supports the insertion of a minibatch of any size $b > 0$, where b can change from one minibatch to another. As b increases, we can expect

Algorithm 1: S-VOILA: Initialization

```
Input: $M$ – total sample size, $r$ – number of strata.
// $S_i$ is the sample for stratum $i$, and $\mathcal{R}_i$ is the
   substream of elements from Stratum $i$
1 Load the first $M$ stream elements in memory, and partition
    them into per-stratum samples, $S_1, S_2, \ldots, S_r$, such that $S_i$
    consists of $(e, d)$ tuples from stratum $i$, where $e$ is the
    element, $d$ is the key of the element, chosen independently
    and uniformly at random from $(0, 1)$.
2 For each stratum $i$, compute $n_i, \sigma_i$. Initialize $d_i \leftarrow 1$ ; // $d_i$
    tracks the smallest key among all elements in
    $\mathcal{R}_i$ not selected in $S_i$
```

Algorithm 2: S-VOILA: Process a new minibatch B of b elements. Note that b need not be known in advance, and can vary from one minibatch to the other.

```
1  $\beta \leftarrow 0$;                    // #selected elements from $B$
2  for each $e \in B$ do
3      Let $\alpha = \alpha(e)$ denote the stratum of $e$
4      Update $n_\alpha$ and $\sigma_\alpha$ ;  // per-stratum mean and std.
         dev. maintained in a streaming manner
5      Assign a random key $d \in (0, 1)$ to element $e$;
6      if $d \le d_\alpha$ then              // element $e$ is sampled

17             $d_i \leftarrow$ smallest key discarded from $S_i$;
```

S-VOILA to have a lower variance, since its decisions are based on greater amount of data. Lines 2–7 make one pass through the minibatch to update the mean and standard deviations of the strata, and store selected elements into the per-stratum samples. If $\beta > 0$ elements from the minibatch get selected into the sample, in order to balance the memory budget at M, β elements need to be evicted from the stratified random sample using the variance-optimal sample size reduction technique from Section 4.

A sample size reduction algorithm takes a current allocation to a stratified random sample, the statistics (volume, mean, and variance) of different strata, and a target sample size M, and returns the final allocation whose total size is M. For the special case of evicting one element, we can use the faster algorithm SingleElementSSR; otherwise, we can use MultiElementSSR. Lemma 3.2 shows that the sample maintained by S-VOILA within each stratum is a uniform random sample, showing this is a valid stratified sample, and Lemma 3.3 presents the time complexity analysis of S-VOILA. Proofs are omitted due to space constraints.

Lemma 3.2. *For each $i = 1, 2, \ldots, r$ sample S_i maintained by* S-VOILA *(Algorithm 2) is selected uniformly at random without replacement from stratum R_i.*

Lemma 3.3. *If the minibatch size $b = 1$, then the worst-case time cost of* S-VOILA *for processing an element is $O(r)$. The expected time for processing an element belonging to stratum α is $O(1 + r \cdot s_\alpha / n_\alpha)$, which is $O(1)$ when $r \cdot s_\alpha = O(n_\alpha)$. If $b > 1$, then the worst-case time cost of* S-VOILA *for processing a minibatch is $O(r \log r + b)$.*

We can expect S-VOILA to have an amortized per-item processing time of $O(1)$ in many circumstances. When $b = 1$: After observing enough stream elements from stratum α, such that $r \cdot s_\alpha = O(n_\alpha)$, the expected processing time of an element becomes $O(1)$. Even if certain strata have a very low frequency, the expected time cost for processing a single element is still expected to be $O(1)$, because elements from an infrequent stratum α are unlikely to appear in the minibatch. When $b > 1$: The per-element amortized time cost of S-VOILA is $O(1)$, when the minibatch size $b = \Omega(r \log r)$.

4 VARIANCE-OPTIMAL SAMPLE SIZE REDUCTION

Suppose it is necessary to reduce a stratified random sample (SRS) of total size M to an SRS of total size $M' < M$. This will need to reduce the size of the samples of one or more strata in the SRS. Since the sample sizes are reduced, the variance of the resulting estimate will increase. We consider the task of *variance-optimal sample size reduction (*VOR*), i.e.,* how to partition the reduction in sample size among the different strata in such a way that the increase in the variance is minimized. Note that once the new sample size for a given stratum is known, it is easy to subsample the stratum to the target sample size.

Consider Equation 1 for the variance of an estimate derived from the stratified random sample. Note that, for a given data set, a change in the sample sizes of different strata s_i does not affect the parameters n, n_i, and σ_i. VOR can be formulated as the solution to the following non-linear program.

$$\text{Minimize } \sum_{i=1}^{r} \frac{n_i^2 \sigma_i^2}{s_i'} \tag{5}$$

subject to constraints:

$$\sum_{i=1}^{r} s_i' = M' \qquad \text{and} \qquad 0 \le s_i' \le s_i \text{ for each } i = 1, 2, \ldots, r, \tag{6}$$

In the rest of this section, we present efficient approaches for computing the VOR.

4.1 Sample Size Reduction by One Element

We first present an efficient algorithm for the case where the size of a stratified random sample is reduced by one element. An example application of this case is in designing a streaming algorithm for SRS, when stream items arrive one at a time. The task is to choose a stratum i (and discard a random element from the stratum) such that after reducing the sample size s_i by one, the increase in variance V (Equation 1) is the smallest.

Our solution is to choose stratum i such that the partial derivative of V with respect to s_i is the largest over all possible choices of i.

$$\frac{\partial V}{\partial s_i} = -\frac{n_i^2 \sigma_i^2}{n^2} \frac{1}{s_i^2}.$$

Given a memory budget M and stratum i, let $M_i = M \cdot n_i\sigma_i / \sum_{j=1}^{r} n_j\sigma_j$ denote the amount of memory that NeyAlloc would allocate to stratum i. We choose stratum ℓ where:

$$\ell = \arg\max_i \left\{ \frac{\partial V}{\partial s_i} \,\middle|\, 1 \le i \le r \right\} = \arg\min_i \left\{ \frac{n_i\sigma_i}{s_i} \,\middle|\, 1 \le i \le r \right\}$$

Lemma 4.1. *When required to reduce the size of a stratified random sample by one, the increase in variance of the estimated population mean is minimized if we reduce the size of S_ℓ by one, where $\ell = \arg\min_i \left\{ \frac{n_i\sigma_i}{s_i} \,\middle|\, 1 \le i \le r \right\}$.*

In the case where we have multiple choices for ℓ using Lemma 4.1, we choose the one where the current sample size s_ℓ is the largest. Algorithm SingleElementSSR for reducing the sample by a single element is a direct implementation of the condition stated in Lemma 4.1. We omit the pseudocode due to space constraints. It is straightforward to observe this can be done in time $O(r)$.

4.2 Reduction by $\beta \ge 1$ Elements

We now consider the general case, where the sample needs to be reduced by $\beta \ge 1$ elements. A possible solution idea is to repeatedly apply the one-element reduction algorithm (Algorithm SingleElementSSRfrom Section 4.1) β times. Each iteration, a single element is chosen from a stratum such that the overall variance increases by the smallest amount. However, this greedy approach may not yield a sample with the smallest variance. On the other hand, an exhaustive search of all possible evictions is not feasible either, since the number of possible ways to partition a reduction of size β among r strata is $\binom{\beta+r-1}{r-1}$, which can be very large. For instance, if $r = 10$, this is $\Theta(\beta^{10})$. We now present efficient approaches to VOR. We first present a recursive algorithm, followed by a faster iterative algorithm. Before presenting the algorithm, we present the following useful characterization of a variance-optimal reduction.

Definition 4.2. We say that stratum i is *oversized* under memory budget M, if its allocated sample size $s_i > M_i$. Otherwise, we say that stratum i is *not oversized.*

Lemma 4.3. *Suppose that E is the set of β elements that are to be evicted from a stratified random sample such that the variance V after eviction is the smallest possible. Then, each element in E must be from a stratum whose current sample size is oversized under the new memory budget $M' = M - \beta$.*

Proof. We use proof by contradiction. Suppose one of the evicted elements is deleted from a sample S_α such that the sample size s_α is not oversized under the new memory budget. Because the order of the eviction of the β elements does not impact the final variance, suppose that element e is evicted after the other $\beta - 1$ evictions have happened. Let s_α denote the size of sample S_α at the moment t right after the first $\beta - 1$ evictions and before evicting e. The increase in variance caused by evicting an element from S_α is

$$\begin{aligned}\Delta &= \frac{1}{n^2}\left(\frac{n_\alpha^2\sigma_\alpha^2}{s_\alpha(s_\alpha-1)}\right) = \left(\frac{\sum_{i=1}^{r} n_i\sigma_i}{nM'}\right)^2 \frac{M'^2_\alpha}{s_\alpha(s_\alpha-1)} \\ &> \left(\frac{\sum_{i=1}^{r} n_i\sigma_i}{nM'}\right)^2\end{aligned}$$

where $M'{}_\alpha = M'\frac{n_\alpha\sigma_\alpha}{\sum_{i=1}^{r} n_i\sigma_i}$. The last inequality is due to the fact that S_α is not oversized under budget M' at time t, i.e., $s_\alpha \le M'_\alpha$.

Note that an oversized sample exists at time t, since there are a total of $M' + 1$ elements in the stratified random sample at time t, and the memory target is M'. Instead of evicting e, if we choose to evict another element e' from an oversized sample $S_{\alpha'}$, the resulting increase in variance will be:

$$\begin{aligned}\Delta' &= \frac{1}{n^2}\left(\frac{n_{\alpha'}^2\sigma_{\alpha'}^2}{s_{\alpha'}(s_{\alpha'}-1)}\right) = \left(\frac{\sum_{i=1}^{r} n_i\sigma_i}{nM'}\right)^2 \frac{M'^2_{\alpha'}}{s_{\alpha'}(s_{\alpha'}-1)} \\ &< \left(\frac{\sum_{i=1}^{r} n_i\sigma_i}{nM'}\right)^2\end{aligned}$$

where $M'_{\alpha'} = M'\frac{n_{\alpha'}\sigma_{\alpha'}}{\sum_{i=1}^{r} n_i\sigma_i}$ The last inequality is due to the fact that $S_{\alpha'}$ is oversized under budget M' at time t, i.e., $s_{\alpha'} > M'_{\alpha'}$. Because $\Delta' < \Delta$, at time t, evicting e' from $S_{\alpha'}$ leads to a lower variance than evicting e from S_α. This is a contradiction to the assumption that evicting e leads to the smallest variance, and completes the proof. □

Algorithm 3: SSR($\mathcal{A}$, M, $\mathcal{L}$): Variance-Optimal Sample Size Reduction

```
Input: $\mathcal{A}$ – set of strata under consideration.
       $M$ – target sample size for all strata in $\mathcal{A}$.
Output: For $i \in \mathcal{A}$, $\mathcal{L}[i]$ is the final size of sample for
        stratum $i$.
$O \leftarrow \emptyset$ // oversized samples
for $j \in \mathcal{A}$ do
    $M_j \leftarrow M \cdot n_j\sigma_j / \sum_{t\in\mathcal{A}} n_t\sigma_t$ // Neyman allocation
        if memory $M$ divided among $\mathcal{A}$
    if $(s_j > M_j)$ then $O \leftarrow O \cup \{j\}$
    else $\mathcal{L}[j] \leftarrow s_j$ // Keep current allocation

if $O = \mathcal{A}$ then
    // All samples oversized. Recursion stops.
    for $j \in \mathcal{A}$ do $\mathcal{L}[j] \leftarrow M_j$
else
    // Recurse on $O$, under remaining mem budget.
    SSR($O, M - \sum_{j\in\mathcal{A}-O} s_j, \mathcal{L}$)
```

Lemma 4.3 implies that it is only necessary to reduce samples that are oversized under the target memory budget M'. Samples that are not oversized can be given their current allocation, even under the new memory target M'. Our algorithm based on this observation first allocates sizes to the samples that are not oversized. The remaining memory now needs to be allocated among the oversized samples. We note that this can again be viewed as a sample size reduction problem, while focusing on a smaller set of (oversized) samples, and accomplish it using a recursive call under a reduced memory budget; See Lemma 4.4 for a formal statement of this idea. The base case for this recursion is when all samples under consideration are oversized, in which case we can simply use NeyAlloc under the reduced memory budget M' (Observation 1). Our algorithm SSR is shown in Algorithm 3.

Let $\mathbb{S} = \{S_1, S_2, \ldots, S_r\}$ be the current stratified random sample. Let $\mathcal{A}$ denote the set of all strata under consideration, initialized to $\{1, 2, \ldots, r\}$. Let O denote the set of oversized samples, under target memory budget for $\mathbb{S}$, and $\mathcal{U} = \mathbb{S} - O$ denote the collection of samples that are not oversized. When the context is clear, we use O, $\mathcal{U}$, and $\mathcal{A}$ to refer to the set of stratum identifiers as well as the set of samples corresponding to these identifiers.

Table 1: An example of variance-optimal sample size reduction from 400×10^6 down to 200×10^6.

i	1	2	3	4	5	6
$n_i\sigma_i$ $(\times 10^9)$	10	8	30	20	8	24
s_i $(\times 10^6)$	15	50	50	45	60	180
round 1 M_i $(\times 10^6)$	20	< 50	60	< 45	< 60	< 180
round 2 M_i $(\times 10^6)$	-	< 50	-	45	< 60	< 180
round 3 M_i $(\times 10^6)$	-	18	-	-	18	54
s'_i $(\times 10^6)$	15	18	50	45	18	54

Lemma 4.4. *A variance-optimal eviction of β elements from $\mathbb{S}$ under memory budget M' requires a variance-optimal eviction of β elements from O under memory budget $M' - \sum_{j\in\mathcal{U}} s_j$.*

Proof. Recall that s'_i denotes the final size of sample S_i after β elements are evicted. Referring to the variance V from Equation 1, we know a variance-optimal sample size reduction of β elements from $\mathbb{S}$ under memory budget M' requires minimization of

$$\sum_{i\in\mathcal{A}} \frac{n_i^2\sigma_i^2}{s'_i} - \sum_{\in\mathcal{A}} \frac{n_i^2\sigma_i^2}{s_i} \tag{7}$$

By Lemma 4.3, we know $s_i = s'_i$ for all $i \in \mathcal{U}$. Hence, minimizing Formula 7 is equivalent to minimizing

$$\sum_{i=O} \frac{n_i^2\sigma_i^2}{s'_i} - \sum_{i\in O} \frac{n_i^2\sigma_i^2}{s_i} \tag{8}$$

The minimization of Formula 8 is exactly the result obtained from a variance-optimal sample size reduction of β elements from oversized samples under the new memory budget $M' - \sum_{i\in\mathcal{U}} s_i$. □

Observation 1. *In the case every sample in the stratified random sample is oversized under target memory M'*, i.e., *$\mathbb{S} = O$, the variance-optimal reduction is to reduce the size of each sample $S_i \in \mathbb{S}$ to M'_i under the new memory budget M'.*

The following theorem summarizes the correctness and time complexity of Algorithm SSR.

Theorem 4.5. *Algorithm 3 (*SSR*) finds a variance-optimal reduction of the stratified random sample $\mathcal{A}$ under new memory budget M. The worst-case time of* SSR *is $O(r^2)$, where r is the number of strata.*

Proof. Correctness follows from Lemmas 4.3–4.4 and Observation 1. The worst-case time happens when each recursive call sees only one stratum that is not oversized. In such a case, the time of all recursions of SSR on a stratified random sample across r strata is: $O(r + (r-1) + \ldots + 1) = O(r^2)$. □

An Example (Table 1). Suppose we have 6 strata with their statistics ($n_i\sigma_i$) and current sample sizes (s_i) showin in Table 1 using a total size of $\sum_{i=1}^{6} s_i = 400$. Suppose that we wish to reduce the sample size down to 200 by reducing each s_i to the target sample size s'_i. The computation involves a sequence of recursive rounds. In the initial round, we allocate 200 samples among all 6 strata using Neyman allocation. Strata 1 and 3 turn out to be not oversized ($M_1 \geq s_1$, $M_3 \geq s_3$), and therefore we set $s'_1 = s_1$ and $s'_3 = s_3$. In Round 2, we exclude strata 1 and 3 from consideration, and the available memory budget which now becomes $200 - 15 - 50 = 135$. This is allocated among strata 2, 4, 5, and 6 using Neyman allocation. Stratum 4 is not oversized ($M_4 \geq s_4$) and therefore we set $s'_4 = s_4$. At the next round 3, we further exclude stratum 4 from consideration, and the available memory budget now becomes $135 - 45 = 90$. When this is allocated among the remaining strata, it turns out that all of them are oversized ($M_i < s_i, i = 2, 5, 6$). We simply set $s'_i = M_i$ for each $i \in \{2, 5, 6\}$, and the recursion exits. Each stratum i now has a new sample size s'_i such that $s'_i \leq s_i$ for every i, and $\sum_{i=1}^{6} s'_i = 200$.

Algorithm 4: `MultiElementSSR`($\mathcal{A}, M$): A fast implementation of Sample Size Reduction without using recursion.

```
Input: The strata under consideration is $\mathcal{A} = \{1, 2, \ldots, r\}$,
       and the volumes and standard deviations. $M$ is the
       target total sample size.
Output: For $1 \leq i \leq r$, $\mathcal{L}[i]$ is set to the final size of sample
        for stratum $i$, such that the increase of the variance
        $V$ is minimized.
Allocate $\mathcal{L}[1..r]$, an array of numbers
Allocate $Q[1..r]$, an array of $(x, y, z)$ tuples
for $i = 1 \ldots r$ do $Q[i] \leftarrow (i, n_i\sigma_i, s_i/(n_i\sigma_i))$;
Sort array $Q$ in ascending order on the $z$ dimension
for $i = (r-1)$ down to 1 do
    $Q[i].y \leftarrow Q[i].y + Q[i+1].y$
$M_{new} \leftarrow M$; $D \leftarrow Q[1].y$
for $i = 1 \ldots r$ do
    $M_{Q[i].x} \leftarrow M \cdot n_{Q[i].x}\sigma_{Q[i].x}/D$
    if $s_{Q[i].x} > M_{Q[i].x}$ then break
    $\mathcal{L}[Q[i].x] \leftarrow s_{Q[i].x}]$
    $M_{new} \leftarrow M_{new} - s_{Q[i].x}$
    // Check the next sample, which must exist.
    $M_{Q[i+1].x} \leftarrow M \cdot n_{Q[i+1].x}\sigma_{Q[i+1].x}/D$
    if $s_{Q[i+1].x} > M_{Q[i+1].x}$ then // oversized
        $M \leftarrow M_{new}$; $D \leftarrow Q[i+1].y$
// Reduce sample size to target.
for $j = i..r$ do
    // Desired size for $S_{Q[j].x}$
    $\mathcal{L}[Q[j].x] \leftarrow M \cdot n_{Q[j].x}\sigma_{Q[j].x}/D$
return $\mathcal{L}$
```

Faster Sample Size Reduction. We present a faster algorithm for variance-optimal sample size reduction, `MultiElementSSR`, with time complexity $O(r \log r)$. `MultiElementSSR` shares the same algorithmic foundation as SSR, but uses a faster iterative method based on sorting. We omit proofs due to space constraints.

Theorem 4.6. *(1) The* `MultiElementSSR` *procedure in Algorithm 4 finds the correct size of each sample of a stratified random sample, whose memory budget is reduced to M, such that the increase of the variance V is minimized. (2) The worst-case time cost of*`MultiElementSSR` *on a stratified random sample across r strata is $O(r \log r)$.*

5 STREAMING SRS OVER A SLIDING WINDOW

We consider the maintenance of an SRS drawn from a *sequence-based* sliding window of the most recent elements from the stream. Given a window size W, the sliding window consists of the W

most recent elements observed in the data stream. We consider the case when the window size W is very large, so that it is not feasible to store the entire window in memory. Similar to the algorithm for infinite window, there are two parts to the algorithm, sample re-allocation and sampling, which are interleaved with each other. We provide the algorithm idea and omit detailed descriptions.

For re-allocating sample sizes, we need the current statistics of each stratum within the sliding window. The mean and variance of a given stratum in an infinite window can be maintained in $O(1)$ space easily in a single pass. However, maintaining the mean and variance over a sliding window is much harder. In fact, it is known that exact computation of the mean and variance over a sliding window requires memory linear in the stream size [21] – thus, if we require these statistics exactly, we have to store the entire window, just to maintain the statistics of different strata! Fortunately, it is possible to approximate these statistics using space poly-logarithmic in the size of the stream; for the mean, see [21, 27], and for the variance [43].

Random sampling over a sliding window is also quite different from the case of infinite windows, and there is significant prior work on this e.g. [9, 13, 24]. We adapt algorithms from prior work to assign to each arriving element a random key, chosen uniformly in $[0, 1]$. The random sample of a certain size within a stratum is defined to be those elements in the stratum that have the smallest keys. Borrowing from prior work [9], we maintain additional recent elements within the window even if they don't belong to the set of keys that are currently the smallest – the reason is that these elements may become the elements with the smallest keys once the window slides and other elements with smaller keys "expire" from the window. The additional space required by these keys is a logarithmic factor in the size of the window (Section 2 in [9]). For each stratum, the algorithm continuously monitors the smallest key that has been discarded from the window.

When new elements arrive in the stream, these are sampled into the SRS, which may cause the size of the sample to increase beyond the memory allocated to the stratum. When this happens, we rely on variance-optimal sample size reduction (Algorithm `MultiElementSSR`) to give us new sample size allocations to different strata, and different strata are sub-sampled according to the new allocations (sub-sampling within a given stratum is handled through selecting only the elements with the smallest keys that are active in the window).

6 VOILA: VARIANCE-OPTIMAL OFFLINE SRS

We now present an algorithm for computing the variance-optimal allocation of sample sizes in the general case when there may be strata that are bounded. Note that once the allocation of sample sizes is determined, the actual sampling step is straightforward for the offline algorithm – samples can be chosen in a second pass through the data, using reservoir sampling within each stratum. Hence, in the rest of this section, we focus on determining the variance-optimal allocation. Consider a static data set R of n elements across r strata, where stratum i has n_i elements, and has standard deviation σ_i. *How can a memory budget of M elements be partitioned among the strata in a variance-optimal manner?* We present VOILA (**V**ariance-**O**pt**I**ma**L** **A**llocation), an efficient offline algorithm for variance-optimal allocation that can handle strata that are bounded.

Algorithm 5: VOILA (M): Variance-optimal stratified random sampling for bounded data

```
Input: $M$ is the memory target
for $i = 1 \ldots r$ do
    $s_i \leftarrow n_i$ // assume total memory of $n$
$\mathcal{L} \leftarrow$ MultiElementSSR($M$)
return $\mathcal{L}$    /* $\mathcal{L}[i] \le n_i$ is the sample size for
    stratum $i$ in a variance-optimal stratified
    random sample. */
```

Neyman Allocation assumes there are no bounded strata (strata with small volumes). Note that it is not possible to simply eliminate strata with a low volume, by giving them full allocation, and then apply Neyman allocation on the remaining strata. The reason is as follows: suppose bounded strata are removed from further consideration. Then, remaining memory is divided among the remaining strata. This may lead to further bounded strata (which may not have been bounded earlier), and Neyman allocation again does not apply.

The following two-step process reduces variance-optimal offline SRS to variance-optimal sample size reduction.

Step 1: Suppose we start with a memory budget of n, sufficient to store all data. Then, we will just save the whole data set in the stratified random sample, and thus each sample size $s_i = n_i$. By doing so, the variance V is minimized, since $V = 0$ (Equation 1).

Step 2: Given the stratified random sample from Step 1, we reduce the memory budget from n to M such that the resulting variance is the smallest. This can be done using variance-optimal sample size reduction, by calling `SSR` or `MultiElementSSR` with target sample size M.

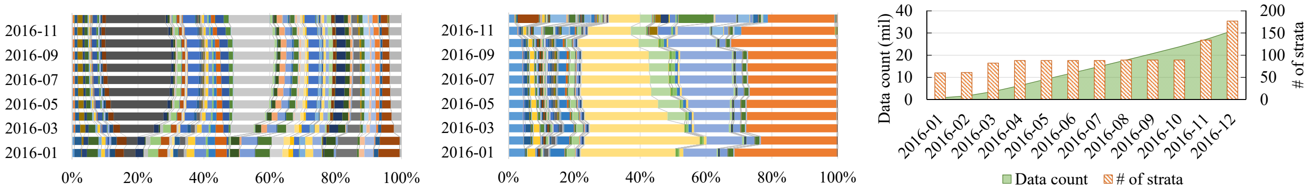
VOILA (Algorithm 5) simulates this process. The algorithm only records the sample sizes of the strata in array $\mathcal{L}$, without creating the actual samples. The actual sample from stratum i is created by choosing $\mathcal{L}[i]$ elements from stratum i, using a method for uniform random sampling without replacement.

Theorem 6.1. *Given a data set $\mathcal{R}$ with r strata, and a memory budget M,* VOILA *(Algorithm 5) returns in $\mathcal{L}$ the sample size of each stratum in a variance-optimal stratified random sample. The worst-case time cost of* VOILA *is $O(r \log r)$.*

Proof. The correctness follows from the correctness of Theorem 4.6, since the final sample is the sample of the smallest variance that one could obtain by reducing the initial sample (with zero variance) down to a target memory of size M. The run time is dominated by the call to `MultiElementSSR`, whose time complexity is $O(r \log r)$. □

7 EXPERIMENTAL EVALUATION

We present the results of an experimental evaluation. The input for our experiment is a (finite) stream of records from a data source, which is either processed by a streaming algorithm or by an offline algorithm at the end of computation. A streaming sampler must process data in a single pass using limited memory. An offline sampler has access to all data received, and can compute a stratified random sample using multiple passes through data. We evaluate the samplers in two ways. The first is a direct evaluation of the sample quality through the resulting allocation and the variance of estimates obtained using the samples. The second is through the accuracy of approximate query processing using the maintained samples for different queries.



(a) Relative (cumulative) frequencies of different strata. The x-axis is the fraction of points observed so far.

(b) Relative (cumulative) standard deviations of different strata.

(c) The number of strata received so far, and the number of records in data.

Figure 1: Characteristics of the OpenAQ dataset.

7.1 Sampling Methods

We compared our stream sampling method S-VOILA to Reservoir, ASRS and Senate sampling. Reservoir is a well-known stream sampling method that maintains a uniform random sample chosen without replacement from the stream - we expect the number of samples allocated to stratum *i* by Reservoir to be proportional to n_i. Senate [1] is a stratified sampling method that allocates each stratum an equal amount of sample space. For each stratum, Reservoir sampling is used to maintain a uniform sample.

ASRS is an adaptive stratified sampling algorithm due to Al-kateb *et al.* (Algorithm 3 in [5]). Their algorithm considers reallocations of memory among strata using a different method, based on power allocation [10], followed by reservoir sampling within each stratum. We chose the power allocation parameter to be 1 in order to obtain a sample of the entire population.

We also implemented three offline samplers VOILA, NeyAlloc, and an offline version of Senate. Each uses two passes to compute a stratified random sample of a total size of *M* records. The first pass is to determine strata characteristics used to allocate the space between strata. The second pass is to collect the samples accordingly to the computed allocation.

7.2 Data

We used a real-world dataset called OpenAQ [37], which contains more than 31 million records of air quality measurements (concentrations of different gases and particulate matter) from 7, 923 locations in 62 countries around the world in 2016. Data is replayed in time order to generate the stream and is stratified based on the country of origin and the type of measurement, e.g., all measurements of carbon monoxide in the USA belong to one stratum, all records of sulphur dioxide in India belong to another stratum, and so on. The total number of strata at different points in time are shown in Figure 1c. We also experimented with another method of stratifying data, based only on the city of origin, whose results are shown at the end of this section. We also experimented with a synthetic dataset. The results obtained were qualitatively similar to the real-world data, and we omit these results due to space constraints.

Each stratum begins with zero records, and in the initial stages, every stratum is bounded. As more data are observed, many of the strata are not bounded anymore. As Figure 1c shows, new strata are added as more sensors are incorporated into the data stream. Figures 1a and 1b respectively show the cumulative frequency and standard deviation of the data over time; clearly these change significantly with time. As a result, the variance-optimal sample-size allocations to strata also change over time, and a streaming algorithm needs to adapt to these changes.

7.3 Allocations of Samples to Strata

We measured the allocation of samples to different strata. Unless otherwise specified, the sample size *M* is set to 1 million records. For all experiments on allocations or variance, each data point is the mean of five independent runs. The allocation can be seen as a vector of numbers that sum up to *M* (or equivalently, normalized to sum up to 1), and we observe how this vector changes as more elements arrive.

Figures 2a, 2b and 2c show the change in allocations over time resulting from VOILA, S-VOILA with single element processing, and S-VOILA with minibatch processing. Unless otherwise specified, in the following discussion, the size of a minibatch is set to equal one day's worth of data. Visually, the allocations produced by the three methods track each other over time, showing that the streaming methods follow the allocation of VOILA. To understand the difference between the allocations due to VOILA and S-VOILA quantitatively, we measured the cosine distance between the allocation vectors from VOILA and S-VOILA. While detailed results are omitted due to space constraints, our results show that allocation vectors due to S-VOILA and VOILA are very similar, and the cosine distance is close to 0 most of the time and less than 0.04 at all times.

7.4 Comparison of Variance

We compared the variance of the estimates (Equation 1) produced by different methods. The results are shown in Figures 3 and 4. Generally, the variance of the sample due to each method increases over time, since the volume of data and the number of strata increase, while the sample size is fixed.

The comparison of different streaming algorithms is shown in Figure 4. Among the streaming algorithms, we first note that both variants of S-VOILA have a variance that is lower than ASRS, and typically close to the optimal (VOILA). The variance of S-VOILA with minibatch processing is typically better than with single element processing. We note that the variances of both variants of S-VOILA are nearly equal to that of VOILA until March, when they start increasing relative to VOILA, and then converge back. From analyzing the underlying data, we see that March is the time when a number of new strata appear in the data (Figure 1c), causing a substantial change in the optimal allocation of samples to strata. An offline algorithm such as VOILA can resample more elements at will, since it has access to all earlier data from the stratum. However, a streaming algorithm such as S-VOILA cannot do so and must wait for enough new elements to arrive in these strata before it can "catch up" to the allocation of VOILA. Hence, S-VOILA with single element as well as with minibatch processing show an increasing trend in the variance at such a point. When data becomes stable again the relative

Figure 2: Change in allocation over time. OpenAQ data.

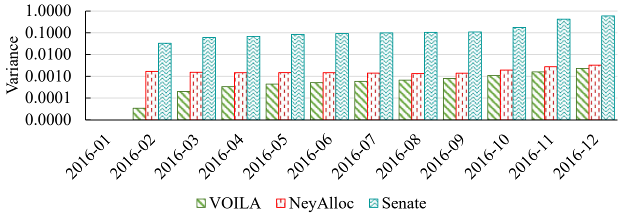

Figure 3: Variance of VOILA compared to NeyAlloc and Senate. Sample size: 1M records, OpenAQ data.

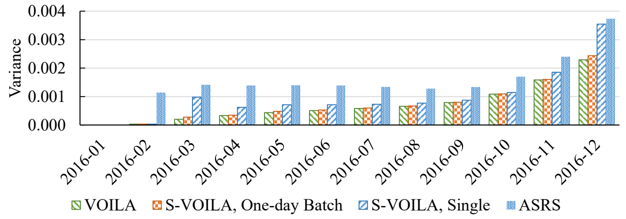

Figure 4: Variance of S-VOILA compared with ASRS and offline VOILA. Sample size 1M records, OpenAQ data.

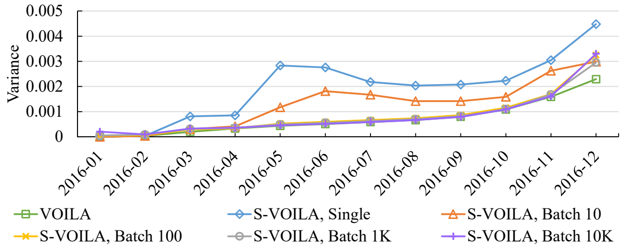

Figure 5: Impact of Minibatch Size on Variance, OpenAQ.

performance of S-VOILA improves. In November and December, new strata appear again, and the relative performance is again affected.

Among offline algorithms, we observe from Figure 3 that Senate performs poorly, since it blindly allocates equal space to all strata. NeyAlloc results in a variance that is larger than VOILA, by a factor of 1.4x to 50x. While NeyAlloc is known to be variance-optimal under the assumption of having all strata being abundant, these results show that it is far from variance-optimal for bounded strata.

Impact of Sample Size: To observe the sensitivity to the sample size, we conducted an experiment where the sample size is varied from 5000 to 1 million. We fixed the minibatch size to 100 thousand records. As expected, in both S-VOILA and VOILA, with single element and minibatch processing, the variance decreases when the sample size increases. The general trend was that the variance decreased by approximately a factor of 10 when the sample size increased by a factor of 10. We omit detailed results due to space constraints.

Impact of Minibatch Size: We further conducted an experiment where the minibatch size is chosen from $\{1, 10, 10^2, 10^3, 10^4\}$. The results are shown in Figure 5. A minibatch size of 10 elements yields significantly better results than single element S-VOILA. A minibatch size of 100 or greater makes the variance of S-VOILA nearly equal to the optimal variance.

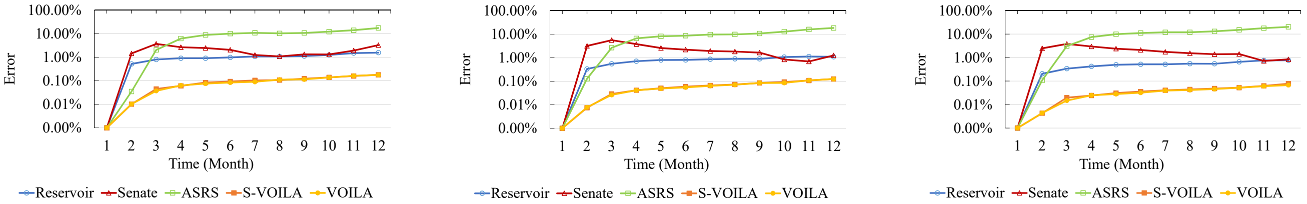
7.5 Query Performance, Infinite Window

We now evaluate the quality of these samples indirectly, through their use in approximate query processing. Samples constructed using S-VOILA and VOILA are used to approximately answer a variety of queries on the data so far. For evaluating the approximation error, we also implement an exact (but expensive) method for query processing Exact that stores all records in a MySQL database. Identical queries are made at the same time points in the stream to the different streaming and offline samplers, as well as to the exact query processor.

A range of queries are used. Each query *selects a subset of data through a selection predicate supplied at query time, and applies an aggregate.* This shows the flexibility of the sample, since it does not have any a priori knowledge of the selection predicate. We have chosen predicates with selectivity equal to one of 0.25, 0.50, and 1.00. We consider four aggregation functions: SUM, the sum of elements; SSQ, the sum of squares of elements; AVG, the mean of elements; and STD, the standard deviation. Each data point is the mean of five repetitions of the experiment with the same configuration. Each query was executed over all received data after one month of data arrived, up to entire year of 2016 in the OpenAQ dataset with thirty-one million records.

Figures 6 and 7 show the relative errors of different aggregations as the size of streaming data increases, while the sample size is held fixed. Both figures show that S-VOILA outperforms other streaming samplers across queries with different aggregation and selectivity. This result shows that S-VOILA maintains a better quality of stratified sample to answer an aggregation over a subset of data accurately. In addition, S-VOILA performs very closely to its offline version, VOILA, which samples from the entire received data. We note that when ASRS evicts elements from per-stratum samples, there may not always be new elements to take their place, hence it often does not use its full quota of allocated memory.

Alternate Methods of Stratification. We also experimented with the OpenAQ data set stratified in a different manner, using the city where the observation was made. Sample results are shown in Figure 8. We still see that S-VOILA outperforms



(a) Selectivity=0.25

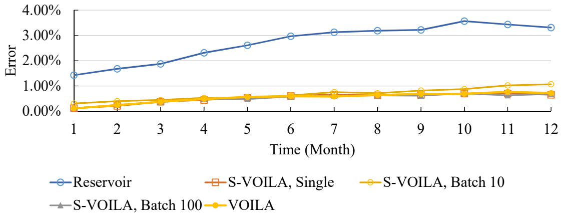

Figure 9: Streaming samplers, impact of minibatch size, sample size = 100,000. (SUM with selectivity 0.5)

Reservoir, Senate, and ASRS. This supports our observation that the sample maintained by S-VOILA is of a higher quality than other streaming samplers, no matter how data is stratified.

Impact of Sample Size. We also explored different sample sizes varied from 500, 000 to 1 million. All methods benefit from increased sample size and the relative performance between different methods remains the same across different sizes.

Impact of Minibatch Size. Figure 9 shows the impact of the minibatch size on the accuracy of streaming samplers for the SUM query with selectivity 0.5. The sample size is set to one hundred thousand for each sampler. S-VOILA with different minibatch sizes has an error less that 1%, often much smaller, while Reservoir has an error that is often 3% or larger. In addition, we observe that S-VOILA with different minibatch sizes is very close to VOILA.

7.6 Sliding Window Streaming

We experimented with streaming algorithms Reservoir and S-VOILA with a sliding window of size $W = 10^6$. The version of Reservoir that was used here maintains a uniform sample over the window by sampling each record with the same selection probability of $\frac{M}{W}$, so it may be more accurately termed "Bernoulli sampling". S-VOILA uses stratified sampling with single element processing, as described in Section 5. As the window slides, we periodically ask for sum of the *value* attribute in the current window. We report the error by compare the estimates from samples with the ground-truth answer. Figure 10 shows the average errors of 5 runs. With a 10% sample rate, as expected, S-VOILA provide an answer with less than 1% error, while Reservoir has an error of about 2-3%.

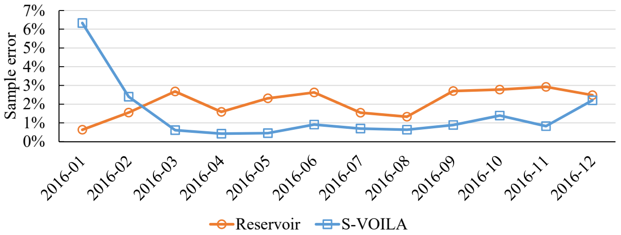

Figure 10: Sample error of window sum query, streaming data with sliding window of 10^6 and sample size of 10^5 records, OpenAQ data.

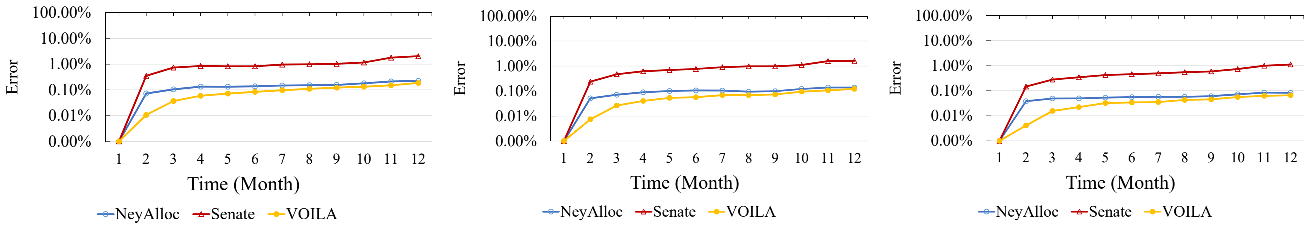
7.7 Offline Sampling

We also compared VOILA with other offline samplers for the SUM query with different selectivities. Figure 11 shows that VOILA always has better performance than Senate and NeyAlloc. Our experiments with other aggregations also showed similar results.



(a) Selectivity=0.25

(b) Selectivity=0.50

(c) Selectivity=1.00

Figure 11: Offline samplers. SUM with different selectivities, sample size = 1 million. OpenAQ data.

8 CONCLUSIONS

We presented S-VOILA, an algorithm for streaming SRS with minibatch processing, which interleaves a continuous, locally variance-optimal re-allocation of sample sizes with streaming sampling. Our experiments show that S-VOILA results in variance that is typically close to VOILA, which was given the entire input beforehand, and which is much smaller than that of algorithms due to prior work. We also show an inherent lower bound on the worst-case variance of any streaming algorithm for SRS – this limitation is not due to the inability to compute the optimal sample allocation in a streaming manner, but is instead due to the inability to increase sample sizes in a streaming manner, while maintaining uniformly weighted sampling within a stratum. Our work also led to a variance-optimal method VOILA for offline SRS from data that may have bounded strata. Our experiments show that on real and synthetic data, an SRS obtained using VOILA can have a significantly smaller variance than one obtained by Neyman allocation.

There are several directions for future research, including (1) restratification in a streaming manner, (2) handling group-by queries and join queries, (3) incorporating general versions of time-decay, and (4) SRS on distributed data.

Boosting SimRank with Semantics

ABSTRACT

The problem of estimating the similarity of a pair of nodes in an information network draws extensive interest in numerous fields, e.g., social networks and recommender systems. In this work we revisit SimRank, a popular and well studied similarity measure for information networks, that quantifies the similarity of two nodes based on the similarity of their neighbors. SimRank's popularity stems from its simple, declarative definition and its efficient, scalable computation. However, despite its wide adaptation, it has been observed that for many applications SimRank may yield inaccurate similarity estimations, due to the fact that it focuses on the *network structure* and ignores the *semantics* conveyed in the node/edge labels. Therefore, the question that we ask is *can SimRank be enriched with semantics while preserving its advantages?*

We answer the question positively and present SemSim, a modular variant of SimRank that allows to inject into the computation any semantic similarly measure, which satisfies three natural conditions. The probabilistic framework that we develop for SemSim is anchored in a careful modification of SimRank's underlying random surfer model. It employs Importance Sampling along with a novel pruning technique, based on unique properties of SemSim. Our framework yields execution times essentially on par with the (semantic-less) SimRank, while maintaining negligible error rate, and facilitates direct adaptation of existing SimRank optimizations. Our experiments demonstrate the robustness of SemSim, even compared to task-dedicated measures.

1 INTRODUCTION

Estimating node similarity in information networks is the cornerstone of many applications, e.g., retrieving similar users in social networks, and a fundamental component in numerous network analysis algorithms, such as link prediction and clustering.

In this work we consider SimRank [13], a well-studied similarity measure for information networks. The intuition behind SimRank is that similar objects are referenced by similar objects, and thus it quantifies node similarity based on the compound similarity of their neighbors. SimRank's popularity stems from its simple declarative definition and its efficient computation, incorporating a broad range of optimizations [15, 39]. However, despite its wide adaptation, it has been observed that for many applications SimRank may yield inaccurate estimations [37, 40], as it focuses solely on the *network structure* and ignores the *semantic information* conveyed in the node/edge labels. Thus, the question we address is the following:

Can SimRank be enriched with semantics while preserving its intuitive, declarative definition and efficient computation?

We answer the question positively, and present SemSim, a refined variant of SimRank, that weights nodes' structural similarity with their semantic similarity and edge weights, yielding an effective, comprehensive measure. SemSim's probabilistic framework, anchored in a careful modification of SimRank's underlying random surfer model, together with dedicated optimizations, allows for execution times essentially on par with the semantic-less SimRank, while maintaining similar negligible error rates. Direct adaptation of existing SimRank optimizations is also enabled.

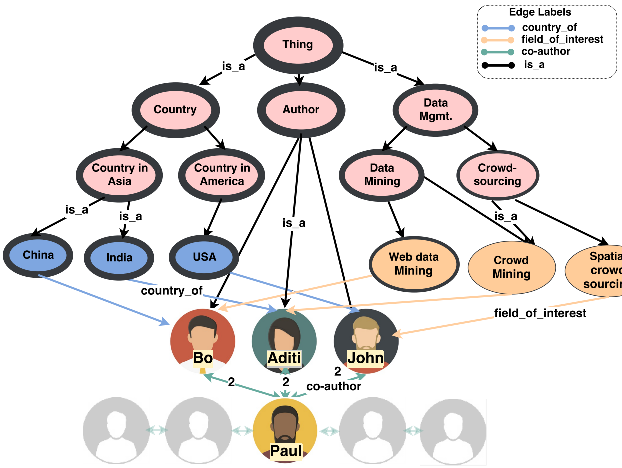

Figure 1: Example information network.

We demonstrate the problem that we tackle with an illustrative example.

Example 1.1. The simple information network depicted in Figure 1 represents a bibliographic database. It includes nodes describing authors, countries and research fields, with edges linking authors to their co-authors, country of origin and fields of interest. A semantic taxonomy is also reflected in this network (pink nodes) where entities are linked to their hypernyms, as indicated by the "is-a" edges. Edge weights reflect the strength of the relations (for conciseness, some weights are omitted but should be assumed to have an identical arbitrary default value). To visually represent the prevalence of a concept in the dataset, we use the width of the borders surrounding the nodes (an explanation of this quantification is provided in the sequel).

We wish to determine which of the authors, Bo or John, is more similar to Aditi. Observe that: (1) all three collaborated with Paul twice (as indicated by the edge weights); (2) their origin countries are all highly prevalent (as indicated by the borders' width), compared to the authors' fields of interest, thus the latter is more *informative* and should have a greater effect on the similarity[1]; (3) Crowdsourcing, the common field of John and Aditi, is more particular (less prevalent) than Data Mining, the field shared by Bo and Aditi. Hence, intuitively, Crowd Mining is semantically closer to Spatial Crowdsourcing than to Web Data Mining. Consequently, John is more similar to Aditi than Bo, even though they reside in different continents. Note, however, that ignoring semantics and considering the *network structure* alone (even including edge weights), Bo and Aditi seem more similar,

[1] Following standard argumentation, an estimation of similarity increases more drastically when indicated by a less frequent event [32].

and indeed, SimRank (like other measures [37, 43]) erroneously derive a higher similarity score for them.

Several refinements for SimRank have been proposed in the literature (see Related Work). For instance, SimRank++ [2] is a variant of SimRank that also considers edge weights, yet semantics is ignored, and, importantly, scalability is not addressed. Other works (e.g. [37]) partially account for semantics by considering only meaningful *meta-paths* (i.e. paths of a specific label patterns) between objects. But as can be seen in the above example (and in our experiments) this does not always suffice to accurately differentiate objects. Alternatively, several semantic measures have been proposed [23, 32], but they typically gauge the similarity based on ontological information and the *Information Content* (IC) of nodes, while the rest of the network structure is ignored. In an attempt to fully account for both structure and semantics, recent works abandon SimRank and rely instead on representation learning, using techniques such as node embedding [4, 30]. While this approach often outperforms a naive combination of structural and semantic similarity measures, a key drawback is that results are hard to explain and interpret, as is often the case with machine learning. Interestingly, we show that our SimRank variant not only retains its intuitive, declarative flavor but also yields more accurate estimations compared to these works.

Next, we provide a brief overview of our results.

The SemSim *similarity measure.* We refine SimRank by weighting nodes' neighbors similarity with their semantic similarity and edge weights. Our definition is modular and allows to inject into the computation any semantic measure, as long as it satisfies three intuitive conditions that are typically satisfied by existing measures. We present SemSim iterative formulation, analogous to SimRank iterative formulation [13]. We prove that SemSim's solution always exists (as was shown for SimRank), and show that its iterative formula converges to its fix-point at least as fast as SimRank, and possibly faster, due to an additional semantic factor (Section 2).

Random-surfer model. SimRank's underlying random-surfer model serves as the basis for many of its optimizations. We establish a corresponding model for SemSim. First, we define the notion of a *Semantic-Aware Random Walk* (SARW), which refines the traditional random walk definition, and prove that SemSim can be computed using SARWs. This interpretation considers the *node-pair graph* G^2, in which a node represents an ordered pair of nodes from the original graph G. Interestingly, we prove that given a threshold s.t. only similarity scores above it are of interest, the semantics can effectively be used to reduce the size of G^2, with the computation of SemSim over the reduced graph yielding the same results as those computed via the full graph G^2. Our experiments demonstrate that a significant reduction of up to three orders of magnitude is achieved in multiple datasets (Section 3).

Approximated similarity scores. Exact computation may still be expensive for large graphs, despite the speed-up gained by the graph reduction. For SimRank, the excessive size of G^2 motivated a battery of optimizations based on a Monte-Carlo (MC) procedure [15, 34, 39]. SimRank basic MC framework returns an approximated SimRank score in $O(n_w \cdot t)$ time, where n_w is the number of walks sampled from each node and t is a bound on their length. To efficiently approximate SemSim we develop an analogous MC framework, thereby enabling a direct application of SimRank optimizations. First, we show that a naïve solution of simply replacing SimRank's underlying uniform distribution with the semantic-aware distribution leads to a quadratic increase of the sample size. To overcome this, we employ *Importance Sampling*, and devise an unbiased estimator for SemSim, which avoids this increase and returns the estimated SemSim score in average time of $O(n_w \cdot t \cdot d^2)$, where d is the average in-degree in the graph G. To further reduce computation cost, we devise a dedicated pruning technique that avoids the computations of unpromising node-pairs and irrelevant (low probability) walks, at the cost of a controlled additive error to the approximated scores. While the worst-case time complexity remains the same, our experiments show pruning to be extremely effective in practice, yielding running times on par with SimRank (Section 4).

Experimental study. We conduct an experimental study over real data, demonstrating the effectiveness of SemSim in multiple practical scenarios. Our results demonstrate the robust quality of SemSim, even compared to task-dedicated measures. The results further exhibit the efficiency and accuracy of our framework and its ability to boost SimRank with semantics while preserving its performance (Section 5).

Finally, related work and conclusions are presented in sections 6 and 7, respectively. For space constraints, proofs are deferred to a technical report [27].

2 PRELIMINARIES

We first explain the data model used in our setting, then present our novel measure, SemSim.

2.1 Data Model

Following [36], we refer to the objects graph as a *Heterogeneous Information Network* (HIN), a flexible graph model that can capture and integrate various types of data. Let $\mathcal{V}$ be the domain of vertices, $\mathcal{L}$ the domain of labels, and $\mathcal{R}^+$ the domain of real positive numbers > 0.

Definition 2.1 (Heterogeneous Information Network). A HIN is a directed weighted graph $G = (V, E, \phi, \psi, W)$, where: $V \subseteq \mathcal{V}$ is a finite set of vertices; $E \subseteq V \times V$ is a set of edges; $\phi : V \longrightarrow \mathcal{L}$ and $\psi : E \longrightarrow \mathcal{L}$ are vertex and edge labeling functions, resp., and $W : E \longrightarrow \mathcal{R}^+$ is an edge weight function.

The edge weight function W associates each edge with a real positive number indicating the strength of the relation. When no knowledge about this strength is available, the weight is set to a default value. For example, in Figure 1, weights are available only for edges with the label *co-author*, where the weights reflect the number of collaborations between authors. Since no information about other weights is available, all other weights were set to 1. For a node v, we denote by $I(v), O(v)$ the set of in and out neighbors of v, resp. An individual in-neighbor is denoted as $I_i(v)$, for $1 \leq i \leq |I(v)|$, if $I(v) \neq \emptyset$ ($O_i(v)$, resp). Throughout the paper we use the variables u, v, u', v' to denote nodes in V. Here we consider directed graphs, but stress that all results can be adapted to the undirected model with minor modifications.

In many cases, the HIN is composed of two subgraphs that are aligned together: one consists of individual objects and their relations, e.g. authors/countries, and their collaboration/residence relationships. The second, ontological-style subgraph is comprises of semantic categories and relationships, e.g. the pink nodes and their "is-a" relations. Objects of the former can be connected to their corresponding categories. For example, in Figure 1 all author nodes are connected to the category *Author*. When semantic information is not included, one can enrich the graph by aligning it with publicly available ontology [5, 26] by applying existing entity alignment tools [28]. Ontologies typically contain a hierarchical taxonomy of concepts, e.g., that *USA* "is-a" a *Country in America* and *Country in America* "is-a" *Country*. Such taxonomies are often leveraged to define semantic similarity measures.

2.2 Similarity Notions

As described above, our semantic-rich graph model contains various types of linked entities, as well as additional knowledge that is captured by the edge weights. Next, we devise a refined version of SimRank [13] that effectively considers all information. We start with a short background on SimRank, then provide the formal definition for SemSim.

SimRank follows the intuitive assumption that: "two nodes are similar if they are related to similar nodes". Formally, given two nodes $u, v \in V$, their SimRank score is defined as follows. If $u = v$ then $simrank(u, v) = 1$, else: $simrank(u, v)$ is given by the following recursive formula *without the red colored parts.*

$$sim(u, v) = \qquad (1)$$

$$\frac{sem(u,v) \cdot c}{N_{u,v}} \sum_{i}^{|I(u)|} \sum_{j}^{|I(v)|} sim(I_i(u), I_j(v)) \cdot W(I_i(u), u) \cdot W(I_j(v), v)$$

where c is a decay factor in $(0, 1)$, $N_{u,v} = |I(u)| \cdot |I(v)|$ and $sim(\cdot, \cdot)$ is the SimRank score of the neighboring pair-nodes. If $I(u)$ or $I(v)$ are $\emptyset$, then the score is defined to be zero.

In SimRank, the assumed graph model is an unweighted homogeneous graph, where all edges and nodes belong to a single type, thus it ignores the labels' semantics and edge weights. We enrich SimRank by weighting, at each step of the computation, the neighbors' similarity with the edge weights and the nodes' semantic similarity. Formally, given a semantic similarity measure $sem(\cdot, \cdot)$, the red parts indicate our refinements to SimRank standard formula: (i) an additional semantic factor is added; (ii) the edge weights are taken into consideration. Correspondingly, the normalization factor is set to:

$$N_{u,v} = \sum_{i}^{|I(u)|} \sum_{j}^{|I(v)|} W(I_i(u), u) \cdot W(I_j(v), v) \cdot sem(I_i(u), I_j(v))$$

where $sim(\cdot, \cdot)$ in the refined formula denotes the refined similarity of the neighbors. Here too, if $I(u)$ or $I(v)$ are the $\emptyset$, then the similarity score is defined to be zero.

Note that according to our definition of similarity, the semantic similarity of the neighboring pairs of nodes appears as well (as the definition is recursive), and therefore, the similarity of two nodes u, v is, in fact, proportional to the semantic similarity of their neighbors.

Importantly, our definition of SemSim considers all neighbor-pairs. An alternative could be to take edge labels into consideration and restrict attention to neighbor-pairs that are pointed by edges having the same label. However, while such formulation requires only minimal technical changes and all our results remain unchanged, our experiments showed it to be less accurate, as this definition may overlook possibly important relations among the objects. Moreover, both definitions yield essentially the same running times and we thus omit this restriction.

Semantic Similarity. Multiple semantic measures have been proposed in the literature [16, 20]. In general, any similarly function $sem(\cdot, \cdot)$ can be employed in SemSim, as long as it satisfies the following constraints. For all $u, v \in V$:

(1) *Symmetry.* $sem(u, v) = sem(v, u)$.
(2) *Maximum self similarity.* $sem(u, u) = 1$.
(3) *Fixed value range.* $sem(u, v) \in (0, 1]$.

Those requirements are used to prove the soundness of SemSim (Theorem 2.3). The first two are typically satisfied by common semantic measures (e.g., [16, 23, 32]). For the third constraint, scores can be normalized into a $[0 + \epsilon, 1]$ range, for a small $\epsilon > 0$ value [29].

We next briefly overview a simple and effective semantic measure that we have used in our experiments (see Section 6 for a discussion on alternatives). Lin [23] is an *Information Content* (IC)-based measure that is defined over concept taxonomies. The IC of a node v is quantify as the negative of its log likelihood: $IC(v) = -\log(P[v])$, where $P[v]$ denotes the frequency of v. I.e., the more prevalent a concept is, the lower its IC value. Intuitively, the similarity between concepts measures the ratio of the amount of information needed to state their commonality to the information needed to describe them. Given two nodes u and v in a taxonomy, their Lin score is defined as:

$$Lin(u, v) = \frac{2 \cdot IC(LCA(u, v))}{IC(u) + IC(v)}$$

where $LCA(u, v)$ is the lowest common ancestor of u and v in the taxonomy.

Note that Lin satisfies the constraints, only if the IC values are in $(0, 1]$ (proof omitted). To estimate the IC of a concept, we adapted the Seco formula [33] in our implementation, providing a simple linear-time (in the size of the taxonomy) algorithm and extended it to our setting. This adaptation ensures the IC values lie within $(0, 1]$ (see [27] for more details).

Entity	IC value
Thing	0.001
Author, Country	0.01
Country in Asia, Country in America	0.015
China, India, US	0.02
Data Management	0.2
Data Mining	0.3
Crowdsourcing	0.85
Web data mining	0.7
Crowd Mining, Spatial Crowdsourcing	0.9
Bo, John, Aditit, Paul	1.0

Table 1: IC values for Figure 1 entities.

We next provide the full computation of SimRank and SemSim for the example introduced in the Introduction (Example 1.1), while using Lin as the integrated semantic measure.

Example 2.2. We computed the IC values (depicted in Table 1) on the same domain ontology used for the AMiner dataset (which includes a taxonomy of CS terms as well as a geographic taxonomy, see experimental results), and set absent edge weights to 1. For both SimRank and SemSim, we set the decay factor c to 0.8 and the number of iterations k was set to 3.

We first review the relevant Lin scores: since all author-nodes are leafs in the taxonomy, their corresponding IC values are all 1, thus *Lin(Bo,Aditi)* = *Lin(John,Aditi)*= 0.01 (which also serves as the upper bound on their SemSim scores). Using the IC values above, we get: *Lin(Spatial Crowdsourcing,Crowd Mining)*= 0.94 and *Lin(Web Data Mining,Crowd Mining)*= 0.37. Next, we briefly overview SemSim and SimRank computation. At the first iteration, for both measures, $R_0 = 0$ for all authors pairs. Iteratively, at the next step, since all three authors share two common neighbors, *Author* and *Paul*, yet the common field-of-interest of Aditi and John is more semantically similar than the common field of Aditi and Bo, we get for SemSim that: R_1*(John,Aditi)* = 0.0073, while R_1*(Bo,Aditi)*= 0.066. Note that in this step the semantic similarity of common neighbors propagates into the computation. On the other hand, according to SimRank, in this step both pairs similarity scores are equal to 0.1. At the last step, according to SemSim R_2*(John,Aditi)* = 0.0076, while R_2*(Bo,Aditi)*= 0.0073, thus, SemSim obtains the desire result that while all authors are fairly similar, John's similarity to Aditi is a bit greater than Bo's. In contrast, according to SimRank, R_2*(John,Aditi)* = 0.12, while R_2*(Bo,Aditi)*= 0.16. These results are due to the fact that both Aditi and Bo reside in the same continent.

We also computed the SimRank scores solely over the collaboration network (i.e., ignoring the semantic relations). Not surprisingly, since the resulted network is symmetric, the obtained similarity scores for both pairs were exactly the same.

2.3 Basic Properties of SemSim

We next show a few of SemSim's properties which will then be used to present a naïve algorithm for computing SemSim, that serves as a baseline which we improve in the following sections.

Following SimRank's iterative form [13], a solution to Equation (1) can be reached by iterating to a fix-point. For the k-th iteration, an iterative function $R_k(u,v)$ denotes the similarity score of u and v in the k-th iteration. Initially, $R_0(u,v)$ is defined as 0 if $u \neq v$ and 1 otherwise. Iteratively, $R_{k+1}(u,v)$ is computed from $R_k(\cdot,\cdot)$ as follows:

$$R_0(u,v) = \begin{cases} 0, u \neq v \\ 1, u = v \end{cases} \tag{2}$$

$$R_{k+1}(u,v) = \tag{3}$$

$$\frac{sem(u,v)\cdot c}{N_{u,v}} \sum_{i}^{|I(u)|} \sum_{j}^{|I(v)|} R_k(I_i(u), I_j(v)) \cdot W(I_i(u),u) \cdot W(I_j(v),v)$$

We can prove that the iterative SemSim form has the following properties:

Theorem 2.3. *$\forall u,v \in V$ and for every $0 \leq k \in \mathbb{N}$:*
(1) Symmetry. $R_k(u,v) = R_k(v,u)$.
(2) Maximum self similarity.$R_k(u,u) = 1$.
(3) Monotonicity. $0 \leq R_k(u,v) \leq R_{k+1}(u,v) \leq 1$.
(4) Existence. The solution always exists.
$0 \leq c < min(argmin_{N_{u,v}}(N_{u,v}), 1)$, the solution is unique.

First, note that the decay factor's upper bound can be found in average time of $O(n^2 \cdot d^2)$, where d is the average in-degree in the graph, by simply iterating over all node-pairs. Second, we observe that the uniqueness property here is a weaker version than the one that was proven for SimRank, where the solution is unique for every $0 \leq c < 1$. Yet, our experiments show that for real-life networks, the upper bound is high enough to comfortably accommodate typical c values chosen for SimRank (e.g., 0.6, as used in [24, 39]).

We can also show (following similar proof for SimRank [46]) that not only the scores are monotone (i.e, $R_k(u,v) \leq R_{k+1}(u,v)$), their differences in consecutive iterations are bounded.

Proposition 2.4. *For every $u,v \in V$ and $k > 0$: $0 \leq R_{k+1}(u,v) - R_k(u,v) \leq sem(u,v) \cdot c^{k+1}$*

This suggests that the iterative form of SemSim converges as fast as SimRank (where the convergence was shown to be c^{k+1} [46]), and possibly faster due to the additional semantic factor. Another useful property is that $sem(\cdot,\cdot)$, the semantic similarity of two nodes, provides a natural upper bound on their SemSim score. This property is highly effective since, as we will show, it can be used to prune un-promising node-pairs.

Proposition 2.5. *For every two nodes $u,v \in V$: $sim(u,v) \leq sem(u,v)$.*

To conclude, Theorem 2.3 provides a simple algorithm for computing SemSim, that computes its iterative form to its fix-point (or up to a required precision bound). We assume that the computation of a single-pair semantic similarity score can be done in constant time (possibly after pre-processing), without materializing the $n \times n$ matrix of scores. Indeed, this is the case for numerous semantic measures [16, 32], Lin's measure included. Given this, the complexity of the iterative algorithm is equivalent to SimRank's complexity [13]: The time complexity is $O(k \cdot d^2 \cdot n^2)$, where $n = |V|$, d is the average in-degree in G and k is the number of iterations. The worst case complexity for a given k is $O(n^4)$.

3 RANDOM SURFER-PAIRS MODEL

The iterative algorithm provided in the previous section has two main disadvantages: (i) it computes all pair-wise scores, even if one is interested only in a single-pair, and (ii) its complexity is prohibitive for large graphs. To address these issues, we provide an alternative interpretation to SemSim, based on the *random surfer model* for SimRank, then, explain how SemSim can be computed efficiently. In essence, we show that with careful adjustments, an analogous random surfer model can be establish for SemSim. The key challenge is to incorporate semantics. We show that SemSim measures how soon two random surfers are expected to meet, if they start in two nodes and randomly walk on the graph backward, while being aware of both edge weights and semantics. We define *Semantic-Aware Random Walks* (SARW), then prove that SemSim can be computed using them. Interestingly, we will see that semantics can be leveraged to speed up the computation.

3.1 Semantic-Aware Random Walks (SARW)

Following [13], we use the definition of a *node-pair graph G^2*, in which each node represents an ordered pair of nodes from G. An edge $e = ((u,u'),(v,v')) \in G^2$ iff both (u,v) and (u',v') are $\in G$. We extend the definition with an assignment of weights: The weight of an edge $e = ((u,u'),(v,v'))$ is defined as: $W_{G^2}(e) := W(u,v) \cdot W(u',v')$. For simplicity, we use the notation of $W(e)$ to indicate an weight in both G and G^2, when the context is clear.

Let us assume that all edges in G have been reversed. For example, Figures 2a and 2b display a graph G and all out-edges from *(A,B)* (after reversal). For simplicity, all edge weights are set to 1. We call a node $(u,v) \in V^2$ a *singleton node* if $u = v$. In SimRank, a surfer chooses the next node uniformly at random out of all out-neighbors of the current node. To incorporate semantics and weights, we devise the following distribution.

Definition 3.1 (Semantic-Aware Probability Distribution). The probability a random surfer traveling G^2 in a current node (u,u') would next move to its out-neighbor (v,v') is:

$$P[(u,u') \to (v,v')] := \frac{W((u,u'),(v,v')) \cdot sem(v,v')}{\sum_{i=1}^{|O((u,u'))|} W((u,u'),O_i(u,u')) \cdot sem(O_i(u,u'))}$$

Using the distribution above, we define SARWs as follows. A walk in G^2 represents a pair of walks in G. Let $w = \langle w_1, ..., w_k \rangle$ denote a walk in G^2, where $w_1, ..., w_k \in V^2$, and $l(w) = |w|$. The walk w has the probability $P[w]$ of traveling within it, where $P[w] := \prod_{i=1}^{k-1} P[w_i \to w_{i+1}]$.

Importantly, this distribution defines a positive probability to *all* paths in G^2. However, as the choice of the next step relies on the semantic similarity of node-pairs, pairs of higher semantic similarity are preferred over pairs of low similarity (typically, pairs whose nodes belong to different categories). Namely, paths that share the same edge label in each step, are likely to get higher probabilities. Nonetheless, even paths that do not share the same labels are considered, as they may also provide relevant information[2]. We provide here an illustrative example for a computation of SARWs.

Example 3.2. Consider again Figure 2b. Observe that author A's current country is *Canada*, and author B's origin country is the *USA*. Noticeably, even though the two edges do not share the same label, this information may be important when assessing similarity. According to our definition we get that since the entities *Canada* and *USA* are semantically similar ($Lin(Canada, USA) = 0.8$), the probability that a random surfer in the node *(A,B)* will move next to its neighbor *(Canada, USA)* is:

$$P[(A,B)\rightarrow(Canada, USA)] = \frac{0.8}{0.8+0.2+0.2+1.0} = 0.36$$

On the other hand, as the two entities *Author* and the *USA* are not semantically similar ($Lin(Author, USA) = 0.2$), the corresponding probability is lower:

$$P[(A,B)\rightarrow(Author, USA)] = \frac{0.2}{0.8+0.2+0.2+1.0} = 0.09$$

The SimRank score of a node $(u,v) \in V^2$ can be computed using all walks from it leading to a singleton node in G^2. Analogously, we prove that SemSim can be computed using all semantic-aware walks from (u,v) leading to singleton nodes in G^2. Let $W = \{(u,v) \rightsquigarrow (x,x)\}$ be the set of all walks in G^2 form (u,v) to any singleton node (x,x). If no such paths exist, then $W = \emptyset$. By definition, (x,x) is the only singleton node in w (after the first meeting, the two surfers halt). Let: $s'(u,v) = sem(u,v)\sum_{w\in W} P[w]\cdot c^{l(w)}$. Theorem 3.3 provides an alternative way to compute the SemSim score of a single pair.

Theorem 3.3. *$\forall u, v$, given c which ensures the uniqueness of $sim(\cdot,\cdot)$: $s'(u,v) = sim(u,v)$*

Using our refined model, one may compute (single pair or all pairs) SemSim scores over G^2. However, for large graphs, its size may be too large. We next explain how the semantics can be effectively employed to reduce the size of G^2.

3.2 Reducing the Size of G^2

In many practical applications one is interested only in node-pairs whose similarity scores are above a given threshold. Semantics provides an efficient tool to prune G^2 in such situations. Intuitively, Prop. 2.5 provides a semantic-based upper bound on the similarity scores, which can be used to avoid materializing un-promising node-pairs. We devise a reduced version of G^2 on which the computation of SemSim (for node-pairs with similarity scores are above a given threshold) yields the same result as that computed via the full graph G^2. Indeed, our experimental results demonstrate a significant reduction in the size of G^2.

Given a threshold $0 < \theta < 1$, we define the graph G^2_θ, which includes only pairs s.t. their semantic scores are $> \theta$. However, simply omitting nodes from G^2 directly affects the similarity scores, thus, may lead to inaccurate scores. We therefore incorporate omitted paths by refining the edge weights and possibly adding new edges. Intuitively, each omitted path is replaced by a corresponding edge, whose weight reflects its probability. If such an edge already exists in G^2, the omitted edge's weight is added to the existing edge weight. Moreover, the weight of omitted path is further weighted by the decay factor c, to ensure the similarity scores would not be affected. Last, to ensure that the probability of choosing a neighbor remains the same as in the original graph G^2, the graph G^2_θ includes a new vertex D, that has only in-neighbors, and serves as a “drain".

Definition 3.4. [G^2_θ] Given a node-pair graph G^2 and a threshold $0 < \theta < 1$, $G^2_\theta = (V_\theta \cup \{D\}, E_\theta, W_\theta)$, where: $V_\theta \subseteq V^2$ is a set of nodes and D is a new node, $E_\theta \subseteq (V_\theta \cup \{D\} \times V_\theta \cup \{D\})$ is the edges set and W_θ is a weight function, defined as follows.

- **Nodes:** A node $(u,v) \in V_\theta$ iff $sem(u,v) > \theta$.
- **Edges:** An edge $e = ((u,u'),(v,v')) \in E_\theta$ iff at least one of the following conditions holds
  (1) The nodes $(u,u'),(v,v')$ are adjacent in G^2.
  (2) There exists a walk in G^2, where $w = \langle(u,u'), w_1, \ldots, w_k, (v,v')\rangle$ and the node-pairs $w_1 \ldots, w_k \notin V_\theta$.
- **Weights:** The weight of an edge $e = ((u,u'),(v,v'))$ is defined as $W_\theta(e) = W_1(e) + W_2(e)$ where: $W_1(e) = W_{G^2}(e)$ if $e \in G^2$ and $(u,u'),(v,v') \in V_\theta$ and 0 otherwise, and $W_2(e) = \sum_{w:(u,u')\rightsquigarrow(v,v')} P[w]\cdot c^{l(w)-1}$, where $t = \langle(u,u'), w_1, ..., w_k, (v,v')\rangle$ is a path in G^2 and the node-pairs $w_1, ..., w_k \notin V_\theta$.
- **Edges to D:** Edges to the vertex D are added as follows: $\forall(u,u') \in V_\theta$ if the sum of all out-edges of (u,u') in the graph G^2_θ is different then the sum of all out-edges of (u,u') in the graph G^2, then $((u,u'),D) \in E_\theta$ and $W_\theta((u,u'),D)$ is set to be the difference.

In the last point, to ensure that all weights are strictly positive, we can prove that for every node in G^2_θ, the sum of out-edges in the original graph G^2 is always $\geq$ than the sum of out-edges in the reduced graph G^2_θ. Additional edge pruning can be done by the removal of all out-edges from singleton nodes. Since only the first meeting point of the surfers affects similarity scores, such edges can be omitted without changing scores (proof omitted). For example, Figures 2b and 2c depict a partial graph G^2 and its reduced version G^2_θ (faded nodes are dropped).

The similarity scores over G^2_θ, denoted as $s_\theta(\cdot,\cdot)$, are defined as the result of the random surfing computation on the reduced graph. I.e., if $(u,v) \notin V_\theta$ then $s_\theta(u,v) = 0$, else: $s_\theta(u,v) = sem(u,v)\sum_{w:(u,v)\rightsquigarrow(x,x)} P[w]\cdot c^{l(w)}$, where w is a path in G^2_θ and $l(w)$ is its length. We can now provide an alternative way to compute SemSim scores over the graph G^2_θ.

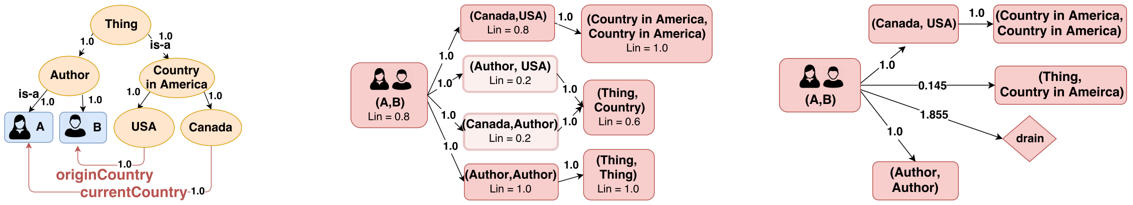
Theorem 3.5. $\forall(u,v) \in V_\theta : s_\theta(u,v) = sim(u,v)$

In conclusion, as we show in our experiments, the size of the graph G^2_θ is considerably smaller than that of G^2 and consequently, computing SemSim over G^2_θ requires exploring far less and shorter paths, hence it is more efficient. However, when considering very large graphs, even this compact representation might still be excessively large. To that end, in the next section, we present an alternative approach that simulates two random surfers directly over G.

4 APPROXIMATED SEMSIM

We next present an alternative approach for an efficient computation of SemSim, based on a solution originally proposed for

[2] In contrast to the meta-path approach [37] that restricts attention only to same-labels paths.



(a) Sample graph G. **(b) All paths from** ***(A,B)*** **in** G^2. **(c) All paths from** ***(A,B)*** **in** G^2_θ.

Figure 2: Example graph G**, its reversed graph** G^2 **and its reduced version** G^2_θ ($\theta = 0.3$, $c = 0.8$).

SimRank [9]. First, we prove that a naïve solution of simply replacing the underlying uniform distribution with the semantic aware distribution leads to a quadratic increase in the sample size. To overcome this, we employ *Importance Sampling*. As employing it still entails a computational overhead, we provide a complementary pruning technique that significantly speeds up computation while maintaining low error rates. We first recall SimRank optimizations while addressing the emerging challenges of their implementation in SemSim, then present our refined framework.

4.1 SimRank's Basic MC Framework

Suppose that we have two reverse walks w_1 and w_2 from the nodes $u, v \in V$, resp., and they first meet at the τ-th step. I.e., the τ-th steps of w_1 and w_2 are identical, but for any $l < \tau$ their l-th steps are different. If the walks do not meet, then $\tau \to \infty$. Given two random walks of length $k-1$, $w_1 = \langle u_1, ..., u_k \rangle$ and $w_2 = \langle v_1, ..., v_k \rangle$, let w denote their *coupled random walk*, where $w = \langle (u_1, v_1), ..., (u_k, v_k) \rangle$. It has been shown in [13] that $simrank(u, v) = \mathbb{E}[c^\tau]$. The authors of [9] suggested a *Monte Carlo* (MC) approximation framework, utilizing this equality, by sampling separated random walks, and approximating the similarity score using the average meeting distance. Specifically, to approximate SimRank, the framework precomputes a set of reversed random walks from each node in G, s.t (i) each set has n_w walks, and (ii) each walk is truncated at step t. Then the estimated SimRank score of u and v is defined as:

$$\frac{1}{n_w} \sum_{l=1}^{n_w} c^{\tau_l}$$

where τ_l denotes the step at which the two walks, sampled from u and v resp., first met, and ∞ otherwise. The space and preprocessing time complexities of this framework are both $O(n \cdot n_w \cdot t)$, and the method takes $O(n_w \cdot t)$ time to answer a single-pair SimRank query.

An important observation underlying SimRank's MC framework is the fact that the probability of a coupled random walk sampled from G^2, can be computed by simply multiplying the two marginal probabilities of the separate walks, sampled from G. Formally, given a coupled walk $w = \langle (u_1, v_1), ..., (u_k, v_k) \rangle$, its probability is:

$$Pr[w] = \prod_{i=1}^{k-1} \frac{1}{|O(u_i, v_i)|}$$

Considering its probability using the separated walks sampled from G, we get:

$$\prod_{i=1}^{k-1} \frac{1}{|O(u_i)|} \prod_{i=1}^{k-1} \frac{1}{|O(v_i)|} = \prod_{i=1}^{k-1} \frac{1}{|O(u_i)||O(v_i)|} = \prod_{i=1}^{k-1} \frac{1}{|O(u_i, v_i)|}$$

That is, in SimRank, one can simply sample walks from each node separately, directly from G, without materializing G^2. We will next show that this is not the case for SemSim, and present a refined sampling method for the SARWs.

4.2 Naïve MC framework for SemSim

Analogously, for SemSim we have: $sim(u, v) = sem(u, v) \cdot \mathbb{E}_P[c^\tau]$, where P is the semantic-aware probability. Note that when using the semantic-aware probability, one can no longer sample the walks separately. To account for the semantic similarity during the sampling process, one must consider *a pair of nodes* in each step. A naïve solution would be to generate a set of SARWs from every node-pair, then directly apply the MC framework. Namely, we can get an adjusted framework for SemSim with the same time complexity and error rate as in SimRank (because the time complexity depends on the number of walks from each pair of nodes, and this solution has the same number, n_w, of walks from each pair). However, in SimRank, the sampling set is of size $O(n_w \cdot t \cdot n)$, whereas this solution requires a much larger sampling set, i.e. $O(n_w \cdot t \cdot n^2)$ walks, as it samples n_w walks for each pair. To avoid this quadratic increase of data storage, we use importance sampling [10].

4.3 IS-based MC framework for SemSim

The core idea of our solution is to sample separate walks directly from G, using a different distribution than the "unknown" distribution P, then, apply importance sampling to estimate the desired similarity scores [10]. For completeness of this paper, we provide a short overview on the importance sampling technique, then present our adjusted framework.

Importance sampling is a general technique for estimating properties of a distribution while only having samples generated from a different one. For a single pair $u, v \in V$, we wish to estimate the expected value of $sem(u, v) \cdot c^{l(w)}$, where w is a coupled random walk drawn from P, i.e.,

$$\mathbb{E}_P[sem(u, v) \cdot c^{l(x)}] = sem(u, v) \cdot \sum P(w) \cdot c^{l(w)}$$

Given n_w samples $w_1, ..., w_{n_w}$ of coupled random walks drawn from P, an empirical estimate of $\mathbb{E}_P[sem(u, v) \cdot c^{l(w)}]$ is:

$$\mathbb{E}_P[sem(u, v) \cdot c^{l(w)}] \approx sem(u, v) \cdot \frac{1}{n_w} \sum_{i=1}^{n_w} c^{l(w_i)}$$

Using a simple manipulation we get:

$$\mathbb{E}_P[c^{l(w)}] = \sum \frac{P(w) \cdot Q(w) \cdot c^{l(w)}}{Q(w)} \approx \frac{1}{n_w} \sum_{i=1}^{n_w} c^{l(w_i)} \frac{P(w_i)}{Q(w_i)}$$

where Q is a distribution s.t $\forall w$ if $Q(w) = 0$ then $P(w) = 0$. Namely, we get an unbiased estimator of the function $c^{l(w)}$ under the distribution P, using samples drawn from Q. In our case, we can only sample separated walks from G (to avoid materializing G^2), while the desired distribution is defined over walks from G^2. Indeed, the expected value of the new estimator is equal to the desired one, that is, for every node-pair u, v we have:

$$sem(u, v) \cdot \mathbb{E}_Q[\frac{P(w) \cdot c^{l(w)}}{Q(w)}] = \tag{4}$$

$$sem(u, v) \cdot \mathbb{E}_P[c^{l(w)}] = sim(u, v)$$

where w is a coupled random walk from u and v, P is the semantic-aware distribution and Q is the proposal distribution. Note that this equality holds for any choice of Q and $sem(\cdot,\cdot)$. Let $\hat{s}_Q(u,v)$ denote the score obtained using the MC simulation with a distribution Q. We can prove the following proposition, that ensures the approximation method has a bounded error (as was proven for SimRank [9]).

Proposition 4.1. *For a node-pair u,v, with at least $1-2e^{-n_w\cdot\frac{\epsilon^2}{2\cdot(1+\epsilon/3)}}$ probability: $|\mathbb{E}[\hat{s}_Q(u,v)]-\hat{s}_Q(u,v)|\leq\epsilon$, where n_w is the number of walks from each node and ϵ is the error rate.*

However, we note that $\mathbb{E}[\hat{s}_Q(u,v)]\neq sim(u,v)$, due to the truncation imposed on the sampled walks. To address this issue, following the analysis provided in [39] we get:

$$|\mathbb{E}[sim(u,v)]-\hat{s}_Q(u,v)|=$$

$$|\mathbb{E}[sem(u,v)\cdot c^{\tau}]-sem(u,v)\cdot Pr[\tau\leq t]\mathbb{E}[c^{\tau}|\tau\leq t]|=$$

$$sem(u,v)\cdot|Pr[\tau>t]\cdot\mathbb{E}[c^{\tau}|\tau>t]|\leq sem(u,v)\cdot c^{t+1}\leq c^{t+1}$$

By Prop. 4.1 and the inequality above, using union bound, we can prove the following.

Proposition 4.2. *For any node-pair u,v and $0<\epsilon,\delta<1$, if $t>log_c(\frac{\epsilon}{2})$ and $n_w\geq\frac{14}{3\epsilon^2}(log(\frac{2}{\delta})+2log(n))$, with at least $1-\delta$ probability: $|\hat{s}_Q(u,v)-sim(u,v)|\leq\epsilon$*

Furthermore, we can prove that the probability of interchanging two nodes in the similarity ranking of a node u converges to zero exponentially in the number of sampled walks n_w.

Proposition 4.3. *For every nodes u,v and v', such that $\delta=sim(u,v)-sim(u,v')>0$ we have:*

$$Pr[\hat{s}_Q(u,v)<\hat{s}_Q(u,v')]\leq 2e^{-\frac{n_w\cdot\delta^2}{2+2\frac{\delta}{3}}}$$

Note, however, that the accuracy of estimation depends on the variance of the estimator, $Var(\hat{s}_Q(u,v))$, which in turn depends on the distribution Q. In general, $Var(\hat{s}_Q(\cdot,\cdot))$ is bounded in $[0,1]$, since the similarity scores are bounded in $[0,1]$. Therefore, we wish to find a distribution Q s.t. (i) the sampling process and probabilities computation can be done efficiently and (ii) $Var(\hat{s}_Q(\cdot,\cdot))$ is minimal. Here, since we do not have a-priori knowledge on either the semantic similarity or the meeting points of coupled walks, we choose Q to be the uniform distribution. See [27] for a discussion of other possible choices.

We are now ready to present Algorithm 1, an MC framework for computing single-pair SemSim scores, assuming, w.l.o.g., that Q is the uniform distribution. Ignore, for now, the lines highlighted in red. At preprocessing, we generate n_w random walks from each node, drawn from Q. Then, when a single-pair query arrives, $sim(u,v)$, we consider the set of coupled random walks starting from u and v. For each coupled walk, if the two walks indeed meet, the probability of their prefix until the meeting point is computed according to the distributions P and Q (lines 10 – 16). Then, the obtained score is added to the total similarity score (line 19). Finally, the estimated score is divided by the number of samples n_w (line 20).

Proposition 4.4. *For every $u,v\in V$, the expected output of Algorithm 1 is $sim(u,v)$, and the average time complexity is $O(n_w\cdot d^2\cdot t)$, where n_w is the number of sampled walks from each node, t is their length and d is the average in-degree in the graph G.*

That is, an additional factor of d^2 is added to our framework's running-time. However, as we will show next, we can compensate for this by employing a pruning-based optimization.

Algorithm 1: IS-based MC framework for SemSim.

```
   Input  : $n_w$ walks of length $t$ from each node, a decay
            factor $c$, and a threshold $\theta$.
1  $sim = 0$
2  if $sem(u,v) \leq \theta$ then
3      return 0
4  for $i$ = 1,...,$n_w$ do
5      Let $w_i$ denote the coupled walk of the $i$-th walks from $u$ and
         $v$
6      Let $k$ be the samllest offset s.t the $i$-th walk from $u$ and from
         $v$ meet
7      if such $k$ exists then
8          Let $\tau(w_i)$ denote the prefix of $w_i$ up to offset $k$
9          Denote $\tau(w_i) = \langle(u_1, v_1), \ldots, (u_k, v_k)\rangle$, $Pw = 1$,
             $Q_W = 1$, $sim_w = 1$.
10         for $i = 1, \ldots, k-1$ do
11             $Pw\cdot = sem(u_{i+1}, v_{i+1})\cdot W(u_{i+1}, u_i)\cdot W(v_{i+1}, v_i)$,
                 $SO = 0$
12             for $I_j(u_i)$ in $I(u_i)$ do
13                 for $I_z(v_i)$ in $I(v_i)$ do
14                     $SO+ = W(I_j(u_i), u_i)\cdot W(I_z(v_i), v_i)\cdot$
                         $sem(I_j(u_i), I_z(v_i))$
15             $Pw/= SO$, $Q_W\cdot = |I(u_i)|\cdot|I(v_i)|$
16             $sim_w = sim_w\cdot\frac{Pw}{Q_W}\cdot c$
17             if $sim_w \leq \theta$ then
18                 break
19         $sim = sim + sim_w$
20 return $\frac{sem(u,v)\cdot sim}{n_w}$
```

4.4 Pruning

Similarly to the idea presented for G^2, we provide a pruning technique for the MC framework, avoiding the similarity computation of low probability walks. Recall that for G^2_θ the suggested technique ensures that scores above a given threshold would not be effected. Here, the approximation error may increase up to a controlled threshold. While in G^2 it is good pruning-wise to use high thresholds, here, if we use too high value the error grows and the scores may become meaningless, thus lower values are advisable. As opposed to the unbiased estimator we devised in the previous section, our pruning technique adds a one-sided additive error to scores. However, as we demonstrate in our experiments, it accelerates the performance significantly, while successfully distinguishing highly similar pairs from the rest.

For a coupled random walk w, let $s(w)$ denote the contribution of w to the similarity score. Since in every estimation we consider n_w coupled walks, it follows that:

$$s(w)=\frac{1}{n_w}\cdot\frac{P[w]\cdot c^{(l(w))}}{Q[w]}$$

Instead of computing the exact score of $s(w)$, our idea is to upper bound it. Concretely, given a coupled walk $w=\langle w_1,..,w_k\rangle$, with a closer look on $s(w)$ we get:

$$s(w)=\prod_{i=1}^{k-1}\frac{P[w_i\rightarrow w_{i+1}]\cdot c}{Q[w_i\rightarrow w_{i+1}]}\leq\prod_{i=1}^{l}\frac{P[w_i\rightarrow w_{i+1}]\cdot c}{Q[w_i\rightarrow w_{i+1}]}$$

where $0<l<k-1$. Namely, $s(w)$ can be bounded in each step in the chain. Therefore, given a threshold θ, we can avoid computing the exact score, if in a certain step, the obtained score is smaller than the bound θ, as from this step on the score can only decrease. Formally, given a threshold $\theta\in[0,1]$ and a coupled walk w, we define $\hat{s}(w)$ as follows:

Table 2: Datasets.

Dataset	Size	Tasks
AMiner	|V| = 0.35M |E| =3M	Entity Resolution
Amazon	|V| = 0.6M |E| =6M	Link Prediction
Wikipedia	|V| = 4.7K |E| =101K	Relatedness
WorNet	|V| = 82K |E| =128K	Relatedness

Definition 4.5 (Approximated coupled walk score). The approximated score of a coupled walk w is defined as:

$$\hat{s}(w) := \prod_{i=1}^{l} \frac{P[w_i \to w_{i+1}] \cdot c}{Q[w_i \to w_{i+1}]} \leq \theta$$

where l is the smallest index this equation holds. If no such l exists, then $\hat{s}(w) = s(w)$.

As in the pruning done for G^2_θ, we can avoid computing scores of all pairs u, v s.t. $sem(u, v) < \theta$ (and again, obtain an error bounded by θ). In such cases, the result score is set to 0.

Consider again Algorithm 1. The highlighted red lines indicate our pruning refinements. In particular, in lines $2 - 3$, similarity scores of node-pairs with low semantic scores are set to 0, and in lines $17 - 18$ we ensure that scores of coupled walks are above θ, and otherwise, are bounded. We can prove that given $\theta \in [0, 1]$, the additional additive error is bounded by θ.

Proposition 4.6. *Given $\theta \in [0, 1]$, the additional additive error of the IS-based MC framework with pruning is bounded by θ.*

To ensure the estimated scores lies in $[0, 1]$, we add the following constraint on θ.

Lemma 4.7. *For every $\theta \in [0, 1 - c]$ and $u, v \in V$, the approximated similarity score $\hat{s}_Q(u, v)$ obtained by Algorithm 1 with pruning lies in $[0, 1]$, where $c \in [0, 1)$.*

This lemma implies that the MC framework with pruning can efficiently capture big differences among similarity scores. But when it comes to small differences, the error of approximation obscures the actual similarity ranking, and an almost arbitrary reordering is possible. However, for many similarity search applications it is sufficient to distinguish between very similar, modestly similar, and dissimilar nodes. In terms of run-time, while the worst-case time complexity remains the same (no pruning is done), our experiments show pruning to be extremely effective in practice, yielding running times on par with SimRank.

Concluding, as mentioned in the Introduction, multiple optimizations techniques have been developed for SimRank based on SimRank's MC framework. Our framework extends for them as well. We discuss this in more details in our technical report [27], providing several examples, and also demonstrate this in our experimental study.

5 EXPERIMENTAL RESULTS

We complement our work with an experimental study, conducted to examine the performance of our measure as well as its usefulness in capturing objects' similarity, compared to measures proposed in previous work.

5.1 Experimental setup

We implemented SemSim in Java 7, and demonstrate its performance using Lin as the integrated semantic measure. All experiments were conducted on a Linux machine with 96GB of memory. We next describe the graph datasets we examined, then detail the parameters setting.

Datasets. We used several graph datasets, commonly used in the literature, which suitably include objects possessing both structural information and semantic meaning, as depicted in Table 2. Unless stated otherwise, all edge weights were set to 1.

AMiner. This graph was extracted from [1], and contains data on 1.5M academic papers. We extracted a weighted co-author graph focused on 30 database conferences. From each paper, we extracted its authors and relevant terms. In addition, we incorporated a domain taxonomy, built by aligning the terms with concepts from DBpedia [5]. The graph includes edges of three types: (1) collaboration edges (with weights reflecting the number of collaborations between two authors); (2) terms-authors edges (where weights correspond to the prevalence of the term in a given author's papers) and (3) taxonomy edges.

Amazon. This dataset was obtained from [18]. It contains 0.5M items from different categories, a domain taxonomy (obtained from Amazon product categorization), and information about co-purchased items. The edge types are: (1) edges between co-purchase items (with weights reflecting the number of times two items were bought together) and (2) taxonomy edges, linking between products to their categories, as well as categories to their super-categories.

Wikipedia. This dataset, obtained from [18], contains 4.7K Wikipedia articles, each is represented by a node. The domain taxonomy was built from Wikipedia categories. The edge types are: (1) links between articles and (2) taxonomy edges.

WordNet. This dataset is the noun sub-part of the lexical base WordNet [26]. The edge types are:(1) part-of relations, the non-hierarchical relations in WordNet and (2) taxonomy edges.

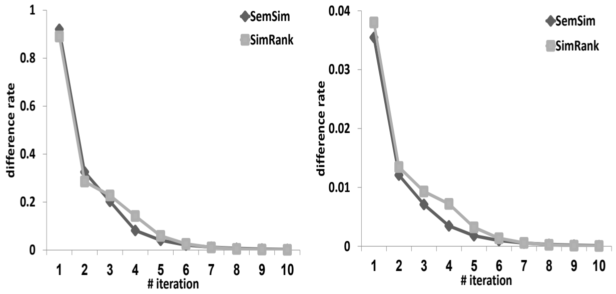
For both AMiner and Amazon datasets, we extracted a smaller versions to be used in the execution of the costly iterative forms of SemSim and SimRank. In AMiner, the small version includes the top 7K authors by number of publications, and in Amazon it includes the top 5K most bought items.

Parameter setting. For all datasets, we found the upper bound on the decay factor c by iterating on all node-pairs u, v computing $N_{u,v}$. We report that in all cases this value was > 0.6, a commonly used value for the decay factor in SimRank [24, 39]. Unless mentioned otherwise, for both SemSim and SimRank we used the following system parameters: The decay factor (c) was set to 0.6, and for the probabilistic framework, a set of 150 random walks of length 15 was sampled from each node. As for the threshold parameter θ used for pruning, we set $\theta = 0.05$. According to our experiments, this choice of the parameters allows for fast execution times, while maintaining negligible error rate.

5.2 Performance Evaluation

We review the performance of SemSim from five aspects: The convergence rate of its iterative form, the size of the reduced graph G^2_θ compared to the full graph G^2, the performance of Algorithm 1, in terms of execution times and error rate and the preprocessing phase.

Convergence. Our experiments validate empirically Prop. 2.4, showing that SemSim converges as fast as, and even faster than SimRank. We measured the average relative and absolute differences between similarity scores at consecutive iterations, for both SemSim and SimRank iterative forms, on different datasets. Results are depicted in Figure 3. Indeed, SemSim converged faster



(a) Avg. relative difference **(b) Avg. absolute difference**

Figure 3: Scores differences in consecutive iterations.

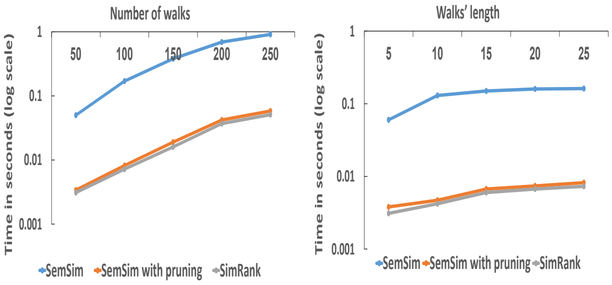
Dataset		G^2	$G^2_\theta, \theta = 0.90$	$G^2_\theta, \theta = 0.95$
AMiner	# nodes	60M	14K	9K
	#edges	2.2B	39M	7.8M
	Avg. # of paths to singletons	17	10	5
	Avg. paths' length	4	3	3
Wikipedia	# nodes	22M	10K	6K
	#edges	10.2B	23.5M	4.7M
	Avg. # of paths to singletons	19	10	6
	Avg. paths' length	5	4	3

Table 3: The size of G^2 and G^2_θ for $\theta = 0.9$ (top ≈ 5K) or $\theta = 0.95$ (top ≈ 1K).

than SimRank, and in all experiments it converged after 5 iteration, i.e., the average (relative and absolute) difference between similarity scores was smaller than 10^{-}3.

Size of G^2_θ. We analyze the effectiveness of the G^2 pruning, demonstrating that when only highly similar objects are of interest (e.g., top-k queries), pruning with high θ values (e.g., 0.9, 0.95) is highly effective, and reduces the size of G^2 significantly. We refer the reader to Table 3, depicting a detailed comparison between the reduced graph G^2_θ (while setting $\theta = 0.9$ and $\theta = 0.95$), and the original graph G^2, constructed from the Amazon and Wikipedia datasets. In addition to the significant reduction in the number of nodes and edges, one can see that the average length of a path and the number of paths leading to singleton nodes (i.e., the number of paths that are considered while computing SemSim) were greatly reduced as well. However, while the measured size of G^2_θ is smaller than G^2 in approximately 3 orders of magnitude, this approach does not trivially scale for immense networks, in which the approximated framework is preferable.

Execution Times. We examine the running time of our MC framework (with and without pruning) as a function of the number of walks, n_w, and the truncation point t, compared to SimRank MC framework. Figure 4 depicts the average measured running times on the Amazon dataset (the results obtained over the other dataset demonstrated similar trends, and thus omitted from presentation). Not surprisingly, without pruning, the average time of SemSim is indeed slower than of SimRank: 0.217 ms and 0.0035 ms for SemSim and SimRank, resp. However, the running times with pruning are significantly faster, becoming close to those of SimRank (in average 0.0038 ms, where $\theta = 0.05$). Additionally, we examined the performance of both measures, using SLING optimization [39] recently suggested for SimRank (described in our technical report [27]), while storing probabilities only for node-pairs with semantic similarity scores >= 0.1. For both measures we achieved a significant improvement in times - 0.00021 ms and 0.00023 ms for SimRank and SemSim resp., with a memory consumption induced by the SLING index of size 1.1GB and 3.2GB, resp.



(a) t is set to 15 **(b) n_w is set to 150**

Figure 4: Average running times for single-pair similarity query.

Dataset		SemSim with pruning $\theta = 0.05$	SemSim	SimRank
AMiner	Pearson's r	0.89	0.91	0.92
	Mean var	0.001	0.001	0.0004
	Max var	0.025	0.027	0.004
	Mean rel. err	0.405	0.397	0.274
	Max rel. err	0.478	0.468	0.364
	Mean abs. err	0.063	0.019	0.018
	Max abs. err	0.080	0.035	0.029

	Mean rel. err	0.366	0.320	0.298
	Max rel. err	0.428	0.399	0.389
	Mean abs. err	0.056	0.020	0.020
	Max abs. err	0.075	0.027	0.025

Table 4: Accuracy of approximation.

Approximation Error. We compared SemSim and SimRank approximated scores to scores computed by their iterative forms, to asses the cost of incorporating semantics. We then evaluated the error of approximation in terms of Pearson's r-correlation (by comparing approximated scores to the ground truth), variance, and error size. We report the error of approximation as measured for the (larger versions of) Amazon and AMiner dataset. In each experiment, we randomly selected 1K node-pairs, and computed the approximated similarity scores in 100 runs (rebuilding the random walks index before each run). The results, provided in Table 4, depict the Pearson's r-correlation values (achieved by comparing the approximated scores to the ground truth ones, obtained by the iterative forms), the (mean and maximal) variance of the estimators, and the (mean and maximal, relative and absolute) errors, as obtained by SemSim (with or without pruning) and SimRank.

As expected, SemSim's mean error is slightly higher than that of SimRank, yet both are in the same order of magnitude (0.366, 0.32, 0.298 for SemSim with pruning, without pruning, and SimRank, resp.). As discussed in Section 5.2, while the error of approximation for SemSim (with and without pruning) is slightly higher than for SimRank, the number of interchanges between the approximated scores and ground truth ones, as measured by the Pearson r-correlation[3], is significantly low and essentially equivalent to SimRank's (with or without pruning). This positive

[3] The Pearson r-correlation measures the "strength" of the linear association between ground truth scores and approximated ones.

result indicates that applying IS does not cause far apart scores to interchange, while maintaining execution times essentially on-par with SimRank.

Preprocessing. We complement the running times experiments by providing details regarding preprocessing time and the space costs of our framework. The offline processing, in which random walks are sampled, took approximately 2.5 minutes (in average over all datasets). While the sampling procedure performed as in SimRank, SemSim requires an additional work due to the semantic similarity measure. Following [11], we processed the taxonomical subpart of the graphs to facilitate constant-time Lin semantic similarity computations at run time. In all cases, the processing time took less 10 minutes. For example: In the Amazon dataset, where the taxonomy contains 2.5M edges, this phase took approximately 7 minutes.

The memory consumption of SemSim's MC framework is prominently due to the random walk index[4]. Additional memory costs for SemSim were due to the Lin semantic measure: storing the IC values and the data structure that allows for a constant time similarity computation (as described in [11]). Overall, the storage size was varied between 5 − 9MB, for all datasets, depending on the size of the taxonomical subpart of the particular graph.

5.3 Quality Evaluation

We examine the usefulness of SemSim compared to an extensive set of alternative measures for assessing node similarity, demonstrating the utility of SemSim when used in typical tasks, in which a similarity measure is required.

We used the following baselines from three common approaches for similarity assessment:

I. Structural-based measures: *SimRank* [13], *SimRank++* [2], a weighted variant of SimRank which ignores semantic information, and *Panther* [43], a random-walks based measure which considers edge weights as well.

II. Semantic similarity measures: *Lin* measure [23], as described in Section 2.2.

III. Measures combining structural and semantic information:. First, we employed *LINE* [38], an ML, node embedding-based similarity measure which accounts for latent semantic relations among the graph nodes. This serves a representative example for the state-of-the-art approach for assessing node similarity. Additionally, we tested *PathSim* [37], a HIN-dedicated similarity measure, which considers edge labels, and *Relatedness* [25] a semantic-aware measure which considers the properties' relating concepts. Last, we employed the *Multiplication* and *Average* competitors, returning the product (resp., average) of independent structural and semantic scores obtained by SimRank and Lin. These measures serve as baselines to our approach that interweaves structure and semantics throughout a recursive computation.

These baselines were examined in typical tasks in which a similarity measure is required: *Term Relatedness*, a problem requiring a measure aware of both semantic and structural knowledge, (tested on Wikipedia and WordNet datasets); *Link Prediction*, in which we used the measures to predict co-purchases in Amazon dataset, and *Entity Resolution* was tested on AMiner dataset, to detect duplication of entities. A ground truth was defined for each task, used to quantitatively evaluate the effectiveness of each competitor.

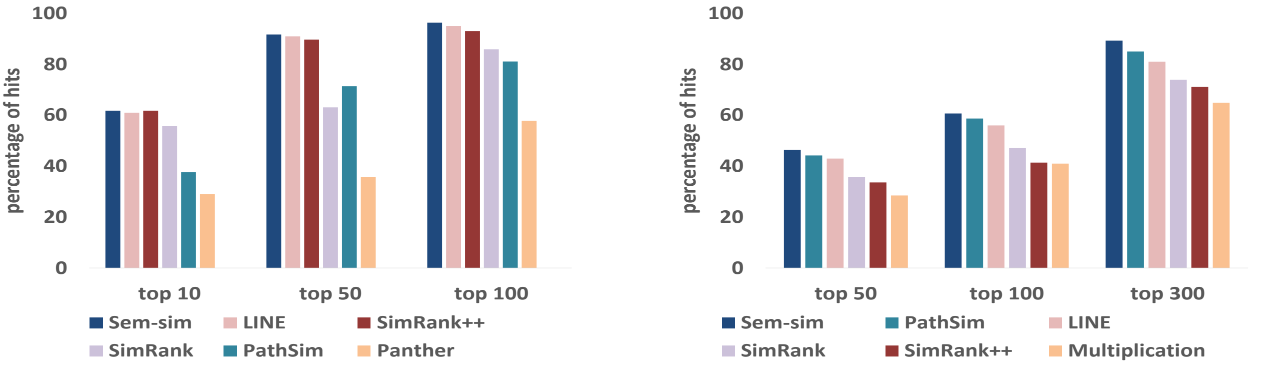
Method	r (Wiki)	p (Wiki)	r (WN)	p (WN)
Panther	0.323	0.0376	0.206	10^{-3}
PathSim	0.293	0.0662	0.332	10^{-3}
Simrank	0.295	0.0641	0.397	10^{-4}
Simrank++	0.296	0.0644	0.395	10^{-4}
Average	0.36	0.0514	0.401	10^{-4}
Multiplication	0.37	0.0508	0.409	10^{-4}
Lin	0.485	0.0015	0.449	10^{-4}
LINE	0.493	0.0001	0.470	10^{-4}
Relatedness	0.510	0.0007	0.488	10^{-4}
SemSim	**0.585**	0.0001	**0.501**	10^{-4}

Table 5: Pearson's r and p-value in the WordsSim-test on Wikipedia (Wiki) and WordNet (WN).

Term Relatedness. Relatedness between terms is a well studied problem that requires a measure aware of both semantic and structural knowledge. To examine the adequacy of SemSim for capturing relatedness, we used two datasets that contain relations between terms: Wikipedia and WordNet. The ground truth was defined by the WordsSim-353 test [8], a public and commonly used benchmark containing pairs of words alongside their *relatedness* scores, as computed by people (e.g. "computer-keyboard" has the score of 0.76). We then compared the scores obtained by each competitor, using the Pearson correlation measure (a commonly used measure to evaluate the accuracy result for this benchmark [25]). We removed pairs of words that were missing in the graph from the benchmark, retaining 40 pairs for Wikipedia and 342 for WordNet. Table 5 depicts the results for all baselines. We note that other corpus-based designated methods were suggested for this task (e.g., [42]), but they require external sources besides the input graph, thus we did not include them in our benchmark. Observe that the structural based measures (e.g., SimRank, SimRank++ and Panther) demonstrate inferior results, as this task greatly relies on the semantic relations among the concepts. Furthermore, naïve semantic measures such as Lin, that perform a rather simplistic similarity comparison (i.e., rely only on the taxonomy "is-a" edges), surpassed both the structural measures, and the the *Average and Multiplication* competitors, yet were outperformed by LINE and the Relatedness measure, which better combine the structural and semantic aspects, and consider all edges in the graph. The Relatedness measure, designated specifically for this task, exceeded the ML-based measure LINE, yet interestingly, it was surpassed by SemSim.

Link Prediction. We next demonstrate how SemSim may be used to predict co-purchases in the Amazon dataset. To compare between different baselines, we omitted 7.5K edges between items from the original dataset, and examined how well the measures can be used to predict those missing links as follows: Given an endpoint of a removed link, we performed a top-k search to find similar nodes to the given endpoint. If, for a given measure, the returned k nodes include the pair endpoint, we counted a "hit", and otherwise a "miss". A similar idea was employed to evaluate similarity search in [43]. The results are depicted in Figure 5(a). For compactness, we omitted measures with particularly low scores. As opposed to the *Relatedness* task, this task relies mostly on structural knowledge, hence structural-based measures (e.g., SimRank++, Panther) outperformed the semantic-based ones (e.g., Lin). Here, LINE was able to outperform most competitors, yet SemSim managed to obtain a slight advantage,

[4] Storage optimization techniques previously developed for SimRank can be directly applied in our settings as well (e.g. [14, 34]).



(a) Link Prediction **(b) Entity resolution**

Figure 5: Prediction in top-k

due to the additional semantic information it accounts for which LINE ignores (i.e., the IC values and the taxonomy relations).

Entity Resolution. Last, we used the similarity measures to identify multiple distinct entries representing the same author (e.g, *Susan B. Davidson* and *Susan Davidson*), or the same term (e.g, *Data structures* and *Data structure*). Using the Levenshtein string distance, we identified 30 pairs representing the same entry (24 term-pairs and 6 author-pairs), and used the baselines to predict duplicate nodes following similar lines to the link-prediction task (i.e., a top-k similarity search). The results are depicted in Figure 5(b), reporting for each baseline the precision in top k, for various values of k, (here again, measures with particularly low were omitted). First, note that the results for all baselines are not particularly high, since information commonly used for entity resolution (such as mail addresses, affiliations, string edit distance, etc.) was not included in the graph. As in the link-prediction task, the structural based measures outperformed the semantic based one (omitted from presentation). This stems from the particular characteristics of the AMiner graph, in which the semantic similarity of all authors nodes is identical (i.e., all authors nodes "is-a" *Author*). Hence, the semantic similarity between authors in this setting is not informative. Here again, the Multiplication/Average baselines demonstrate inferior results. It should be pointed out that PathSim outperforms most competitors, as it is a structural measure that also considers the edge labels, thus accounts for some semantics. However, SemSim managed to get an advantage, even if sometimes marginal, for all tested values of k.

In summery, as demonstrated, SemSim outperformed the competitors in all tasks mentioned above. In some tasks the advantage was marginal compared to the second-best for a specific task, yet we note that the second-best competitor was *different* in each task, illustrating the robustness of SemSim. For the rest of the baselines, results varied depending on the amount of semantics conveyed in the dataset, and of the degree to which the task is semantically complex. To conclude, the experiments indicate that even in cases where only partial semantics is available, SemSim serves as a robust measure and exploits this information to get an edge over the competitors.

6 RELATED WORK

SimRank is a popular measure and its potency was demonstrated in various scenarios [2, 6]. Several extensions that enrich it with more information (e.g. edge weights [2], particular paths [6] or second order walks [41]) were suggested, but they do not make full use of semantics available and thus, as illustrated in our experiments, yield less accurate estimations in semantic-sensitive tasks. Moreover, the optimization technique used in SimRank++ was build on *matrix multiplication* rather than random walks, and consequently, scalability issues were ignored. One of the contributions of this work is an efficient computation scheme, applicable also to several of these variants (e.g. [2, 45]).

As mentioned, a prominent body of work has focused on SimRank approximation techniques. These works are categorized into (a) matrix-based approaches [19], and (b) random walk-based approaches [14, 39]. A recent survey [44] advocates that the latter approach is more scalable, compatible with updates in the graph, and can be trivially parallelized. Therefore, we chose to extend it in accordance with our setting. As mentioned in Section **??**, the contributions of these works are applicable for SemSim, requiring only minor adaptations.

In our experiments we use Lin [23], a simple and effective *Information Content* (IC)-based semantic measure. However, as explained in Section 2, any other measure can be incorporated, given that it satisfies three intuitive constraints. Examples of other applicable semantic measures include: (i) IC-based measures [32], (ii) Edge-counting measures, which use the length of the shortest path between nodes in the estimation of similarity [31], and (iii) Feature-based measures [20, 42]. The former two regard a domain ontology, while the latter usually involves additional sources (e.g. textual corpus [20]).

Heterogeneous Information Network (HIN) is a ubiquitous model for real-world data, as it enables enriching simple graphs with additional useful information [36]. This, however, makes the assessment of node similarity challenging, as HIN paths convey latent semantic information. The majority of existing similarity measures for general networks do not consider all available information in the HIN. Specifically, measures such as [13, 43, 45] focus solely on the network structure, while measures suggested in [23, 32] concern only with the semantic information as implied by hierarchical relations. More recent works propose HIN-dedicated measures [35, 37], advocate considering only meaningful meta-paths between objects. But the choice of appropriate paths is made a-priori, and requires intimate knowledge of the dataset and the specific information needs[5] [22]. In contrast, SemSim is a generic measure that encompasses all available information, and automatically prioritizes meaningful paths.

As opposed to the declarative approach, recent work in the field of *representation learning* [4, 30] suggests *embedding* techniques that discover low-dimensional representations of graph nodes in a vector space. While this approach often outperforms

[5] Otherwise, an average of all paths can be taken, resulting in inferior results.

dedicated similarity measures for HINs (as demonstrated), a key disadvantage is that the results are hard to explain and interpret. Moreover, as we showed, SemSim not only retains its declarative definition but also yields more accurate similarity estimations in multiple tasks.

Incorporating semantic and structural information when determining relations between graph objects has also been proven useful in several related domains. Works in *ontology matching* and *entity resolution* suggest using both taxonomy edges and structural properties of nodes to properly align entities [12, 28]. However, their goal is different, as they aim to identify equivalent representations of the same entity, thus some of the core techniques employed (e.g., string matching) cannot be directly applied for measuring similarity between different objects. It would be interesting to investigate in future work whether SemSim can be employed in such contexts. An example domain where we showed such incorporation to be successful is similarity estimation for images that convey semantics, as we illustrated in [7], a demo that employed SemSim for the retrieval of similar Internet Memes.

7 CONCLUSION AND FUTURE WORK

In this paper we present SemSim, a similarity measure that refines SimRank with semantics, while preserving its intuitive definition and scalable computation. We introduce Semantic-Aware Random Walks, an extension of the traditional notion of random walks, that preserves properties necessary for applying existing SimRank's optimizations. Our probabilistic framework employs Importance Sampling along with an effective pruning technique, and maintains a negligible error rate. Our experiments further demonstrate the quality and robustness of SemSim in multiple practical scenarios, as well as the efficiency of our algorithms.

Several interesting directions are left for future research. First, in practice, information networks are often dynamic and may induce uncertainty, hence it would be important to extend SemSim to such settings. The use of parallelism and compact indexing mechanisms [3, 21], to achieve further computation speedup, are also an interesting direction for future work. Last, we have focused here only on single-pair queries. We intend on developing optimizations facilitating single-source and top-k similarity queries, inspired by [17, 46].

ABSTRACT

Deciding whether a query graph is a subgraph of some other in a very large database of small graphs is a problem of major interest in many application domains. As an example, it arises in the searching for specific molecular substructures in currently available molecular databases, whose sizes may reach levels close to one hundred million. State of the art methods to solve this problem follow a *filter-then-verify* (FTV) paradigm, where an indexing technique is first used in a filtering stage to obtain result candidates and a subgraph isomorphism algorithm is next applied to the candidates in a verification stage to obtain the final result. Among all the available techniques of the state of the art, two of them have demonstrated better performance when applied to large datasets, namely, the GraphGrepSX (GGSX) and CT-Index (CTI). In this paper, three new indexing techniques, one based on GGSX and two based on CTI, are proposed. In particular, Bitmap GGSX (BM-GGSX) leverages the use of bitmaps in the trie structure used by GGSX to achieve performance gains of around 90% in the filtering stage. Column-Wise CT-Index (CW-CTI) exploits a column-wise representation of the fingerprints (bitmaps) used by CT-Index to reduce the filtering times around 80% for small queries (8 edges). Finally, K-Means CT-Index (KM-CTI), constructs a binary tree of bitmaps from the CT-Index fingerprints to reach filtering time reductions of around 70% for medium queries (20 edges) and 75% for large queries (40 edges).

1 INTRODUCTION

Graph database research is a topic to which much attention has been paid by the data management community during the last decade. Two major types of graph databases may be found in real problems. In a first type, the database consists of just one very large graph. This is, for example, the kind of database available in the semantic web. Amongst the required query functionality, many applications need to identify all the instances of a specific subgraph that occurs inside the database graph. This NP-complete problem, known in the literature as *subgraph matching*, is solved through the application of *subgraph isomorphism* algorithms [4, 12, 20, 21, 26, 27].

A second type of database contains a very large number of small graphs. Typical examples of this type of databases are molecular databases. For each molecule recorded in such a database it is recorded, among other properties, its structure, i.e., a small graph whose vertices are atoms and whose edges are bonds between atoms. The current size of these databases is already very large, reaching levels close to one hundred million molecules, like in the PubChem dataset[1], and it is increasing. Among other queries of interests, it is important to provide functionality to find all the molecules whose molecular structure (graph) contains a specific query substructure (subgraph) [5, 6].

Finding all the graphs in a database that contain a specific subgraph is known in the literature as the *subgraph decision* problem. A straightforward strategy to solve this problem is a linear search, i.e., the application of a *subgraph isomorphism* algorithm to each graph of the database. This strategy could be the appropriate for not selective queries that return most of the database graphs. Besides, given its simplicity, it is also straightforward to a obtain parallel implementation following this strategy. However, in the general case, a filter-then-verify (FTV) strategy based on indexing will get much better performance. In FTV approaches, query processing is split in tho stages, namely *filtering* and *verification*. In the filtering stage, an index structure is searched to obtain an initial set of candidate graphs. In the second stage, a subgraph isomorphism algorithm is applied to each candidate to refine the final result. Many FTV methods have been proposed in the literature [2, 3, 8, 15, 20, 24, 25, 28, 29].

Among the proposed FTV solutions, GraphGrepSX (GGSX) [2] and CT-Index (CTI) [15] have demonstrated an excellent performance when applied to large datasets of small graphs, as it is the case of molecular databases. Both of them rely on the encoding, in the index structures used during the filtering stage, of features contained in the graph, such as paths, trees, and cycles. In particular, GGSX generates a trie structure with all the paths contained in each graph up to a maximum length. Each node of the trie represents a specific path and references all the graphs of the database that contain such path, storing also the number of times that the path is repeated in each graph. During the filtering stage, the database trie is used to obtain all the graphs that contain all the paths of the query up to a maximum length, at least the number of times that the path is contained in the query.

The indexing technique used by CTI is completely different. CTI generates a fingerprint (bitmap) for each database graph

[1] https://pubchem.ncbi.nlm.nih.gov/

as follows. First, graph features are extracted. CTI may work with either paths or trees, and with cycles. Each feature of the graph up to a maximum length is extracted, and represented in a canonical string format. A hash function is next applied to each extracted string to obtain integer numbers that range from 0 to the fingerprint length. The bits of the fingerprint located at the positions defined by those integers are set to 1. In the filtering stage, bitmap containment is tested between the query fingerprint and the fingerprint of each database graph.

In this paper, three new FTV solutions are proposed for subgraph search in large databases of small graphs. The paper focus on the filtering stage, improving GGSX and CTI structures and algorithms to obtain filtering time reductions between 70% and 80%, whereas the verification stage of the three techniques relies on the parallel execution in a multi-thread architecture of a improved version of the VF2 [4] subgraph isomorphism algorithm already proposed by CTI [15]. In particular, the main contributions of the present work are summarized as follows.

1. Bitmap GGSX (BM-GGSX) takes advantage of the incorporation of compressed bitmaps in the representation of graph references in the GGSX trie nodes. This enables a drastic reduction of the filtering time (around 90% less than GGSX), maintaining the index size and building time almost unaltered. When compared with the techniques based on CT-Index also proposed in this paper, BM-GGSX offers good response times for medium and large queries, but it is worse for small queries. Besides, BM-GGSX is also much worse in both index size and building time.
2. Column-Wise CT-Index (CW-CTI) adopts a column-wise storage structure for the CT-Index fingerprints, where the same bit position of all the fingerprints of all the graphs are recorded together in a compressed bitmap. During the filtering stage, only the bit positions with a 1 in the query fingerprint have to be accessed, which makes the filtering time dependent on the query size. Regarding index size and building time, CW-CTI gets the best results.
3. K-Means CT-Index (KM-CTI) applies recursively the K-Means clustering method on CT-Index fingerprints to construct a bitmap binary tree that is used to discard sets of fingerprints during the filtering stage. KM-CTI index size and building time is worse than CW-CTI, but better than BM-GGSX. Regarding filtering time, it is competitive with BM-GGSX in medium and large queries, thus it is a good complement of CW-CTI.
4. An extensive evaluation of the performance of all the techniques is undertaken using real databases of molecular graphs of different sizes. A first experiment is conducted to determine the best parameter values to tune the methods. The objective of the second experiment is to test the scalability of the techniques with increasing database sizes. Real databases with sizes ranging from 200000 to one million molecules were built from the PubChem dataset. Notice that those sizes are much larger than even the synthetic datasets used in previous surveys [11, 13].

The remainder of this paper is organized as follows. Section 2 reviews related work, with special attention to the original GGSX and CT-Index methods. The proposed BM-GGSX, CW-CTI and KM-CTI methods are described in detail in Sections 3, 4 and 5, respectively. Section 6 is devoted to the discussion of the evaluation experiments and, finally, Section 7 concludes the paper and outlines some lines of potential future work.

2 RELATED WORK

The current state of the art classifies the subgraph querying problem into two different subproblems. The first one, named *matching problem*, deals with extracting all subgraph isomorphic embeddings of a query graph q in a single graph G. The second one, usually called *decision problem*, is focused in retrieving the ID of every graph g, stored in a given dataset G, which satisfies that the query graph q is a subgraph of g.

The matching problem has been widely studied over the years, and there are several proposals to solve it. As mentioned in the introduction, a subgraph isomorphism algorithm must be applied to ensure that the verified graph contains at least one subgraph that matches exactly the query graph. In [16], the authors provide a performance comparison of six of the most relevant solutions at the time. Among these algorithms, Ullmann [21], VF2 [4], and QuickSI [20] were originally designed for handling small graphs, while GraphQL [12], GADDI [26], and SPath [27] were designed for handling large graphs. The tests were accomplished in four real-world datasets with different size and characteristics, containing two of them multiple and small graphs, and the other two single and relatively large graphs. The study concluded that GraphQL was the only algorithm that completed all the queries, while QuickSI performed the best for both small and large data graphs, even though it was designed for handling small graphs, since the cost of its recursive call is the lowest. The study also concluded that all existing algorithms had problems in their join order selections. Since the survey was published, new algorithms designed for handling large graphs have been proposed [10, 19], showing an improvement in the performance by addressing the issues of matching order selection. Recently, a new approach [1] proposes a new framework to minimize the redundant Cartesian products.

The *decision problem* is typically arising in the scope of applications with big datasets of small graphs. Since this is a NP-complete problem, and datasets contain often a large number of graphs, deciding whether a query graph q is contained in every graph g in the dataset G, by applying one by one a subgraph isomorphism algorithm would be very costly. Due to this, a pruning phase must be undertaken in an early stage of the process in order to select a reasonable number of candidates to be tested with a subgraph isomorphism algorithm. This idea is carried out by the techniques based in the filter-then-verify (FTV) paradigm. FTV techniques rely in building an index of the graph dataset, through decomposing each graph into features (i.e., paths, trees, cycles, etc.), and store them in an appropriate structure (e.g., trie, fingerprints, etc.). The search algorithm of FTV techniques is divided into two different stages. The first stage, called *filtering stage*, aims at obtaining a *candidate set* of graphs. To do this, the query graph q is decomposed into its corresponding features, according to the applied technique, which are used to retrieve from the index a reduced *candidate set* with the graphs that contain all the query features. The *candidate set* is tested finally with a subgraph isomorphism algorithm in the second stage, called *verifying stage*.

A performance comparison of different indexing techniques [3, 20, 24, 25, 28, 29] for subgraph query processing is provided in [11]. The above survey is extended in [13], by including three new algorithms [2, 8, 15] and also by performing an exhaustive performance and scalability study, varying different dataset features such as number of nodes and graphs. According to the conclusions of [13], CT-Index [15] and gCode [29] have the smallest index size. Regarding query processing time, this study concludes that the approaches that build the index with graph features (Grapes [8], GraphGrepSX [2], and CT-Index [15]) outperform the others, and, among them, those that use simpler features (Grapes and GraphGrepSX) obtain the best results. The techniques that show a better scalability are GraphGrepSX, Grapes, and CT-Index. However, Grapes, fails to build an index for large datasets due its memory requirements. Finally, the survey shows that algorithms based in mining techniques (gIndex [24] and Tree+Δ [28]) are only competitive for small datasets.

Recently, two new methods that employ caching on top of existing FTV techniques have been proposed (iGQ [22] and GraphCache [23]). They take advantage of the fact that, in real-world scenarios, most current queries have subgraph or super-graph relations with the future ones. Therefore, they use a caching system with past queries and their answers, including some novel replacing strategies, to improve the performance of existing methods. Another recent work [14], after analyzing both matching and decision problems, it concludes that there exist algorithm specific straggler queries that are challenging only for specific approaches. Based on the above observation, a novel framework is proposed in [14] that leverages parallel execution and query rewriting to achieve better overall performance.

Based on the conclusions of [13], we select GraphGrepSX and CT-Index as the base of the present work, to develop improved indexing structures to solve the decision problem. Notice that our experiments consider databases whose size is between 10 and 20 times larger than those of [13], and, therefore, we discarded Grapes due to its problems with large databases. Finally, the results of the present work may be incorporated in complex query processing frameworks, as the one proposed in [14], which may also leverage in caching techniques [22, 23].

2.1 GraphGrepSX

GraphGrepSX, GGSX for short henceforth, decomposes each graph in paths up to a maximum length p specified by the user. Repeated paths are taken into account. With these paths, in the index building stage, GGSX incrementally builds a trie with a depth equal to the maximum path length p. Each node of the trie represents a path from the root to that node, and stores a list of key-value pairs, where the key represents the ID of a graph in the dataset that contains the path represented by the node, and the value is the number of times that the path appears in the graph. Figure 1 shows an example of a small trie. Each node of the trie records a large list of key-values pairs, although only two of them are depicted in the figure due to space limitations. Thus, as it is represented at the bottom left node of the trie, path “CCC” is contained 4 times in graph G_1, 5 times in graph G_3 and 3 times in graph G_n. Notice that the size of the main structure of the trie is completely dependent on the chosen maximum path length p, which in practice is a short value. On the other hand, the lists of key-value pairs recorded in each node increase their size linearly with the size of the database.

In GGSX, as in any other FTV technique, subgraph query processing is divided into two stages: filtering and verification. In the filtering stage, a trie is built using all the paths of the query whose length is lower or equal to the chosen maximum length p. The number of repetitions of each path is only recorded now for leaf nodes. The filtering algorithm performs a joint breadth-first traversal of query and database tries. When a query leaf node is reached, the number of repetitions r recorded in the query trie node is compared with the list of repetitions recorded in the database trie node, obtaining the set of graphs that contain at least r times the relevant path. Such list of graphs is maintained to be intersected with subsequent lists obtained from the remainder query trie leaf nodes. The final list of graphs resulting from all the intersections is tested, in the verification stage, using the VF2 subgraph isomorphism algorithm.

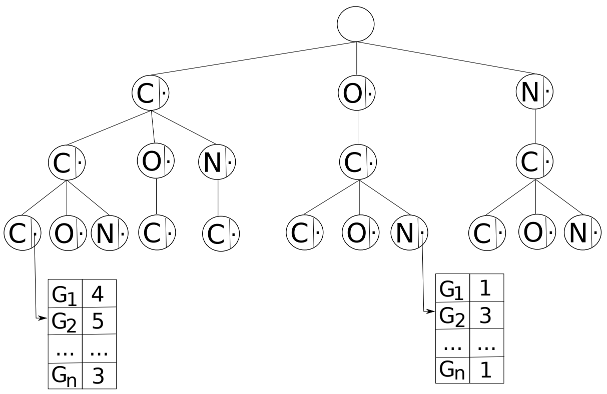

Figure 1: Trie structure used as indexing in GGSX.

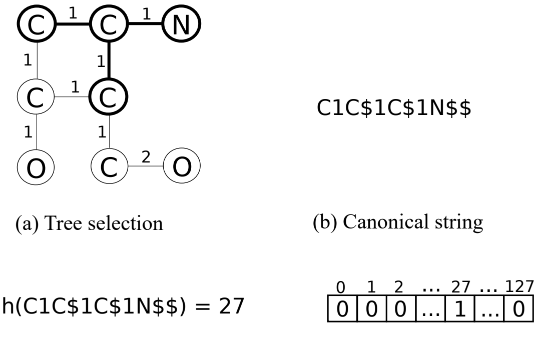
Overall, it is expected that the chosen p value should have an impact in different aspects: the index size (should increase with p), the index construction time (should increase with p), the filtering time (should increase with p) and the verification time (should decrease with p). To the best of our knowledge, there is not, currently, any mathematical model for the determination of the best expected p value for a given dataset, therefore, it has to be chosen based on some benchmarking.

2.2 CT-Index

CT-Index uses a list of bitmaps of a fixed size f called fingerprints, for indexing purposes in the filtering phase. Roughly speaking, either paths or trees, and cycles of each graph are hashed to integers between 0 and f, which are next used to activate bits in the graph fingerprint. To generate all the possible either paths or subtrees, and cycles, a maximum length p is again considered. Figure 2 illustrates the creation of a fingerprint from a given graph. First, all possible features, either paths or trees, and cycles of a maximum length p are generated from the graph. A specific tree contained in a graph is depicted in Figure 2(a). Next, the extracted features are encoded in a canonical string format (see Figure 2(b)). A hash function is next applied to the generated canonical string to obtain an integer. Integer number 27 is obtained from the string in the example of Figure 2(c). Finally, the relevant bit of the graph fingerprint is set to 1 (see Figure 2(d)). It has to be noticed that the hash function may generate the same integer for different features (collisions). Such collision have a negative effect, decreasing the number of pruned graphs in the filtering stage.

CT-Index is also a FTV technique, with relevant filtering and verification stages. In the filtering stage, a fingerprint is obtained for the query graph as described above, using the same fingerprint size 2^f and the same feature maximum length p. The query fingerprint is then tested for bitmap containment with each fingerprint in the index. Bitmap containment is performed by first splitting both fingerprints (query FQ and database FD) into a sequence of long integers (query LQ and database LD), and then



(a) Tree selection

(b) Canonical string

(c) Hashing of feature

(d) Insertion in fingerprint

Figure 2: Fingerprint construction process. In (a) a tree feature is selected. In (b) the feature is transformed into a canonical string. It is hashed in (c). In (d) the hashed value is set in the fingerprint.

Figure 3: Comparison between (a) GGSX and (b) BM-GGSX graph repetitions storage technique.

testing bitmap containment between each pair of (LQ, LD) using bitmap operations $(LQ \wedge LD = LQ)$.

CT-Index uses, in the verification stage, a version of the VF2 subgraph isomorphism algorithm, improved with additional heuristics.

It is noticed that with this technique, two parameters may be chosen to construct the index, namely, the maximum feature length p and the fingerprint size 2^f. It is expected that the maximum feature length should not have an impact either in the index size or in the filtering time. However, increasing p should have a positive impact in the verification time (more graphs should be discarded in the filtering phase) and should have a negative impact in the index construction time (more and larger features have to be processed). Regarding the fingerprint size 2^f, on one hand, it has clearly a negative impact in the index size, and therefore in the filtering time (larger fingerprints have to be compared). On the other hand, however, it should have a positive impact in the verification time, by reducing the number of collisions generated by the hash function.

3 BITMAP GGSX

In this section, an evolution of the GGSX method, called Bitmap-GGSX (BM-GGSX), is explained in detail. We modify the original GGSX method in the following three aspects: i) The labels of the graph edges are now considered, improving the performance of the method in graphs such as molecule structures, whose edges contain bound type information (simple bound, double bound, etc.). ii) Very large compressed bitmaps are now exploited to provide a more compact and efficient representation of the list of pairs (graph id, repetitions) recorded in each trie node. iii) The original VF2 subgraph isomorphism algorithm used in the verification stage was replaced by the parallel execution, in a multi-thread architecture, of the improved version of VF2 algorithm provided by the CT-Index implementation.

The original GGSX method discards the edge labels during the construction of the trie structure. On one hand, this reduces the size of the structure, and as a consequence it reduces also the filtering time. But, on the other hand, it increases the number of candidates for the verification stage, which is in general more costly. To incorporate edge labels in the trie, we modify the structure of the trie nodes by adding a new field that records edge labels. Now, the interpretation of a trie node changes from interpreting it as a graph node of a path, as it is in the original GGSX, to interpreting it as the combination of a graph node with the edge that precedes it in the path. Obviously, given that paths start at node and not at edges, the nodes of the first level of the trie have always null edges. Clearly, this new trie structure has more nodes in each level, enabling the representation of a larger number of different paths of the same length.

In the original GGSX method each node of the tree records a list of pairs (i, r), where i is an identifier of a graph (integer index) that contains the path represented by the trie node and r is the number of times that such path appears in the graph. Such lists are replaced in BM-GGSX by an structure that exploits the use of bitmaps. In particular, each trie node records now an array of bitmaps. The bitmap recorded at the index r of the array has a 1 in its position i if, and only if, the graph with identifier i contains the path represented by the trie node at least r times. Figure 3 illustrates the difference between the representation of graph references and repetition in both GGSX and BM-GGSX. Bitmaps are compressed in BM-GGSX using the Enhanced Word-Aligned Hybrid method [17].

The algorithm of the filtering stage that exploits the above structure is illustrated in Figure 4. First, as it is shown in the left part of the figure, the query is processed to obtain its trie structure. Remember that, now, each node contains a pair of (node label, edge label) and that the number of repetitions in the query trie is recorded only in the leaf nodes. As in the case of GGSX, a joint breadth-first traversal of both query and database tries is performed, obtaining now, for each leaf node of the query trie, the bitmap recorded in the position of the array whose index matches the number or repetitions recorded in the leaf node. This is illustrated in the central part of the figure. Finally, a binary AND operation is performed between all the compressed bitmaps, to obtain the result bitmap, which will contain a 1 in the positions of all the graphs containing, at least the number of times required, all the paths of maximum length of the query.

Notice that, as it is shown in Figure 3, if the bitmap recorded at the index r of the array of a trie node has a 1 in position i, then all the bitmaps recorded in indices lower than r must also have a 1 at position i. This inserts redundant information in the structure, but, as a consequence, it also enables better performance during query processing, since only one of the bitmaps of each candidate node of the trie has to be accessed.

4 COLUMN-WISE CT-INDEX

The index structure used by CT-Index consists of one fingerprint for each graph of the database. Those fingerprints are sequentially generated and recorded during the index construction and sequentially processed during the query evaluation. The collection of all fingerprints might be seen as a matrix, where each

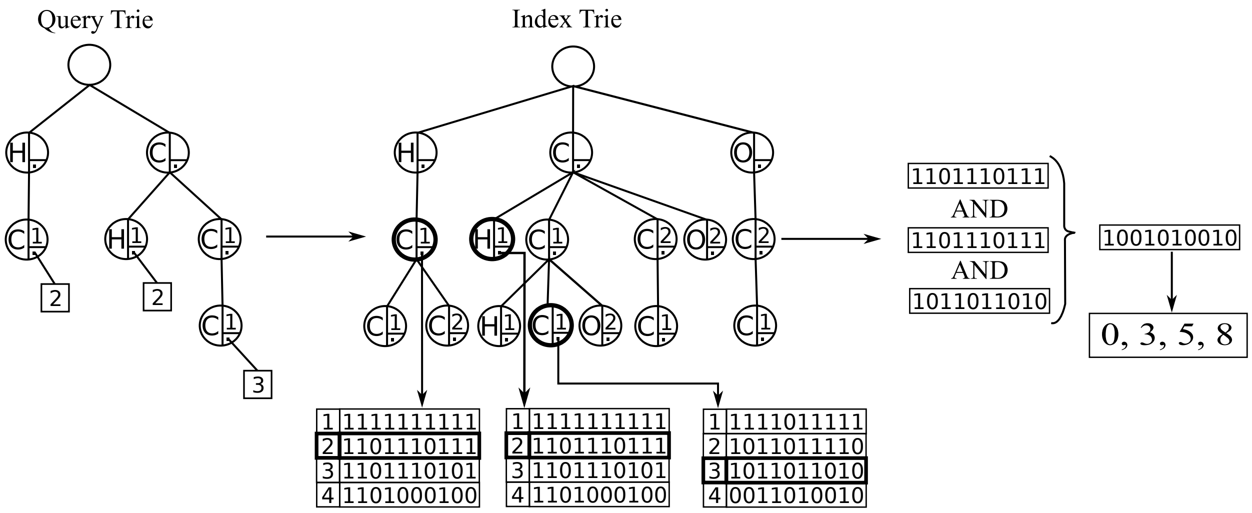

Figure 4: Example of filtering stage in BM-GGSX.

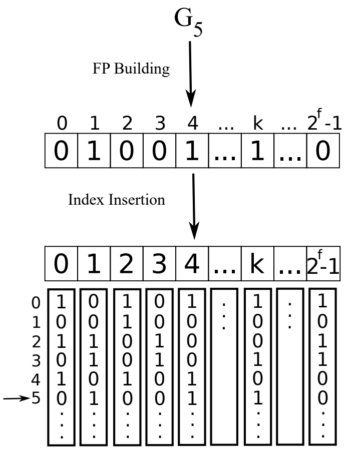

Figure 5: Example of a new graph(ID = 5) insertion in the CW-CTI index.

row is a fingerprint and each column a bit position inside the fingerprint. It is noticed that such matrix is recorded row-wise in CT-Index. The Column-Wise CT-Index, in short CW-CTI, leverages the use of compressed bitmaps by recording and processing the fingerprints column-wise. Thus, if 2^f is the chosen size for the fingerprints, then the index of CW-CTI is a sequence of 2^f bitmaps, such that fingerprint number b has a 1 at position i if, and only if, the fingerprint of molecule number i has a 1 in the position b of its fingerprint. The bitmaps of CW-CTI are much larger than the fingerprints of CT-Index, and they are likely to contain larger sequences of repeated bits, so, they are good candidates for the use of bitmap compression. Enhanced Word-Aligned Hybrid compression [17] is used in the present implementation, which enables the reduction of index size compared to the original CT-Index.

The building stage of CW-CTI is similar to that of CT-Index. Each fingerprint is constructed exactly in the same way, however, now each bit of the obtained fingerprint is appended to the end of each corresponding CW-CTI bitmap. This process is illustrated in Figure 5 for a specific graph G_5.

Figure 6 illustrates the algorithm of the filtering stage of CW-CTI. It is noticed that the algorithm is completely different from the one of CT-Index. First, the fingerprint of the query is obtained in the same way that it is obtained for CT-Index. Next, for each 1 in the query fingerprint, the compressed bitmap recorded at the relevant column of the CW-CTI structure is obtained. Remember that such compressed bitmap contains a 1 for each graph whose fingerprint has a 1 in the same position. Finally, all the obtained bitmaps are intersected to produce the final result of the filtering stage. The result compressed bitmap will contain a 1 for each candidate graph, i.e., each graph whose fingerprint is binary contained in the query fingerprint.

The verification stage in CW-CTI performs a subgraph isomorphism test to the final candidate set of graphs with the improved version of the VF2 used in the CT-Index method, except that now this algorithm is executed in parallel in a multi-thread architecture.

As it was already stated, CW-CTI requires, in general, less storage than the original CTI-Index, due to the use of bitmap compression. The number of candidates obtained from the filtering stage is exactly the same as the one obtained by CTI, however, the verification time should be better, due to the use of a parallel execution of the VF2 algorithm. Regarding the filtering time, it is noticed that the number of binary *AND* operations between compressed bitmaps required is directly determined by the number of 1s in the query, i.e., by the number of different features in the query, which is higher as the query size increases. Therefore, it is expected to behave better with smaller queries.

5 K-MEANS CT-INDEX

In this section K-Means CT-Index (KM-CTI), a new proposal based in the CT-Index method, is described. This new method was constructed with the aim of reducing the number of fingerprint comparisons made in the filtering stage of the CT-Index algorithm. It is reminded that CT-Index performs a comparison between the query fingerprint and each of the fingerprints of the database, therefore, it is expected that the filtering time will increase linearly with the database size. KM-CTI uses a binary tree of bitmaps, where the leaf nodes correspond to the database fingerprints, and parent nodes are constructed by performing

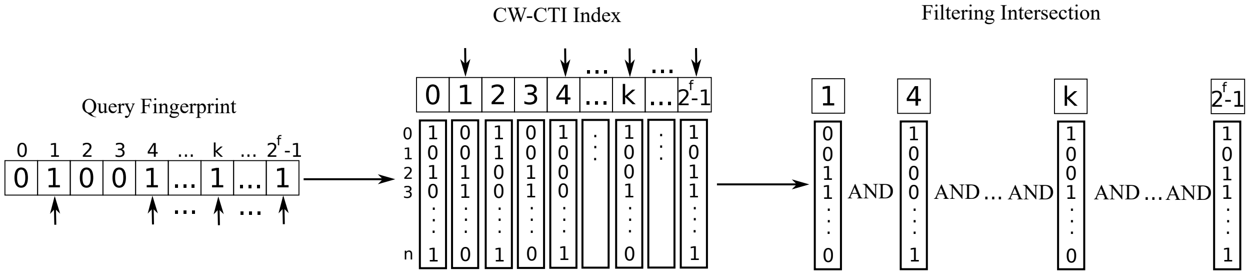

Figure 6: Example of filtering stage in CW-CTI.

the binary *OR* operation between two children. If the comparison between the query fingerprint and a given node of the tree returns false, then the whole branch below the node may be directly discarded. Thus, if the database is large enough, then searching the KM-CTI binary tree will require less comparisons than the number of database fingerprints, reducing the time of the filtering stage.

An example of the use of a KM-CTI binary tree to evaluate the fingerprint of an input query is illustrated in Figure 7. It is noticed that, in the binary tree, all the fingerprints are in the leaf nodes, and each parent node contains the binary *OR* of its children. The query is first compared with the root node. Given that the query is binary contained in the root node, then it has to be compared with each of the two children. The comparison with the left children is positive, and therefore the process has to continue through the left branch. However, the comparison with the right child is negative, therefore the whole branch may be discarded. In the figure, highlighted nodes have been compared with the query and nodes of dark color represent positive results in the comparison. Therefore, in this example, the algorithm performs 7 comparisons (instead of the 8 comparisons that the original CI-Index would require) to select two fingerprint candidates for the verification stage. Again, the chosen algorithm for the verification stage is the VF2 version proposed by the original CT-Index method, and again, this algorithm is executed in parallel in a multi-thread architecture.

The KM-CTI binary tree will offer a good performance if the internal nodes discard large numbers of fingerprints with few comparisons. To achieve this, pairs of bitmaps have to be combined under parent nodes in a way that minimizes as much as possible the number of 1s in those internal nodes. This behavior during the tree construction is achieved in KM-CTI through the application of the K-Means [7, 18] clustering algorithm, recursively to the original set of fingerprints, as it is explained below.

In general, K-Means is used to distribute a set of elements in K clusters, in a way that a given distance measure is minimized between the elements of each cluster. Broadly speaking, the algorithm works as follows. First, K elements of the set are aleatory chosen as centroids of the K clusters. Next, each element is assigned to the cluster corresponding to its nearest centroid. Once the first cluster have been defined, a new centroid is chosen for each cluster by computing some kind of mean between the elements of the cluster. The processes of assigning elements to their nearest neighbor centroid and computing new centroid are iteratively repeated until the elements of each cluster do not change in two consecutive iterations.

To construct the tree, K-Means is first applied with $K = 2$ to the original set of fingerprints, to obtain two clusters. The binary *OR* of the elements of each cluster is computed to obtain the two children of the root node of the tree. This process is recursively repeated inside each cluster until one of the two following conditions hold: i) the elements per cluster reach two (two original fingerprints), ii) the K-Means method cannot subdivide the cluster further. At this stage the tree is completed. The number of fingerprints contained in a leaf node may be greater than two if they are either equal, or so similar that they cannot be subdivided further.

To be able to apply K-Means to sets of bitmaps, both a distance measure and a mean calculation method have to be defined. The number of 1s in common between elements of the same cluster must be maximized, in order to to minimize the 1s in the binary *OR*. If b_1 and b_2 are two bitmaps, then the distance between b_1 and b_2, denoted $d(b_1, b_2)$, is defined in the current proposal as follows.

$$d(b_1, b_2) = \begin{cases} 0, & \text{if } b_1 \subseteq b_2 \lor b_2 \subseteq b_1. \\ count1s(b_1 \oplus b_2), & \text{otherwise.} \end{cases} \tag{1}$$

In the above definition, $b_i \subseteq b_j$ is used to denote that b_i is binary contained in b_j, i.e., $b_i \land b_j = b_i$. The *XOR* binary operation between two bitmaps b_i and b_j is denoted by $b_i \oplus b_j$, and $count1s(b)$ denotes the number of 1s of a bitmap b. It is noticed that the above definition of distance between bitmaps is based on the well-known Hamming distance [9], that counts the number of 1s in the *XOR* of the bitmaps.

The mean calculation method enables obtaining a representative centroid bitmap from all the bitmaps of a cluster. If $zeros(i)$ is the number of 0s in position i of all the bitmaps of the cluster and $ones(i)$ is the number of 1s in position i of all the bitmaps of the cluster, then value of the bit at position i of the mean of the bitmaps of the cluster is 0 if $zeros(i) > ones(i)$ and 1 otherwise.

The calculation of distance and mean between bitmaps if illustrated in Figure 8 through various examples. Note that KM-CTI is an in-memory index, therefore a binary tree is expected to offer better results than trees of higher order. The value of K, however, can be increased to obtain an structure suitable for secondary storage, as it is the B-tree.

As it is the case of the tree based indexes of conventional alphanumerical data, KM-CTI is expected to improve the performance of the sequential search adopted by CT-Index, if the query is selective enough. Therefore, it is expected that KM-CTI will behave better with large query graphs than with small ones.

6 EVALUATION

In this section, the experiments performed and their results are described and discussed. The system setup, datasets and queries are described in a first subsection. Next, the benchmark undertaken to select the appropriate values for maximum path length

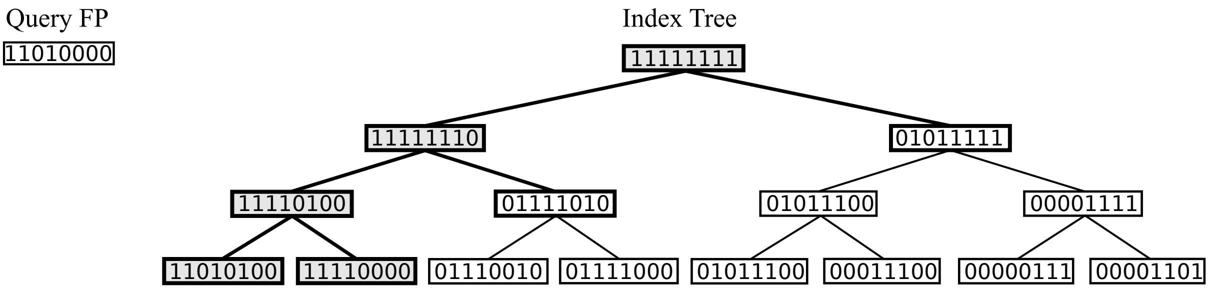

Figure 7: Example of filtering stage in KM-CTI. Highlighted nodes represent the tested ones, and the nodes filled with color are the ones that passed the test.

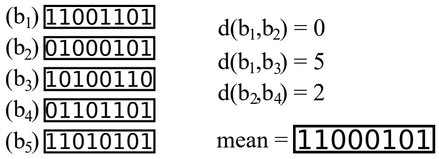

Figure 8: Example of distance and mean measures between bitmaps used in KM-CTI.

and fingerprint size is described. Finally, the last subsection is devoted to the comparison of the performance of the various techniques, with different query and database sizes.

6.1 System Setup, Datasets and Queries

The experiments were performed on a CentOS Linux release 7.4.1708, with 2 processors Intel(R) Xeon(R) CPU E5-2630 v4 (2.20 GHz, 10 cores) and 384 GB RAM. The GGSX implementation in C++ was obtained from the authors, and reimplemented in Java. For the CT-Index method, a jar was obtained from one of the authors website, and then a reverse engineering technique was applied in order to obtain the code. All the new methods were implemented in Java, reusing the above two base implementations. The experiment executions were executed using a JVM with 32GB. The verification stage in BM-GGSX, CW-CTI, and KM-CTI methods was performed using 10 threads.

Two different datasets were used to construct databases of different sizes for the experiments. The AIDS[2] dataset has already been used to evaluate other previous works of the state of the art [2, 8, 13, 15, 16]. It is composed of 42689 graphs, with an average of 45.70 vertices and 47.71 edges per graph. PubChem[3] is a molecular dataset that has currently around 96 million compounds, with an average of 41.40 vertices and 42.16 edges per graph.

In both experiments queries of sizes ranging from 4 to 40 edges (4, 8, 12, 16, 20, 24, 28, 32, 36, 40) were used. For each size, a set of 1000 query graphs was constructed. The construction of the queries was performed in the same way as in previous works [13, 15], by extracting subgraphs from the dataset. For each query, a graph was randomly selected according to a uniform distribution. A vertex of the graph was randomly selected according to a uniform distribution to act as starting point from which to make the query graph grow. From this starting vertex, a random tree was created until the desired size was reached. The size of the query was given by the number of edges of its graph. Two different sets of queries were constructed. One for the AIDS dataset, and the other for the PubChem dataset.

6.2 Parameter Selection

The objective of this first experiment was twofold. The first aim is to test the behavior of the different techniques, including the two methods obtained from the state of the art (GGSX and CT-Index), and the three new proposals, with two different datasets and query sizes. At the same time, the experiment aims at testing the performance of each technique with different values of its parameters, including maximum path length for all the methods and fingerprint size for those based in CT-Index.

The experiment was executed on two databases, AIDS on the one hand and 200k molecular structures obtained from PubChem (PubChem200k) on the other hand. The 1000 queries extracted from each dataset were evaluated 5 times with each method, and the experiment was repeated 4 times at different moments. As it was expected, the size and building time of the BM-GGSX trie structure increases with the maximum path length used. Regarding the CT-Index based methods, the size of the indexes is only affected by the fingerprint size, whereas both fingerprint size and maximum path length have a negative impact on the index building time.

Regarding query response time, Figure 9(a) shows the comparison (subdivided into filtering, query building and verification times) between the original GGSX and BM-GGSX on the AIDS database, using different maximum path lengths and query sizes. As it is shown in the figure, the reduction in filtering time achieved by BM-GGSX is huge (around 90% of reduction in many cases). Due to this large difference, the original GGSX method was not considered for subsequent experiments. As it can be observed in the figure, using different values for the maximum path length (4, 5, 6 and 7) does not show to have a significant impact in the query response time.

Figures 9(b-d) show the query response times obtained with the three CT-Index based methods on the AIDS database, using different maximum path lengths, fingerprint sizes and query sizes. In general, for small queries, where the query building time is not important, a maximum path length higher than 4 offers better results, whereas the fingerprint size does not show a significant impact in the response time. For larger queries, the query building time becomes very significant, due to the few candidates retrieved from such a small database, and therefore, increasing the maximum path length impacts negatively in the response time.

The results of the experiment on the PubChem200k database are illustrated in Figures 10(a-d). In particular, Figure 10(a) shows

(c) Response times (ms) of CW-CTI on Pubchem200k for different fingerprint sizes, maximum tree lengths and query sizes.

(d) Response times (ms) of KM-CTI on Pubchem200k for different fingerprint sizes, maximum tree lengths and query sizes.

Figure 10: Response times of the methods on the PubChem200k database using different parameters.

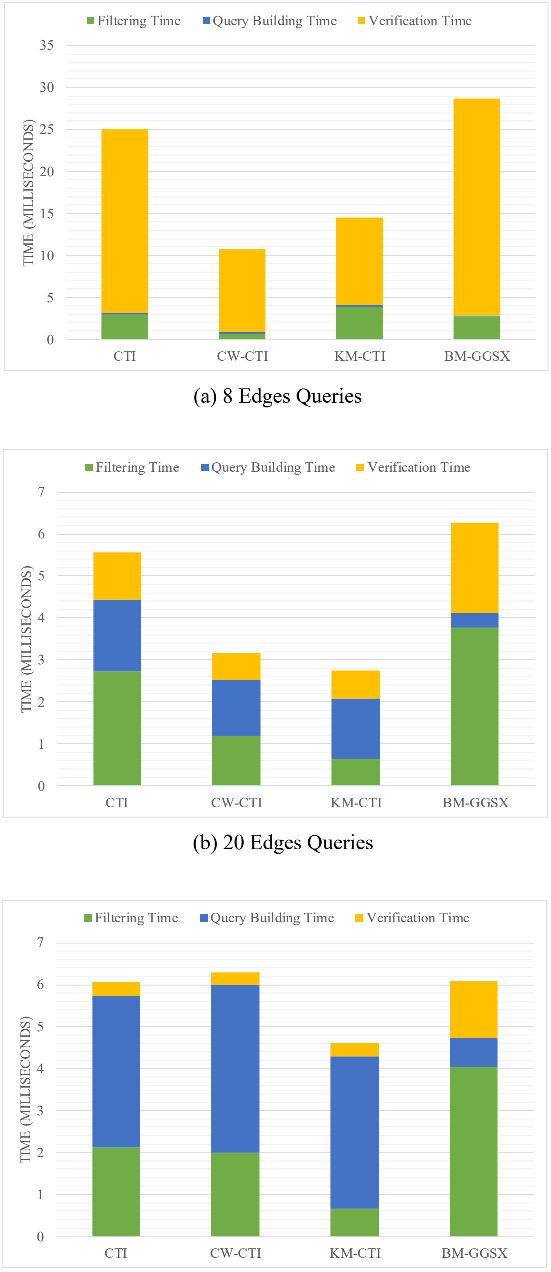
the response times obtained by BM-GGSX, with different maximum path lengths and with different query sizes. As it may be observed, the way the queries are constructed and the the much larger size of the database, compared to AIDS, causes the verification time to be the most significant one in this experiment. Again, the maximum path length does not show a clear impact in the total response time for BM-GGSX. Regarding the methods based on CT-Index (see Figures 10(b-d)), again, significant differences cannot be observed in general between different values of fingerprint size and maximum path length, although maximum path lengths higher than 4 provide slightly better results in most cases.

Based on the above experimental results, and also taking into account relevant decisions made in a previous survey [13], in the subsequent experiment we decided to use the same values of 6 for the maximum path length and of 4096 for the fingerprint size, for all the methods. The objective of such new experiment is the comparison of the performance of all the methods (except the discarded original GGSX), for increasing database and query sizes and the results and relevant discussion are given in the next subsection.

6.3 Performance comparison

In this section, the results of the performance comparison of all the methods (except the discarded GGSX) are discussed. As it was already stated, a maximum path length of 6 and a fingerprint size of 4096 were chosen. First, the results of the experiments described in the previous subsection are used to compare the performance of all the methods on the AIDS database. Figures 11(a-c) show the filtering, query building and verification times of queries of different sizes on the AIDS database. As it may be observed in Figure 11(a), CW-CTI has the best performance for small queries, both in filtering time and also in total response time. This is due to the few intersections between compressed bitmaps that the technique has to perform when few 1s are present in the query fingerprint. However, as the query size increases, the performance of CW-CTI deteriorates, reaching the same performance of CTI for large queries, whereas the performance of KM-CTI improves. The reason is that, with large queries, with many 1s in their fingerprints, many branches of the KM-CTI binary tree of bitmaps will be discarded during the filtering stage.

A second experiment was undertaken to compare all the methods, except the discarded GGSX, with increasing database and query sizes. To achieve this, 10 databases with sizes ranging from 100k to one million graphs were extracted from the PubChem dataset. All the index structures were created for each database, and relevant index size and index building time results were obtained. Figure 12 shows the index size and index building time for each of the analyzed methods. Index building time scales well for CT-Index and CW-CTI methods, growing linearly, and ranging from less than 6 minutes to index 100k graphs, to around 1 hour to index the largest dataset of one million graphs. KM-CTI index building time grows linearly as well, but with a higher slope than CT-Index and CW-CTI methods, being more than 3 times slower for the largest dataset. This is due to the recursive application of the K-Means method to construct the binary tree of bitmaps. BM-GGSX has the worst performance of all methods, taking more time to index 200k graphs, than CT-Index and CW-CTI methods to index one million. Its index building time increases drastically with the size of the dataset, and it needed more than 14 hours to index the largest database of one million graphs.



(a) 8 Edges Queries

(b) 20 Edges Queries

(c) 40 Edges Queries

Figure 11: Performance comparison of the methods on the AIDS database.

Regarding the index size, BM-GGSX performs again the worst among all the proposed methods, showing a big slope in its scalability plot, going from 155MB in the shortest dataset to almost 1.4GB in the largest one. CW-CTI performs the best, scaling slightly better than CT-Index method, due to the use of compressed bitmaps in its storage structure. KM-CTI doubles the space of CW-CTI and CT-Index, due to the additional bitmaps stored in the internal nodes of its binary tree. However, its size is still almost half of that required by BM-GGSX.

(d) 8 Edges Total Query Response Time

(e) 20 Edges Total Query Response Time

(f) 40 Edges Total Query Response Time

Figure 13: Filtering time and total query response time for increasing database and query sizes.

Once the indexes were created, the 1000 queries of each size (from 4 edges to 40 edges), generated for the previous experiment from the 200k PubChem database, were executed four times for each database size, and the whole experiment was repeated three times in different moments. Figures 13(a-c) depict the filtering time of each method. It is reminded that the main contribution of the present work is on the index structures used in the filtering stage of the methods. BM-GGSX and CW-CTI obtain the fastest filtering time for small queries (around 80% of reduction with respect to CTI), as it is shown in Figure 13(a), whereas KM-CTI and CTI offer a similar performance. It is reminded that CW-CTI was expected to behave well with small queries that have few 1s in their fingerprints. On the other hand, small not selective queries, with few 1s in their fingerprints, do not leverage the binary tree of KM-CTI. As the query size increases, CTI and BM-GGSX keep their performance figures, however, CW-CTI and KM-CTI invert their positions. With queries of large sizes, with many 1s in their fingerprints, CW-CTI has to perform many intersections between large compressed bitmaps. On the other hand, KM-CTI behaves better, as many branches of its binary tree are discarded during the evaluation. This situation is clearly shown in Figures 13(b) (around 70% of reduction with respect to CTI) and 13(c) (around 75% of reduction with respect to CTI). These results are completely aligned with those already described for the AIDS database above.

To complete the analysis of the results, the total query response times are shown in Figures 13(d-f). First, looking at the scale of the total response times, it is noticed that, in these databases, contrary to what it was observed with AIDS, the filtering time does not have a great impact on the total response time, since the verification time is the largest one by difference. In spite of this, it is shown how the three methods proposed in the present work outperform the CT-Index method. This is mainly due to the parallel execution in a multi-thread architecture of the VF2 subgraph isomorphism algorithm. It is also noticed that, BM-GGSX, which had the best results in filtering time for all the query sizes, does not show a good total response time for small queries. The reason for this lost of performance is the use of paths as graph features in BM-GGSX, contrary to the use of trees in CT-Index based techniques, which enable the generation of a larger number of different features in small graphs, reducing the number of candidates to verify. The small differences between CW-CTI and KM-CTI are caused by the already mentioned differences in filtering time, since both the effectiveness of their filtering stage and their verification stage are identical.

7 CONCLUSIONS

In this paper, three new FTV methods for subgraph search on large databases of small graphs are proposed. The methods are based on already existing state of the art solutions, namely GGSX and CT-Index, and provide improvements both in filtering and verification response times. BM-GGSX improves GGSX through the incorporation of compressed bitmaps for the representation of graph references, and reaches the best filtering times for all types of queries and the best total response times for medium and large queries. However, it does not improve the bad figures that GGSX already have in both index size and index building time. CW-CTI exploits also compressed bitmap inside a column-wise structure for the storage of the CT-Index fingerprints, obtaining very good performance for small size queries. KM-CTI uses the K-Means clustering method on CT-Index fingerprints to construct a binary tree of bitmaps, which is used during the filtering stage to reduce the required fingerprint comparisons. KM-CTI has very good performance for medium and large queries, with the cost of increasing the index size and building time with respect to the original CT-Index, but keeping the figures much lower than those reached by BM-GGSX. Thus, a combination of CW-CTI and KM-CTI covers all the query sizes with performances either similar of better than those of BM-GGSX, but keeping both index size and building times inside a reasonable range.

Future research work is related to the implementation of the proposed techniques in distributed large scale data processing architectures, to reach reasonable performances for databases of sizes larger than 100 million graphs, as it will be the case of the PubChem dataset in the near future. The results will be incorporated in a query engine prototype that is being implemented in the scope of the NEXTCHROM project, co-funded by the Spanish government and the company Mestrelab Research S.L.

ABSTRACT

Knowledge Graphs (KGs) have become ubiquitous in organisations. They provide a unified and structured model to store the data as well as facilitate effective search to fulfill many complex information needs. One of the ways to query these KGs is to use SPARQL queries over a database engine. Since SPARQL follows exact match semantics, the queries may return too few or no results. Recent works have proposed *query relaxation* where the query engine judiciously replaces a query predicate with similar predicates using weighted relaxation rules mined from the KG. However, the space of possible relaxations is potentially too large to fully explore and users are typically interested in only top-k results, so such query engines use top-k algorithms for query processing. Nevertheless, they still process all the relaxations, many of whose answers do not contribute towards top-k answers. We propose Spec-QP, a query planning framework that speculatively determines which relaxations will have their results in the top-k answers. This reduces the computational overheads and gives faster response times with good precision over top-k results. We tested Spec-QP over two database engines, PostgreSQL and Virtuoso, with two datasets – XKG and Twitter – to demonstrate the efficiency of our planning framework at supporting relaxations in query engines.

1 INTRODUCTION

Knowledge Graphs (KGs) such as YAGO [34], DBPedia [2] and Freebase [5] are typically stored as RDF triples of ⟨s p o⟩ where s is the subject, o is the object and p is the predicate. These RDF KGs are queried using the SPARQL query language, that, at its core consists of *triple patterns*. For example, the following SPARQL query asks: "Which singers also write lyrics and play guitar and piano?".

```
SELECT ?s WHERE{
   ?s 'rdf:type' <singer>.
   ?s 'rdf:type' <lyricist>.
   ?s 'rdf:type' <guitarist>.
   ?s 'rdf:type' <pianist>
}
```

where ?s is a variable to be bound in each of the four triple patterns and to be returned as a result.

Original	Relaxations
<singer>	<vocalist>,<jazz_singer>, <artist>
<lyricist>	<writer>
<guitarist>	<musician>, <instrumentalist>
<pianist>	<percussionist>

Table 1: Example relaxations

An exhaustive list of such singers in the KG can be computed, but users who issue such queries typically want only the top-k, *ranked* results. Ranking of SPARQL query results has been studied before in [9, 12, 23] and they typically make use of *scores* for each triple in the KG[1]. However, a problem that users sometimes face when they issue such queries is *low recall*. That is, the KG may not have k results to return (in some cases, the KG may have *zero* results if one or more of the triple patterns do not have a match). In these cases, it is desirable to *relax* the query by replacing one or more of the triple patterns, while ensuring that the query still reflects the original information need. For example, a possible relaxation of the query above is to change the triple pattern ⟨?s 'rdf:type' <singer>⟩ to ⟨?s 'rdf:type' <vocalist>⟩. Previous works have dealt with doing these relaxations *automatically* and ranking the corresponding results [10, 18, 31, 42]. In this paper, we address the problem of *efficiently evaluating* these relaxed queries.

Query Processing. Processing queries and their relaxations to return top-k results is computationally expensive. For example, assuming that every triple pattern in the above query has relaxations as shown in Table 1, would lead to a total of 48 unique queries (that is, original query, query with one relaxation, query with two relaxations, etc.). A naive method would compute the results to each query, sort the results by score and return the top-k.

Since the user is looking for only top-k answers, the naive method can be improved upon by using top-k operators. They can compute results from *all* relaxations simultaneously, but in a way that drastically reduces wasteful computations. The following two top-k operators can be employed for achieving this: *Incremental Merge* [35] (to process the relaxations for a given triple pattern) and *Rank Join* [19] (to compute (partial) join results in sorted order). However, this method still results in wasted resources, since not all relaxations contribute a result to the top-k.

[*] Work done while at the Max Planck Institute for Informatics.

[1] The scores could be based on confidence values, popularity, etc.

Approach and contributions. In this paper, we propose a *speculative* approach for pruning the space of possible relaxations for a given query. We make use of precomputed statistics about the distribution of scores of the matches to triple patterns in order to speculate on the requirement of relaxations for each triple pattern in order to get top-k results. This precomputed metadata is an approximation of the score distribution of the answers from the corresponding triple pattern and not the actual scores. This is like computing histograms, or simpler. Each of these statistics can be computed in one pass as part of the statistics collection phase of any database system that does cost-based optimization of queries.

When a user enters a query, we estimate the top answer scores that can be achieved using the possible relaxations. This estimation is done using the score distributions and the join cardinality estimates. We then prune those relaxations which are unlikely to contribute triples to the top-k answers based on the top score estimates. This results in reduced computation and faster response times. Also, the amount of search space traversed is reduced by pruning unnecessary relaxations and this, in turn, leads to reduction in memory requirements. The runtime reduction combined with reduced memory requirements leads to an overall improvement on memory consumed over time. This is especially beneficial for servers where the total resource consumption per query is important, as it is inversely proportional to the achievable throughput. Or equivalently, the cost of running the server for a given load is proportional to the cost per query and this improvement implies that the server can run the service with lesser budget in terms of money. *Note that our work is orthogonal to any query engine as it can be deployed on top of any existing RDF-specific database engine.*

Our main contributions are summarized as follows.

i. A model for the score distribution of individual triple patterns.
ii. A technique to estimate the scores of answers to a query using the above model and using it to predict the presence of answers from each triple pattern's relaxations in the top-k.
iii. Pruning the space of relaxations to achieve significantly faster response times while maintaining high accuracy, thereby aiding *cost-effective* exploration of KGs.
iv. Thorough experimental evaluation of the proposed technique over two database engines – PostgreSQL and Virtuoso – with two real world datasets to demonstrate its efficiency over the baseline.

Organisation. The rest of the paper is organised as follows: section 2 introduces useful definitions and explains the top-k operators based query processing approach. Section 3 outlines Spec-QP, the proposed speculative approach to query planning and its execution. Section 4 discusses the experimental results. Section 5 lists the related work and finally section 6 concludes the paper with future work directions.

2 PRELIMINARIES

This section introduces some preliminary definitions that will be used henceforth.

Definition 2.1. **Knowledge Graphs (KGs)**
Given a set of entities $\mathbf{E}$ and predicates $\mathbf{P}$, a triple t is a tuple $t = \langle \mathtt{s\ p\ o} \rangle$ such that, $t \in \mathbf{E} \times \mathbf{P} \times \mathbf{E}$, $\mathtt{s} \in \mathbf{E}$, $\mathtt{p} \in \mathbf{P}$ and $\mathtt{o} \in \mathbf{E}$. Here, s is called the "subject", p is the "predicate" and o is the "object" of the triple t. Each triple is associated with a score, denoted by $S(t)$. These scores represent confidence values or popularity of the triples as previously studied in [9, 12, 23]. A set of such tuples can be represented as a graph, which we call a Knowledge Graph, $\mathbf{KG} \subseteq \mathbf{E} \times \mathbf{P} \times \mathbf{E}$.

Definition 2.2. **Triple pattern query**
A triple pattern is of the form $q = \langle \mathtt{SPO} \rangle$, where S, P and O could either be entities or predicates from the KG or variables. Variables are always prefixed with a question mark. A triple pattern matches any triple in the KG having the same values in the designated field. The variables are then bound to the corresponding values in the triple. A triple pattern query is a set of triple patterns, $\mathbf{Q} = \{q_1, q_2, ... q_n\}$.

Definition 2.3. **Answer for a Triple pattern query**
Given a triple pattern query $\mathbf{Q}$ and a KG, an answer for the query, denoted by A, is a mapping of the variables in $\mathbf{Q}$ to values in the KG such that the application of this mapping to each triple pattern $q_i \in \mathbf{Q}$, denoted $A(q_i)$, results in a triple in the KG. The set of all the answers to a query is denoted by the set, $\mathbf{A}$. That is,

$$\mathbf{A}(q_i) = \{A(q_i) : A \in \mathbf{A}\} \tag{1}$$

Definition 2.4. **Score of an answer**
The relative score of a triple t which matches the triple pattern q is denoted by $S(t|q)$ and is computed as follows:

$$S(t|q) = \frac{S(t)}{\max\limits_{t_i \in \mathbf{A}(q)} (S(t_i))} \tag{2}$$

The value ranges between 0 and 1. The score of an answer A to a query $\mathbf{Q}$ is the aggregation of the relative scores of the triples resulting from applying the answer mapping to each triple pattern q_i in the query. That is,

$$S(A|\mathbf{Q}) = \sum_{q_i \in \mathbf{Q}} S(A(q_i)|q_i) \tag{3}$$

The triple and answer scores have been studied previously in [10, 18, 31, 42].

Definition 2.5. **Weighted relaxation rule**
A weighted relaxation rule r is a triple $r = (q, q', w)$ which implies that triple pattern q can be relaxed to q', and $w \in [0, 1]$ denotes the reduction in scores of the triples matching the relaxed triple pattern. Automatic computation of relaxations and the corresponding weights have been studied in [10, 42].

For example, ⟨?x 'rdf:type' <singer>⟩ could be relaxed to ⟨?x 'rdf:type' <vocalist>⟩ with a weight of 0.8, i.e., r = (⟨?x 'rdf:type' <singer>⟩, ⟨?x 'rdf:type' <vocalist>⟩, 0.8).

Definition 2.6. **Relaxed Query**
Given a query $\mathbf{Q}$ and a relaxation $r = (q, q', w)$, we say that r applies to $\mathbf{Q}$ if $q \in \mathbf{Q}$. The result of applying r to $\mathbf{Q}$ is a new query $\mathbf{Q'} = (\mathbf{Q} \setminus q) \cup q'$ called the relaxed query. The relaxed query so obtained can further be relaxed by relaxing any of $\mathbf{Q'} \setminus q'$ triple patterns. The score of an answer A obtained through relaxation r applied to a query $\mathbf{Q}$ is equal to $w \times S(A|\mathbf{Q'})$.The score is reduced further for each subsequent relaxation in a similar manner. Since the same answer could be obtained from multiple relaxed queries, the score of an answer A with respect to the original query and a space of possible relaxations is defined as the maximum score obtained through any (relaxed) query,

$$S(A) = \max_{\mathbf{Q'}}(w \times S(A|\mathbf{Q'}))$$

, where $w = 1$ for the original query, $\mathbf{Q}$.

2.1 Non-Speculative Query Processing (NSpec-QP)

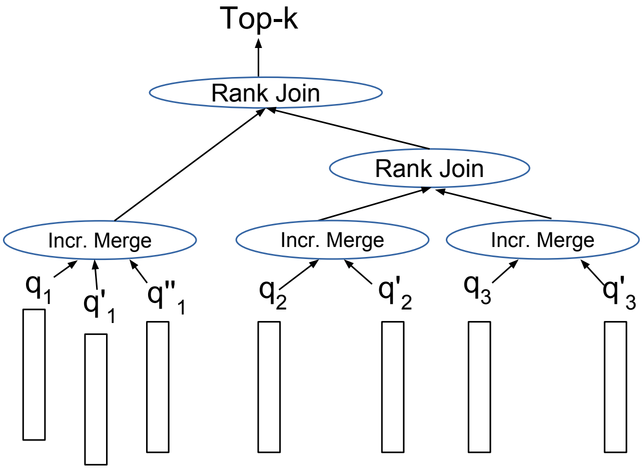

Figure 1: Query plan generated by NSpec-QP for the query Q = $\{q_1,q_2,q_3\}$. One incremental merge operator is required for each triple pattern and its relaxations. A rank join operator takes in two sorted lists and produces a ranked list of (partial) answers from the join.

As mentioned in the Introduction, we can compute results from *all* relaxations simultaneously using two top-k operators: *Incremental Merge* [35] and *Rank Join* [19]. The execution strategy is essentially a variant of the Fagin's NRA algorithm [11]. It computes the exact top-k as it computes all applicable relaxations. It has been used by systems supporting relaxations such as TriniT [42].

Given the query Q = $\{q_1,q_2,q_3\}$, and the relaxations, $r_1 = (q_1,q'_1,w_1), r_2 = (q_1,q''_1,w_2), r_3 = (q_2,q'_2,w_3)$ and $r_4 = (q_3,q'_3,w_4)$, Figure 1 shows the query plan generated using this approach. Incremental Merge is used to efficiently scan the list of matches to a triple pattern and all its relaxations to output only one merged list sorted in descending order of scores. Each of the three incremental merge operators in the example takes as inputs the sorted lists of matches[2] for each triple pattern, q_1, q_2 and q_3 and their relaxations, each multiplied by their relaxation weights. Each of them outputs a combined sorted list of triples for each triple pattern along with its relaxations. The rank join computes a join of the two sorted inputs in an incremental manner until enough results have been produced, while minimising the number of answers read from each list to get top-k answers. This helps avoid computing the entire join and then sorting over it. The inputs for Rank Joins are either the outputs of Incremental Merges or Rank Joins. Both operators use priority queues for already seen answers and maintain upper bounds to estimate scores of other answers that can be obtained by reading further into the lists at any given point. This avoids accessing entire lists of (partial) answers and aids early termination.

However, the top-k operators still process relaxations from *all* the triple patterns, many of which do not contribute triples towards the top-k answers. Our technique aims to eliminate this inefficiency.

3 SPEC-QP – THE SPECULATIVE FRAMEWORK FOR OPTIMIZING QUERY PLANS

We propose Spec-QP, a speculative query planning framework which speculates the useful relaxations for a query. It uses a predictor to predict whether the relaxations of a triple pattern in a query are likely to be required for producing the top-k answers. We eliminate the relaxations for those triple patterns which are predicted to be not required. The predictor uses an expected score estimator to estimate the expected scores at given ranks for a (relaxed) query and then, predicts the requirement of relaxations of a triple pattern for getting top-k answers based on the estimates. The estimator is based on precomputed statistics about the distribution of the scores for triple pattern matches. We first describe the estimator and then give details of the speculative planning approach.

3.1 Expected score estimator

The expected score estimator is based on order statistics and estimates the expected scores at given ranks for the original as well as relaxed queries. These are used by the query planner to predict the presence of answers from a relaxation in top-k.

The m matching triples for a triple pattern, q_i, have scores represented by the independent and identically distributed (i.i.d.) random variables $X_{i1},X_{i2},...,X_{im}$, each with a common distribution, $f_i(x)$. Here, $f_i(x)$ is the probability distribution for the scores of the answers for a triple pattern (or relaxation), q_i, from the *KG*. The cumulative distribution function (cdf) is represented by $F_i(x)$. The set $\{X_{i1},X_{i2},...,X_{im}\}$ is a sample of size m taken from the distribution $F_i(x)$. The set of the observed values of answer scores $\{x_{i1},x_{i2},...,x_{im}\}$ of random variables $\{X_{i1},X_{i2},...,X_{im}\}$ is called a realization of the sample. $X_{i(1)},X_{i(2)},...,X_{i(m)}$ are random variables resulting from arranging the values of each of $X_{i1},X_{i2},...,X_{im}$ in increasing order, and $X_{i(j)}$ is called the j^{th} order statistic.

Given these random variables and their distributions, we need to estimate the score distribution for the answers of the query, Q. $X_{Q1},X_{Q2},...,X_{Qn}$ are the random variables representing the scores of the n answers to the query, Q (possibly composed of a single triple pattern). $X_{Q(1)}$ is the first order statistic corresponding to the lowest scoring answer among all the n answers of Q, and $X_{Q(n)}$ is the n-th (or largest) order statistic corresponding to the highest scoring answer (ranked 1). A relaxed answer would appear in top-k only when its expected highest score ($X_{Q'(n')}$) amongst its n' answers exceeds the expected k^{th} highest score of the original query ($X_{Q(n-k+1)}$[3]). In order to compute the expected value at a given rank, we use the result given in [7]:

For i.i.d. random variables, $X_1,X_2,...,X_m$ each with a common distribution, $f(x)$, the expected value of i^{th} order statistic, $X_{(i)}$ can be approximated as $E(X_{(i)}) \approx F^{-1}(\frac{i}{m+1})$ where $F(x)$ denotes the cdf and m is the size of the sample.

Using this, the expectation of $X_{Q(i)}$ can be approximated as $E(X_{Q(i)}) \approx F_Q^{-1}(\frac{i}{n+1})$ where $F_Q(x)$ denotes the cdf of the scores for the answers to the query, Q and n is the no. of answers of Q .

We now give the details of the construction of the probability density function (pdf) of these random variables.

[2] Recall that each triple is associated with a score.

[3] Note that it is $n - i + 1$ and not i since the n^{th} order statistic represents the highest value with rank 1.

3.1.1 Score Distributions for the matches to Triple Patterns: For every triple pattern q_i in the *KG*, we store the following 4 precomputed statistics about the scores $\boldsymbol{\sigma^i}$ of the matching triples:

- m_i: the total number of triples matching the triple pattern.
- σ_r^i: the score of the answer at rank r where r represents the rank within which 80% of the score mass is contained for the triple pattern matches.
- S_r^i: the cumulative score of the answers over all the ranks 1 through r.
- $S_{m_i}^i$: the cumulative score of the answers over all the ranks 1 through m_i.

We now estimate the score distribution for answers to triple pattern q_i. [4] $f_i(x)$ and $F_i(x)$ are used to denote the pdf and cdf respectively.

The pdf can be modelled as a 2-bucket histogram in the following way:

$$f_i(x) = \frac{S_{m_i}^i - S_r^i}{S_{m_i}^i} \frac{1}{\sigma_r^i} \text{ for } 0 \le x < \sigma_r^i$$
$$\frac{S_r^i}{S_{m_i}^i} \frac{1}{1 - \sigma_r^i} \text{ for } \sigma_r^i \le x \le 1$$

This pdf gives us the following cdf:

$$F_i(x) = ax \text{ for } 0 \le x < \sigma_r^i$$
$$bx + c \text{ for } \sigma_r^i \le x \le 1$$

where

$$a = \frac{S_{m_i}^i - S_r^i}{S_{m_i}^i} \frac{1}{\sigma_r^i} \text{ and } b = \frac{S_r^i}{S_{m_i}^i} \frac{1}{1 - \sigma_r^i}$$
$$\text{and } c = \frac{S_{m_i}^i - S_r^i}{S_{m_i}^i} - \frac{S_r^i}{S_{m_i}^i} \frac{\sigma_r^i}{1 - \sigma_r^i}$$

Our technique depends on statistical estimates – specifically, what the score of the k^{th} result is for a specific (original) query. This estimate can be made as accurate as possible, provided sufficient space and time are available. At one extreme, we can assume uniform distribution for the score of a triple pattern and at the other, we could consider every single data point (the actual distribution). In particular, if we had every single data point as a single-bucket histogram, that would then give us 100% accuracy on the k^{th} score. But this would be no different from actually computing the result. Our solution of 2-bucket approximation strives for the sweet spot on this spectrum and is based on the fact that even though datasets are different, their score distributions typically follow a power law distribution – a "fat" head, and a "long" tail. The narrow and tall bucket represents the interval which has 80% of the score mass. The longer bucket represents the long tail having only 20% of the score mass.

3.1.2 Score Distribution for the Triple Pattern Query: The score of an answer for the triple pattern query is the sum of the scores of the individual triples in the answer. Since each triple is contributed by one triple pattern in the query and we have estimates for their scores, we can estimate the scores for answers to the query using the following approach.

```
Input: The query $\mathbf{Q} = \{q_1, q_2, ...q_n\}$.
Output: The query plan, QP
QP ← $\{\{\mathbf{Q_1}\}\}$, where $\mathbf{Q_1} = \mathbf{Q}$
$f_{\mathbf{Q}}(x) \leftarrow f_1 * f_2 * .. * f_n(x)$
Get $E_{\mathbf{Q}}(k)$ from "expected score estimator".
for $q_i \in \mathbf{Q}$ do
    $q_i' \leftarrow$ top-weighted relaxation for $q_i$
    $\mathbf{Q'} \leftarrow \mathbf{Q} - \{q_i\} \cup \{q_i'\}$
    $f_{\mathbf{Q'}}(x) \leftarrow f_1 * f_2 * ... * f_i' * .. * f_n(x)$
    Get $E_{\mathbf{Q'}}(1)$ from "expected score estimator".
    if $E_{\mathbf{Q'}}(1) > E_{\mathbf{Q}}(k)$ then
        QP = $\{\{\mathbf{Q_1}\} - \{q_i\}, \{q_i\}\}$
    end
end
return QP
```

Algorithm 1: PLANGEN generates the query plan.

Let us assume our triple pattern query, $\mathbf{Q} = \{q_1, q_2\}$. $\{X_{11}, X_{12}, ..., X_{1m}\}$ represents the m triples matching q_1 and $\{X_{21}, X_{22}, ..., X_{2m'}\}$ represents the m' triples matching q_2. The scores for triples matching these triple patterns have the distributions $f_1(x)$ and $f_2(x)$ respectively, as defined earlier. The scores of **Q**'s n answers are represented by the random variables $X_{Q1}, X_{Q2}, ..., X_{Qn}$. Each of these is a sum of two random variables, one from $\{X_{11}, X_{12}, ..., X_{1m}\}$ and another from $\{X_{21}, X_{22}, ..., X_{2m'}\}$. The pdf for the sum of the random variables is given by the convolution of the two individual pdfs, $f_1 * f_2(x)$. Hence, the pdf for the scores of the answers to the query is given by the convolution of the pdf's of the scores for matches to the constituent triple patterns. The resulting pdf is a multi-piece-wise linear function. Given the number of results in the combined distribution, $n = m_{12}$, we can estimate σ_r^{12}, S_r^{12} and S_n^{12} using the expected score computation from order statistics. This again results in a two-bucket histogram for the distribution of the scores of the answers to the query. For the computation of m_{12}, we use the estimates for join selectivity[5], ϕ_{12} as $m_{12} = m * m' * \phi_{12}$. For three or more triple patterns, we repeat the above process the required number of times to get the final histogram representing the score distribution for answers to the query.

3.1.3 Score prediction. Once we have constructed the pdf and cdf representing the scores for the answers of a given query, we can estimate the expected score, $X_{Q(n-i+1)}$ at a given rank i as $E(X_{Q(n-i+1)}) \approx F_Q^{-1}(\frac{n-i+1}{n+1})$ where $F_Q(x)$ denotes the cdf of the query answer scores and n is the no. of answers for **Q**. Given these estimates for scores at various ranks, we now generate the query plan.

3.2 Query Planning

Query Plan: Given a query **Q**, a query plan consists of subsets of triple patterns $\mathbf{Q_1}, \mathbf{Q_2}, ..., \mathbf{Q_s}$ where

i. each $\mathbf{Q_i}$ consists of one or more triple patterns from **Q**,
ii. the $\mathbf{Q_i}$'s are pairwise disjoint, and
iii. the union of $\mathbf{Q_i}$'s equals **Q**.

For example, a query plan for the query $\mathbf{Q} = \{q_1, q_2, q_3\}$, will be $\{\{q_1, q_3\}, \{q_2\}\}$. The singletons correspond to the triple patterns which require relaxations.

[4] Note that the ranks will not be explicitly reflected here, it is just the distribution of the answer score values from which each score in $\{X_{i1}, X_{i2}, ..., X_{im}\}$ is assumed to be independently sampled.

[5] Traditional database systems use multiple heuristics to estimate join selectivity. For the purpose of this work, we have taken exact join selectivity values.

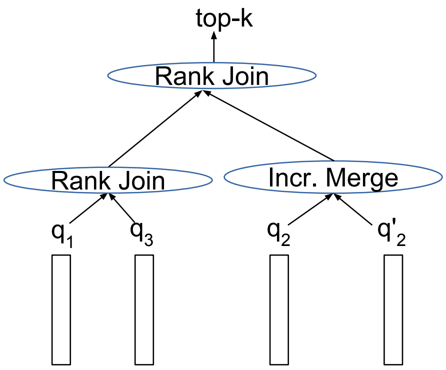

Figure 2: Query Plan when Q = $\{q_1, q_2, q_3\}$ and only q_2's relaxations are predicted to be in top-k. Only q_2 requires an incremental merge. q_1 and q_3 are joined using a rank join over the sorted answer lists for each of them. One rank join is required to join these results.

3.2.1 Query plan generation. The key task in the planning approach is to identify the triple patterns whose relaxations do not contribute towards the top-k answers. We save on computations over such triple patterns by never processing their relaxations. For each triple pattern, only the top-weighted relaxation has the highest top score due to normalization of scores as per Definition 2.4, i.e, the top score from each relaxation is equal to its weight. Hence, we need to check only the top-weighted relaxation for each triple pattern for its potential to contribute answers towards top-k.

Given a query **Q** and the score distribution for each triple pattern, the query plan is generated as outlined in Algorithm 1. PLANGEN first predicts the requirement of relaxations for each triple pattern. For prediction, the query planner uses the "expected score estimator" described in Section 3.1, which gives estimates of the expected scores at k^{th} rank for the original query, $E_{\mathbf{Q}}(k)$ and top rank for the highest weighted relaxed query, $E_{\mathbf{Q}'}(1)$ (for a given triple pattern at a time). If the topmost score from the relaxed query obtained by relaxing a given triple pattern exceeds the k^{th} score from the original query, it predicts that the triple pattern's relaxations are required. Note that our estimator takes into account join score distributions and join cardinalities for estimating the expected score for a given query.

The query plan, **QP** returned by PLANGEN will have at most one subquery, $\mathbf{Q_1}$ of size > 1, called the "join group" (non-relaxed triple patterns), the rest will be only singletons (triple patterns to be relaxed).

3.2.2 Query Execution. Given a speculative query plan **QP** = $\{\mathbf{Q_1}, \mathbf{Q_2}, .., \mathbf{Q_s}\}$ with s subsets generated by the speculative query planner, we execute it in the following manner.

(1) The join group, $\mathbf{Q_1}$ is executed as (left-deep) rank joins over the answer lists (sorted by score) for each triple pattern. Note that, none of the triple patterns in this group are relaxed.
(2) The singletons are processed by Incremental Merge operator for each.
(3) Rank joins are performed over the join group and singletons.

Figure 2 illustrates this approach for the query **Q** = $\{q_1, q_2, q_3\}$, when we predict that only q_2 needs to be relaxed. The query plan to be executed is $\{\{q_1, q_3\}, \{q_2\}\}$. We use a rank join to compute the join between sorted lists of matches for q_1 and q_3 and require incremental merge only for q_2 and its relaxations. One rank join is required to join these results. The equivalent NSpec-QP plan for this query will be $\{\{q_1\}, \{q_2\}, \{q_3\}\}$, i.e., all triple patterns occur as different subsets and each of them are processed by incremental merges followed by rank joins over all these incremental merges (refer Figure 1).

4 EXPERIMENTAL EVALUATION

This section discusses the experimental evaluation performed for demonstrating the performance of the speculative planner.

4.1 Setup

Baseline. We compare Spec-QP with the NSpec-QP system (refer Section 2.1) which involves Incremental Merges for relaxations and Rank Joins for joins. It processes *all* the relaxations and outputs the true top-k. Existing works which focus on optimized computation of top-k joins without relaxations or on determining relaxations for user queries are orthogonal to our work. The scoring scheme used by the existing systems supporting relaxations do not use fine-grained scores (scores for individual triples). For our setting, NSpec-QP is the closest baseline to the best of our knowledge. We have not shown comparisons with the naive method (i.e., compute answers to all combinations of relaxations and then sort them to get top-k) because it is obvious that it is the most inefficient technique.

Datasets. We have evaluated over the following two datasets:

i. Extended Knowledge Graph (XKG)[42]:
   a. Format: RDF format dataset consisting of YAGO2s triples and "textual" content triples constructed from Clueweb by using OpenIE techniques and Named Entity Disambiguation (NED). The triple scores for YAGO2s triples are equal to the number of inlinks into the subject. Triple score for Clueweb data is equal to the number of times a particular triple was encountered during extraction.
   b. Size: XKG has about 105 million triples.
ii. Twitter:
   a. Format: Constructed from trending tags over the month of April 2017 using Twitter Streaming API. The triples are of the form: $\langle tID, hasTag, T\rangle$ where tID is the unique ID for a tweet containing term T. The score for each triple is equal to the number of retweets for the tweet in that triple.
   b. Size: 18 million unique triples.

Queries and relaxations. The evaluation queries and relaxations for the datasets are as follows:

i. XKG: We evaluated on 65 queries which were manually constructed so as to have non-empty result sets. Each query had 2-4 triple patterns and each triple pattern had at least 10 relaxations. The relaxations were obtained using the scheme outlined in [42].
ii. Twitter: A query over this dataset queries for IDs of those tweets which have all the queried terms. For example, the following query queries for IDs of all those tweets which contain the terms '`#intoyouvideo`', '`#ariana`' and '`dangerous`':

```
SELECT ?s WHERE{
    ?s <hasTag> <#intoyouvideo>.
    ?s <hasTag> <#ariana>.
```

k	XKG	Twitter
10	0.7	0.72
15	0.88	0.78
20	0.91	0.8

Table 2: Precision over each dataset.

```
    ?s <hasTag> <dangerous>
}
```

The testset of 50 queries was constructed manually using combinations of most frequent tags and terms. Each query had either 2 or 3 triple patterns, with each triple pattern having at least 5 relaxations. The relaxations were generated using the co-occurrence frequencies i.e. the relaxation weight, w for the relaxation, r = (⟨`?s <hasTag>` <T_1>⟩,⟨`?s <hasTag>` <T_2>⟩,w) will be equal to:

$$w = \frac{\#tweets\_having\_T_1\_and\_T_2}{\#tweets\_having\_T_1}$$

For example, a possible relaxation for `<#intoyouvideo>` is `<video>`.

Note that the number of results decrease on increasing the number of triple patterns in a query. Due to this, we have restricted our testsets to have only 2-4 triple patterns' queries with non-empty result sets. Also, even though each triple pattern has at least 5-10 relaxations, relaxing only one or two triple patterns alone generates about 100 additional answers. Our planner aims to be able to predict the useful relaxations.

Metrics. We measure the following metrics for each query to demonstrate the quality and efficiency of our technique:

i. Quality:
   a. Precision: The fraction of true top-k results (of NSpec-QP) in the top-k results of Spec-QP. Note that precision and recall have identical values in our setup, because they have the same denominator k.
   b. Prediction accuracy: The number of queries for which we could identify all and only correct relaxations.
   c. Score error: The average of absolute error for Spec-QP vs. NSpec-QP top-k scores, i.e., $\frac{1}{k}\sum_{i=1..k}\left|score_i^{NSpec-QP} - score_i^{Spec-QP}\right|$ We also note the standard deviation.

ii. Efficiency:
   a. Runtimes: We measure the time taken to plan and execute each query.
   b. Memory used: We measure the total no. of answer objects created as it directly corresponds to the amount of search space traversed to arrive at top-k answers. This number includes all the intermediate answer objects encountered by Incremental Merges and Rank Joins.

System setup. The experiments were conducted on a Dell Blade server with 24 Intel(R) Xeon(R) CPU E5-2420 @ 1.90GHz processors and 32GB RAM. The database engine was used to retrieve the matches for triple patterns in sorted order. Each query was evaluated using both the techniques- NSpec-QP and Spec-QP, over two database engines, postgresql-9.5 and Virtuoso, for three values of k, namely 10, 15 and 20. To have a warm cache, we conducted 5 consecutive runs for each query and considered the average of the last 3 runs for each technique.

4.2 Quality evaluations

We first discuss the quality of results obtained by Spec-QP and then provide the statistics for runtimes and memory consumptions. *Note that the quality of results will be the same over any database engine as it depends only on the accuracy of our speculative technique.*

4.2.1 Precision. The precision values for the datasets are given in Table 2. The precision is about 0.7-0.9 for both the datasets, i.e., about 80% of the answers belonged to true top-k. Also, since the answers are sorted according to the scores, the answers outside the true top-k appeared at lower ranks. That is, for a query having a precision value of 0.8 for k=10, top-8 answers belonged to the true top-10.

4.2.2 Prediction Accuracy. A detailed analysis of the number of queries for which we could predict the correct relaxation(s) over each dataset is given in Table 3. Each query required some triple patterns to be relaxed to generate top-k answers. The prediction accuracy is at least 70% for all types of queries over XKG and queries requiring 3 relaxations over Twitter. As the value for k was increased, queries increasingly required relaxations to generate sufficient answers. For Twitter, most of the queries required all triple patterns to be relaxed. This is due to the absence of sufficient triples corresponding to each term and fewer relaxations (predicate is not relaxed) for each triple pattern. Nevertheless, we were able to identify the requirement of all the relaxations in such a scenario.

4.2.3 Average score error. To judge the quality of approximate results returned by Spec-QP, we computed the score deviations of the approximate answers at each rank given by Spec-QP from the true top-k. The average score deviations for various values of k are given in Table 4. The percentages in brackets show the average percentage deviation from the original scores. Note that the maximum possible score for an answer to a 2 triple pattern query can be 2, for a 3 triple pattern query, it will be 3 and so on.[6]

XKG. Even though k=10 has lowest precision, the score deviations from true top-k answers are low (about 0.1 for 2 triple pattern queries). That is, for a query with 2 triple patterns if the actual answer at a given rank has a score of 1.5, the score of the approximate answer would be about 1.4. The deviations are even lower (only about 0.01) for higher values of k and tolerable for achieving faster runtimes.

Twitter. There is only one 2 triple pattern query that required both triple patterns to be relaxed but had a wrong speculation of relaxations for all values of k. However, its score deviation is constant over all values of k as it has only 11 results (including relaxations). The deviations are only 0.5 for 3 triple pattern queries with $k = 10$, which is only 16% deviation from the original scores. The deviations for higher values of k are very low being only 6% in the best case. For k=20, for a query with 3 triple patterns if the actual answer at a given rank has a score of 2.5, the score of the approximate answer is about 2.32.

4.3 Efficiency evaluations

The average runtimes and memory values over PostgreSQL and Virtuoso for XKG grouped by the number of triple patterns in

[6] This is because the maximum score for a matching triple for each triple pattern can be 1.

Dataset	XKG			Twitter		
k	10	15	20	10	15	20
queries requiring 1 relaxation	5(6)	5(5)	-(-)	-	-	-
queries requiring 2 relaxations	21(30)	22(26)	18(19)	1(2)	1(2)	1(2)
queries requiring 3 relaxations	12(18)	16(19)	27(31)	35(48)	38(48)	39(48)
queries requiring 4 relaxations	7(11)	14(15)	14(15)	-	-	-

Table 3: Prediction accuracy for various values of k grouped by the number of triple patterns requiring relaxations in the queries to generate true top-k results. The number indicates the number of queries for which Spec-QP could identify all and only these relaxations. The numbers in brackets show the total number of such queries.

Dataset	XKG			Twitter	
#TP k	2	3	4	2	3
10	0.1(5%)±0.1	0.2(8%)±0.3	0.1(3%)±0.2	0.16(8%)±0.0	0.5(16%)±0.5
15	0.08(4%)±0.08	0.1(3%)±0.2	0.01(1%)±0.04	0.16(8%)±0.0	0.32(10%)±0.3
20	0.07(4%)±0.06	0.07(2%)±0.1	0.01(1%)±0.03	0.16(8%)±0.0	0.18(6%)±0.1

Table 4: Avg. score deviations for the approximate top-k from the true top-k grouped by the number of triple patterns (#TP) in the queries. The percentages in brackets show avg. percentage deviation from the score of the true answer at that rank.

the queries and the number of relaxations required by them have been given in Figures 3 and 4 respectively. The graphs for Twitter are given in Figures 5 and 6.

4.3.1 Runtime comparisons. It is evident from the runtime graphs (refer Figures 3 and 5) that Spec-QP is faster than NSpec-QP in all cases. It avoids unnecessary computation of *all* relaxations when only few relaxations are capable of giving top-k answers. Most of the queries require only 2 or 3 relaxations (Refer Table 3) to produce top-k answers and Spec-QP either identifies the correct relaxation(s) or gives good quality approximate results. Also, fewer the number of relaxations required, faster is Spec-QP over NSpec-QP. For k=15 and k=20, the gain margin lowers but Spec-QP is still faster than NSpec-QP. This is because on seeking more answers, the original query is insufficient to get top-k answers and needs multiple relaxations. It is especially prominent for XKG queries with 4 triple patterns; for k=15 and k=20, none of the queries could get top-k answers with less than 3 relaxations. The difference in the runtimes however clearly demonstrates the savings achieved by eliminating the requirement of even 1 relaxation. In particular, Spec-QP outperforms NSpec-QP by a factor of upto 1.5 for queries with 3 triple patterns.

Note that the key optimization for sorted access, in any database engine, is to use ordered index scans. This is what PostgreSQL does too. Also, even if the underlying database system is further optimized for sorted results, both techniques would benefit and therefore the gains of Spec-QP over NSpec-QP would be of the same order. PostgreSQL is faster than Virtuoso as it uses indices intensively for optimized retrieval. We have shown results over Virtuoso to demonstrate the practical applicability of our technique over any quad store.

4.3.2 Memory requirement comparisons. We measured the total number of answer objects created as it directly corresponds to the amount of search space traversed to arrive at top-k answers. This number includes all the intermediate answer objects encountered by the incremental merges and rank joins.

The memory comparison graphs are given in Figures 4 and 6 for XKG and twitter respectively. We found that NSpec-QP consumes the most memory for all the cases. This is because it traverses a significant amount of the search space, consisting of the original query and all its possible relaxations, in order to compute the top-k. Spec-QP consumes upto 2-3x less memory to compute top-k answers as it prunes a significant amount of the search space. The savings by Spec-QP is achieved by eliminating the need for processing relaxations of triple patterns which do not contribute triples towards top-k answers. This is particularly evident for the cases where the queries with 3 triple patterns require only 1 or 2 relaxations. The memory requirements reduce by a factor of 2.5 over both the datasets.

4.4 Discussion and remarks

We showed that Spec-QP prunes unnecessary relaxations and has faster response times over the baseline for various values of k. It predicts the correct relaxations 70-80% of the time with good approximations for answers outside top-k. Our technique depends on statistical estimates – specifically, what the score of the k^{th} result is for a specific (original or relaxed) query. Our solution of 2-bucket approximation strives for the sweet spot between assuming a uniform distribution and the actual distribution (every single data point in individual buckets of the histogram), and is built on the fact that even though datasets are different, their score distributions typically follow a power law distribution – a "fat" head, and a "long" tail.

The strategic pruning of relaxations using our model also reduces the search space traversed and in turn, the memory requirements for each query. Spec-QP is especially useful for servers where the total resource consumption per query is inversely proportional to the achievable throughput. The cost per query determines the cost of running the server for a given load. For instance, the queries having 3 triple patterns have 1.5x faster response times and 2.5x less memory requirements resulting in an overall 4x gain. This implies that the server can run the service with 4x less money. Hence, Spec-QP provides cost-efficient support for flexible querying using relaxations over SPARQL query

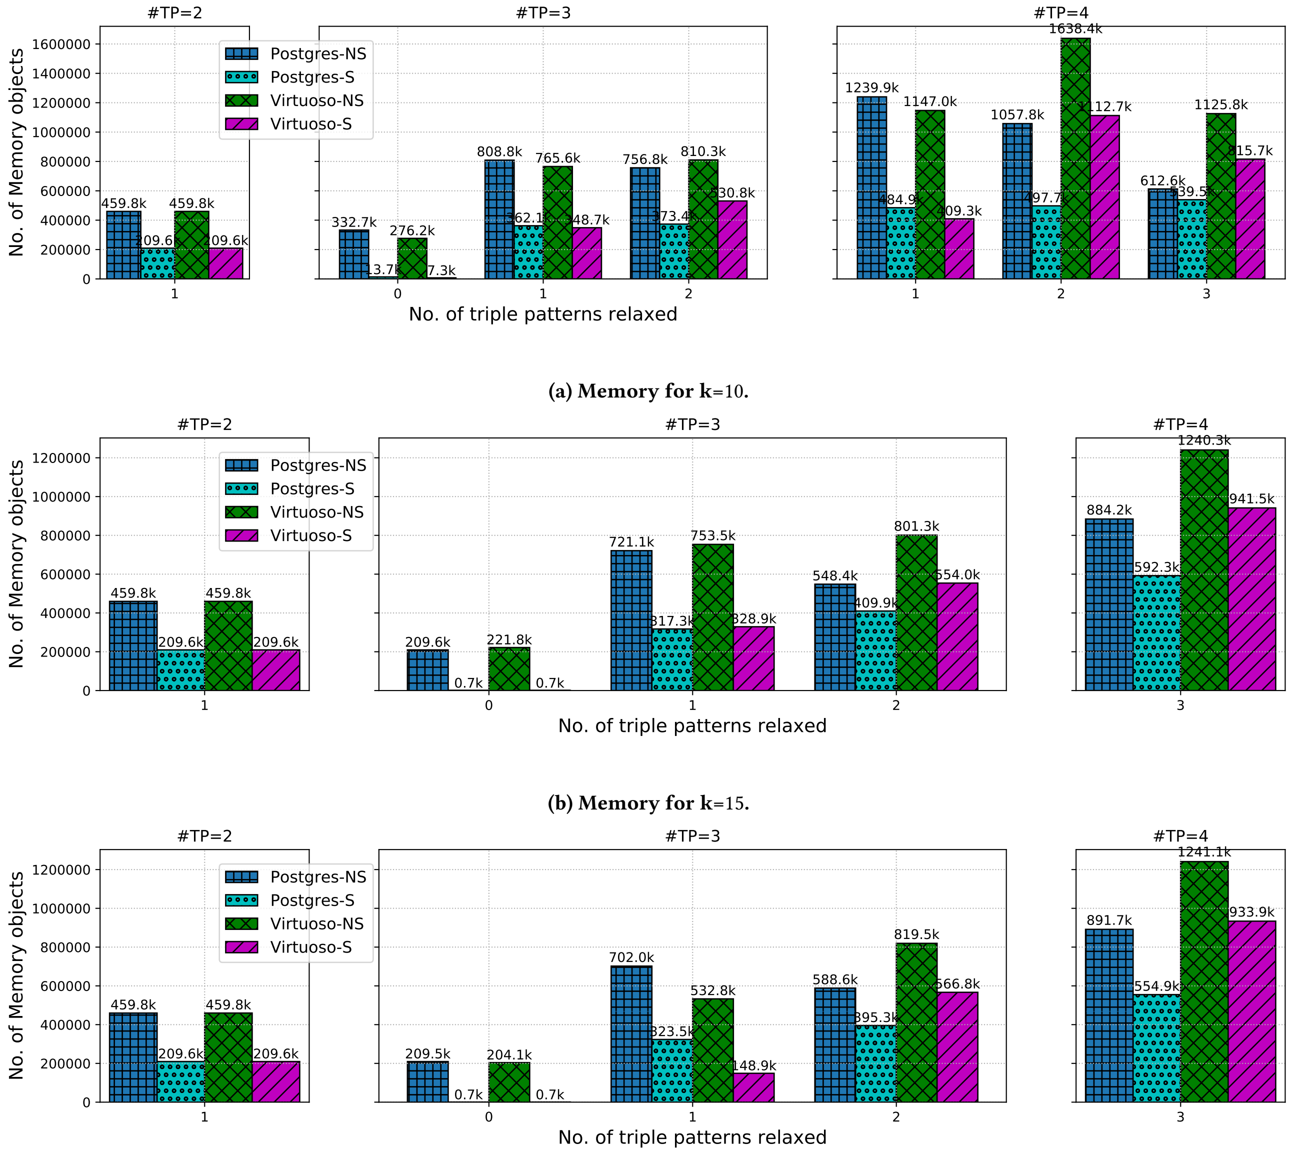
engines. This, in turn, aids effective exploration of knowledge graphs by new users.

5 RELATED WORK

Top-*k* query processing

FRPA [13] and Hash Rank-Join (HRJN*) [20] represent the state-of-the-art relational rank-join algorithms. HRJN* has been shown to perform well in practice, however, FRPA showed that it was not instance-optimal for a variant of the rank join problem that they considered. HRJN[21] is based on ripple join algorithm. It maintains two hash tables in-memory for storing the input tuples seen so far, the stored input tuples are used for finding join results. These results are then given as inputs to a priority queue, which outputs them in the order specified by the ranking function. Nested Loops Rank Join (NRJN) [19] is similar to HRJN except that unlike HRJN it does not store input tuples, but rather follows a nested-loop strategy. Pull/Bound Rank Join (PBRJ) [33] is an algorithm template that generalized previous rank join algorithms and provided tight upper bounds. DRJN [8] is an efficient algorithm for computing rank joins in distributed systems. This body of work is orthogonal to our problem.

Theobald et. al. [37] dealt with top-k query evaluation for joins over multiple index lists with pruning providing probabilistic guarantees. It uses histograms and dynamic convolutions to predict the top-*k*. Our case, however differs in that we consider



(a) Memory for k=10.

(b) Memory for k=15.

(c) Memory for k=20.

Figure 4: Memory comparisons over XKG queries for k=10, 15 and 20 grouped by the no. of triple patterns (#TP) in the query and the number of relaxations required. All the legends in the graphs for efficiency have 'NS' for NSpec-QP and 'S' for Spec-QP.

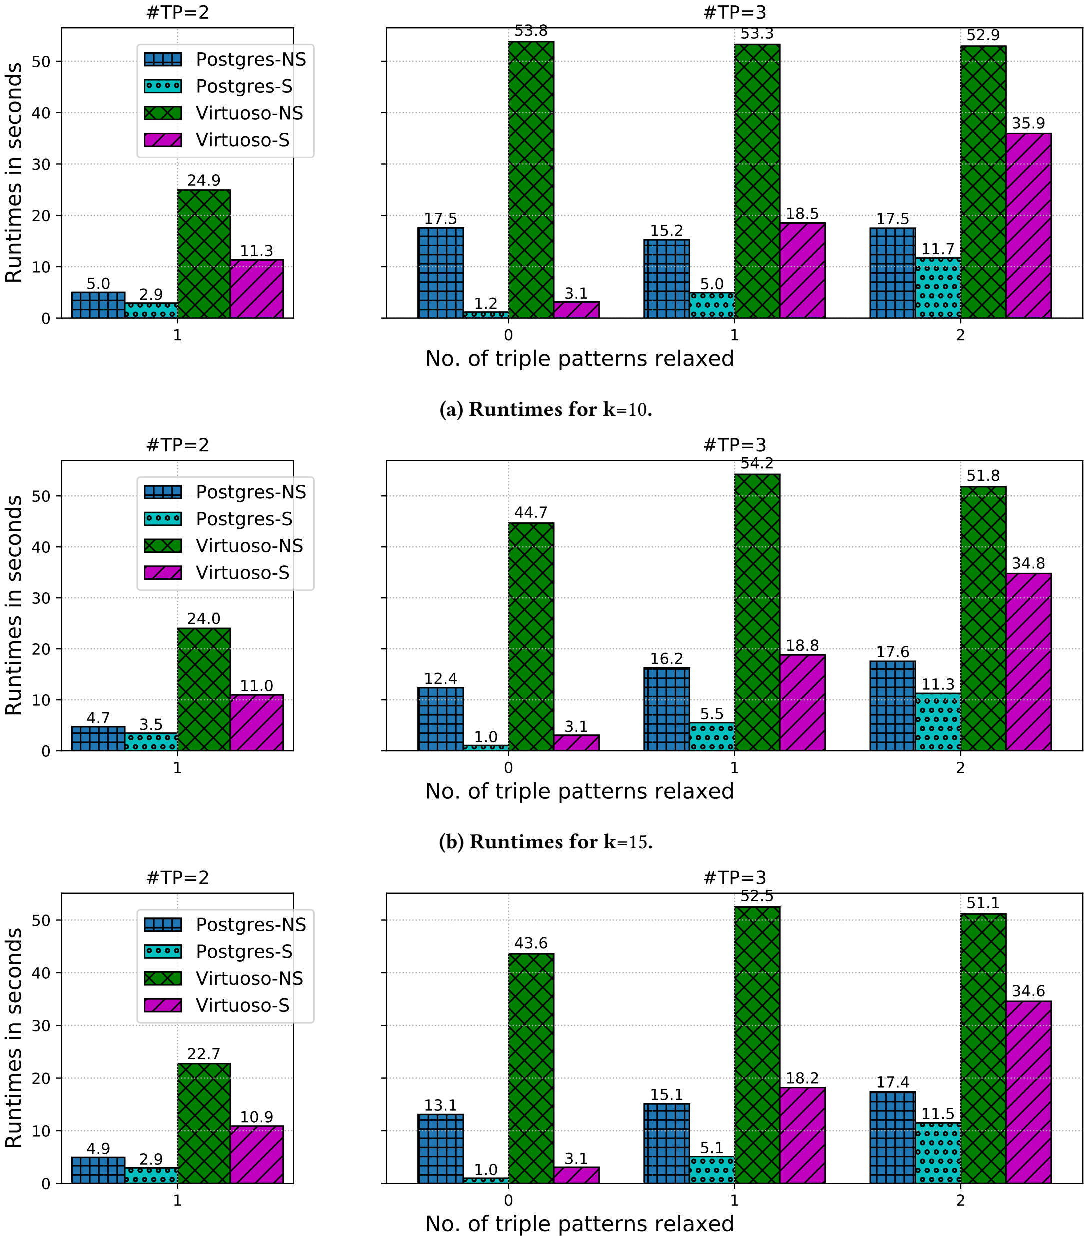
graph structured data and also, support multiple relaxations. The IO-Top-k [4] deals with top-*k* query evaluation with pruning using sorted access (SA) scheduling. Other works include top-*k* processing over xml data [36] and for data distributed over multiple nodes [44].

Top-*k* queries on graphs

Only few works address the problem of top-*k* processing over RDF graphs. The SPARQL-RANK framework proposed by [27] makes use of different index permutations used in native triple-stores for fast random access and early termination. Another framework introduced by Wang et al. [41] used MS-tree-based filtering and pattern-matching functions to evaluate top-*k* answers. The work in [43] uses an approach similar to HRJN[21] for computing top-*k* star joins. However for RDF data, SPARQL-RANK showed experimentally that it outperformed HRJN. The performance gain was attributed to the unsorted nature of numerical attributes present in indexes build by RDF engines. QUARK-X [25] proposes using extra indexes and metadata to process top-*k* queries on RDF graphs. All of these works however do not optimize over possible relaxations.

Query Reformulation in IR

Various strategies have been proposed to reformulate queries in IR over documents. These include measures of query similarity [3], or using summary information included in the query-flow graph [1]. Another approach by Hristidis et. al. [16] relies on



(a) Runtimes for k=10.

(b) Runtimes for k=15.

(c) Runtimes for k=20.

Figure 5: Runtimes comparisons over Twitter for k=10, 15 and 20 grouped by the no. of triple patterns (#TP) in the query and the number of relaxations required. All the legends in the graphs for efficiency have 'NS' for NSpec-QP and 'S' for Spec-QP.

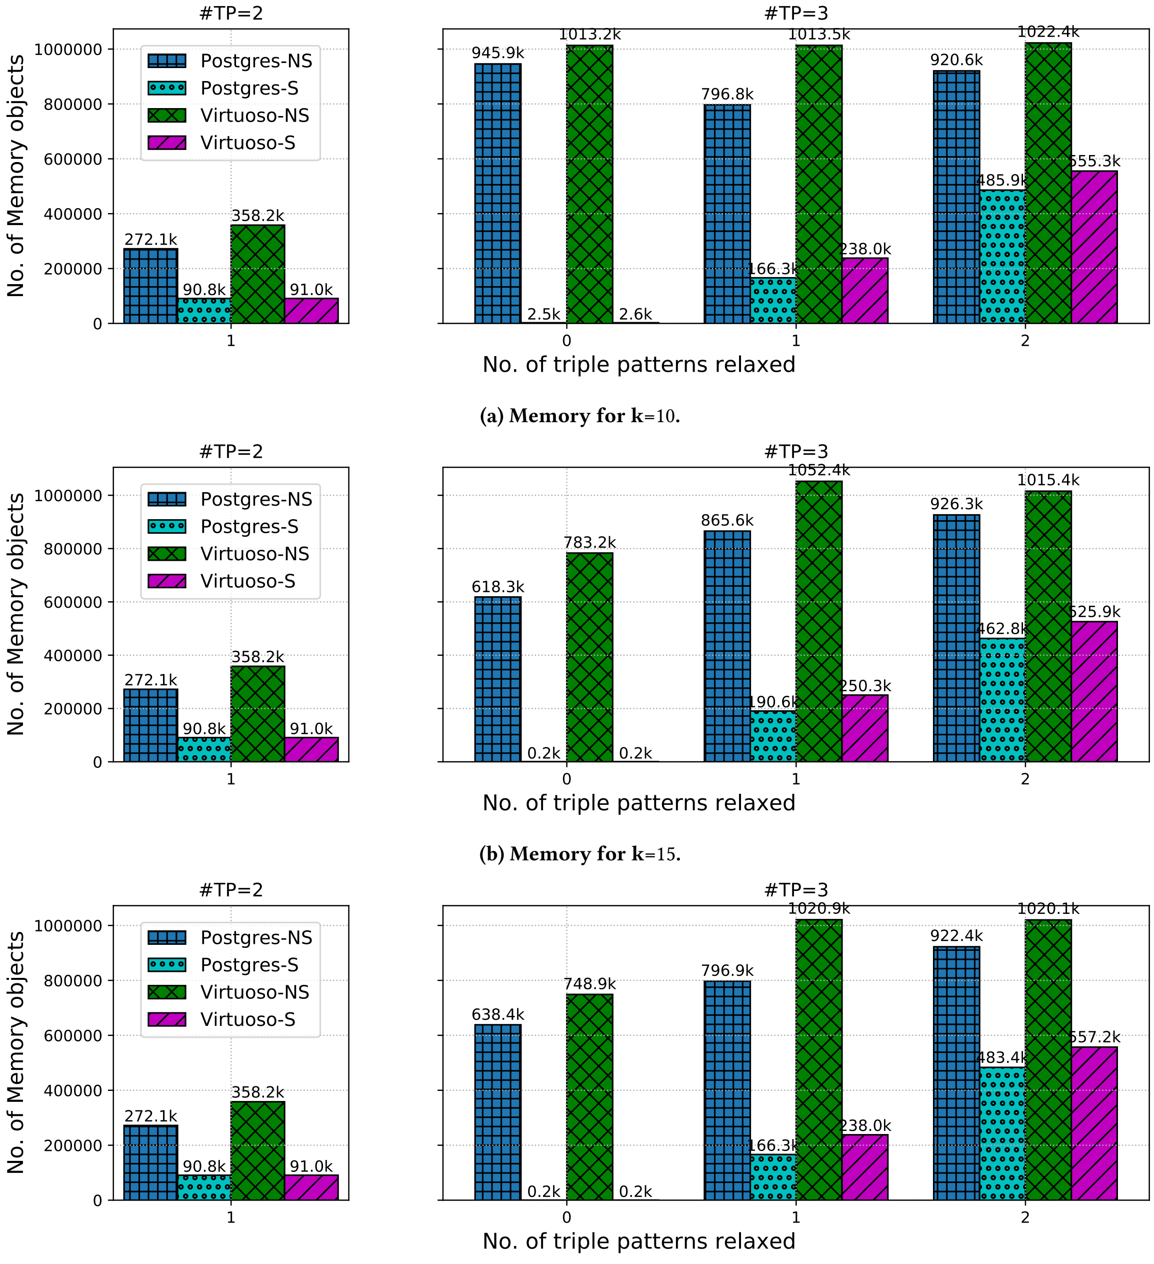
suggesting keyword relaxations by relaxing those which are least specific based on their idf score. These reformulations can be used as relaxations for our setting.

Faceted Search (Many answers problem)

A related optimization problem is the one encountered when we have many-answers, i.e. those where given an initial query that returns a large number of answers, the objective is to design an effective drill-down strategy to help the user find acceptable results with minimum effort [22, 26, 32]. We solve a related problem, where we try to solve both empty-answer and many-answers problem in an efficient manner by generating additional scored answers using relaxations.

Query Relaxation in relational databases

Query relaxation in relational databases is quite common. The work [24] relaxes joins and selections in relational databases by suggesting alternative queries based on the "minimal" shift from the original query. Another work [40] suggests user ranking of the query edges so as to generate relevant differential queries with minimum deviation. "Why Not" queries are studied in [6, 38], where, given a query Q that did not return a set of tuples S that the user was expecting to be returned, they design an alternate



(a) Memory for k=10.

(b) Memory for k=15.

(c) Memory for k=20.

Figure 6: Memory comparisons over Twitter for k=10, 15 and 20 grouped by the no. of triple patterns (#TP) in the query and the number of relaxations required. All the legends in the graphs for efficiency have 'NS' for NSpec-QP and 'S' for Spec-QP.

query Q' that (a) is very similar to Q, and (b) returns the missing tuples S, however the rest of the returned tuples should not be too different from those returned by Q. The paper [28] relaxes one constraint at a time and is interactive. It also tries to minimize the cost by suggesting low cost relaxations which lead to non-empty answers. DebEAQ [39] first tries to debug why the query is returning empty answer and then tries to relax it with minimum change to the original query. It is also limited only to property graphs.

Query Relaxation over graphs

The closest to our works are those which deal with relaxations over graphs. The work in [15, 29–31] considers query relaxation for conjunctive regular path queries. Users are allowed to specify query predicates which can have approximations and/or relaxations (using *APPROX* and *RELAX* operators respectively) during query time. The system then computes the approximations/relaxations with their relative evaluation costs to support query rewriting. Another work [17] computes approximate answers using a Bayesian network to rank and score relaxed queries. Two algorithms are described in [18]. The first algorithm is based on best-first strategy and relaxed queries are executed in order. They prune relaxations which do not give new results. The other algorithm executes the relaxed queries as a batch and avoids the unnecessary execution cost. The idea of Maximal Succeeding Subqueries (MSSs) is exploited in [14] using Lattice-based and Matrix-based approaches to minimally refine the user query. The scoring scheme used by these existing systems supporting relaxations however, do not use fine-grained scores (scores for individual triples) as in our case. TriniT [42] proposes the notion of eXtended Knowledge Graphs (XKG) with fine-grained scores for triples and allows relaxations for queries over them. It uses a technique similar to NSpec-QP to evaluate the queries.

6 CONCLUSION AND FUTURE WORK

We have proposed Spec-QP, a strategy for top-k query processing in a scenario where a query can have multiple relaxations. To achieve this, we have used a speculative approach for pruning the relaxations which are not likely to contribute answers to the top-k results. The speculation is based on precomputed statistics about the distribution of scores for triple pattern matches. The relaxations of triple patterns predicted to not contribute towards top-k answers are not processed, thereby reducing top-k computations and leading to faster response times and reduced memory requirements.

We have experimented over two real world datasets – XKG and Twitter – to show that Spec-QP is a cost-efficient technique for supporting relaxations. This is especially useful for servers in aiding exploratory querying over knowledge graphs by new users without an exponential increase in the budget. We also demonstrated the practical usability of our technique by implementing it over two popular database engines – PostgreSQL and Virtuoso. As future work, we would like to support more complicated relaxations for the queries like replacing a triple pattern with a chain of triple patterns, etc. Another orthogonal area of work is to find meaningful and useful relaxations for a given triple pattern.

ABSTRACT

Mutual Information (MI) is an established measure for linear and nonlinear dependencies between two variables. Estimating MI is nontrivial and requires notable computation power for high estimation quality. While some estimation techniques allow trading result quality for lower runtimes, this tradeoff is fixed per task and cannot be adjusted. If the available time is unknown in advance or is overestimated, one may need to abort the estimation without any result. Conversely, when there are several estimation tasks, and one wants to budget computation time between them, there currently is no efficient way to adjust it dynamically based on certain targets, e.g., high MI values or MI values close to a constant. In this article, we present an iterative estimator of MI. Our method offers an estimate with low quality near-instantly and improves this estimate in fine grained steps with more computation time. The estimate also converges towards the result of a conventional estimator. We prove that the time complexity for this convergence is only slightly slower than non-iterative estimation. Additionally, with each step our estimator also tightens statistical guarantees regarding the convergence result, i.e., confidence intervals, progressively. These also serve as quality indicators for early estimates and allow to reliably discern between attribute pairs with weak and strong dependencies. Our experiments show that these guarantees can also be used to execute threshold queries faster compared to non-iterative estimation.

1 INTRODUCTION

Motivation. Detecting and quantifying dependencies between variables is an essential task in the database community [10, 13, 20, 30]. Conventional methods such as correlation coefficients and covariance matrices only detect linear or monotonous dependencies. *Mutual Information* (MI) in turn is an index that captures any linear and nonlinear dependency [1, 5]. Probability distributions of the variables in question serve as input to compute the MI. For real-world data however, these distributions are not available. In this case, MI must be estimated based on samples.

Various estimators for MI have been proposed [15, 23, 33], and some offer good results even for small samples [15]. However, continuous variables with an unknown distribution continue to be challenging, since their multivariate distribution is substituted only by a limited sample. A prominent approach for estimation of MI between continuous variables without assumption of the distribution is the nearest-neighbor based method by Kraskov et al. (KSG) [19].

While good estimators are available, they are very rigid in their time requirements and regarding the estimation quality. Once the computation has started, they impose a fixed time requirement and do not yield aby preliminary result if they are terminated prematurely. They also are unable to exploit 'easier' queries like whether the MI value is above a certain threshold but instead determined the value. Such features are highly relevant for high-dimensional data and data streams with irregular arrival rate as we showcase with the following two scenarios.

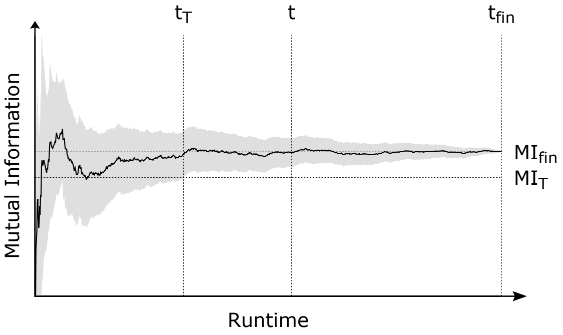

Figure 1: MI estimation with dynamic time allocation.

Scenario 1. Consider a modern production plant with smart meters installed on each machine. A first step in data exploration is determining which attributes are strongly dependent. For instance dependencies among currents or energy consumption may offer insights into production sequences. For this first step, a query like "Which pairs of measurements have a MI value above the threshold MI_T?" often suffices. With conventional MI estimators, each pair either induces high computational costs, or results are uncertain because of low estimation quality.

Scenario 2. Think of a database with financial data and its real-time analysis. To maintain a diverse portfolio, it is important to track the relationships between stocks. Because bids and trades happen irregularly, new information and market prices arrive at irregular speed. Thus, it is not known how much time is available to monitor stock relationships in the presence of incoming data. Current MI estimators cannot adapt during execution. They risk not producing a result in time, or estimates are of low quality.

To improve upon these shortcomings, we study estimation of MI with dynamic allocation of computation time. Ideally, such an estimator should not only offer preliminary results, but also indicate its remaining uncertainty. Figure 1 shows exemplary progression over time of such an estimator based on our experiments with real data. The black line indicates the preliminary estimate after a certain runtime, and the gray area shows the (expected) maximum error of the preliminary estimate. To obtain the definitive result $\mathtt{MI}_{\mathtt{fin}}$, a user would require time $\mathtt{t}_{\mathtt{fin}}$. However, he could also stop the estimator as soon as the estimate is above a threshold $\mathtt{MI}_{\mathtt{T}}$ with certainty, or he can use the preliminary result available after time $\mathtt{t}$.

In this work, we focus on iterative estimation of MI in order to offer this functionality. Here, 'iterative' means quickly providing an estimate, but with the option to improve the estimation if there is time left. In other words, improving the estimate with some time available is what we call an *iteration.* At the same time, an iterative estimator can terminate the estimation, i.e., stop iterating, when the result is good enough. For efficiency, it is important that computations from previous iterations remain useful and are not repeated or discarded in a later iteration. So far, efficient iterative estimators for MI do not exist.

Challenges. The most significant feature of an estimator is its quality of estimation. This is even more so for iterative methods because both "preliminary" and "final" estimation quality are important. In other words, the estimate should already be useful after a few iterations, and estimation quality must level up to the one of conventional estimators after many iterations. Ideally, this convergence should happen after a known, finite number of iterations. In this article, we target at respective formal guarantees.

Next, the quality of preliminary estimates is crucial for usability. Determining if a preliminary result is "good enough" or interesting enough to merit additional computation time requires some information on its certainty. The number of iterations alone is insufficient, as the result quality depends on many other factors such as data characteristics, required accuracy and time constraints. Instead, each estimate requires an individual indicator of the uncertainty remaining.

While the time spent to improve the estimate iteratively is committed dynamically, it must of course be used efficiently. Many conventional estimators use data structures that are expensive to build and cheap to use, such as space-partitioning trees [19, 31, 32]. Such an upfront activity is undesirable for an iterative estimator whose first estimate must arrive soon. At the same time, runtime and scalability do remain important characteristics of the estimator. In other words, an iterative estimator must feature guaranteed efficiency for both individual iterations and final estimates.

Contributions. In this article, we present IMIE, our Iterative Mutual Information Estimator. To prove its practical usefulness, we establish several features both formally and experimentally.

Quality of Estimation. In Section 4, we propose a design for IMIE such that estimates converge to the same value as with the KSG. To make early iterations useful, IMIE also offers statistical error bounds for its early estimates. More precisely, an early estimate provides a confidence interval for the final estimate. We describe the specifics and the statistical soundness in Section 4.3.

Complexity. We study the time complexity of initialization and of individual iterations of IMIE. In Section 5 we establish an amortized time complexity for IMIE and the nearest-neighbor search used. This complexity is competitive with existing non-iterative estimators. To be precise, we show that iterating IMIE until convergence is only slightly slower in terms of time complexity than computing the KSG directly with optimal algorithms.

Experimental Validation. We show that IMIE complements the formal guarantees established so far with good actual performance. To do so, we perform extensive experiments using both synthetic and real data sets in Section 6. On the one hand, we show that the concrete runtime and estimation results of IMIE are comparable to the ones of conventional estimation methods. On the other hand, the experiments show the practical benefits of the early results from IMIE. For instance, IMIE finds attribute pairs above a threshold value significantly faster than non-iterative estimators.

2 RELATED WORK

Iterative estimation of MI is interesting from two perspectives. On the one hand, it is methodically interesting, as it can be considered an *anytime algorithm.* On the other hand, it is interesting to consider the benefits it provides over current methods in different settings. Important application scenarios are dependency analysis in high dimensional data and data streams, cf. Scenario 1 and 2.

Anytime Algorithms. Anytime algorithms [36] use available time to increase their result quality. One can obtain a low-quality result after a short time and a better one when waiting longer. In data analysis, anytime algorithms exist for clustering [22], classification [35] and outlier detection [2]. So far however, there is no anytime algorithm to estimate MI. So while there is no direct competitor, IMIE extends the set of tools available as anytime algorithms. Additionally, there has been more general work on the optimal use of available anytime algorithms [11, 18], which may improve the performance of IMIE in larger systems.

MI on Data Streams. Estimating MI on streams has received some attention recently. The MISE framework [14] summarizes a bivariate stream such that the MI for arbitrary time frames can be queried. To this end, MISE offers parameters for the balance between accuracy of older queries and resource requirements both in terms of memory and computation time. In contrast, the DIMID estimator [4] processes a bivariate stream as sliding window for monitoring tasks. This approach provides fast updates between time steps by approximation with random projection. MI estimation in sliding windows has also been the focus of [32]. That paper provides lower bounds for estimates using Equation 5 both in general and for updates in sliding windows. It also features two dynamic data structures, DEMI and ADEMI, to maintain such estimates using either simple or complex algorithms and data structures.

These approaches have limitations. First, they all impose the necessary execution time, i.e., one cannot adapt this time after the start of stream processing. If the rate of new items increases, the estimator may be unable to keep up. If it decreases, the estimator cannot use this time to improve results. Second, the approaches are all focused on bivariate streams. While MI is defined for exactly two variables, the number of attribute pairs grows quadratically in the number of dimensions. In contrast, the only information IMIE maintains on a stream is based on individual dimensions and thus scales linearly with the dimensionality. Third, the approximate results of MISE and DIMID are difficult to use. Their estimation quality is only known on average; this average defines the perceived quality of individual estimates. So if one estimate has a very small error, it is less likely to be appreciated, while the error of a particularly bad estimate may be assumed to be smaller.

Dependencies in High Dimensional Data. Even though MI is defined for exactly two variables, it has many applications with high-dimensional data. Prominent ones are image registration [25], which uses MI between two high-dimensional variables, and feature selection [24], which targets at the MI between attributes and a classification label. But estimating the MI between all pairs of attributes has received little attention, despite being the non-linear equivalent of correlation matrices. [26] uses a different approach, i.e., kernel density estimation, and removes redundant computations that arise when using this estimator for each pair. This approach has a worse computational complexity than a pair-wise application of the KSG estimator, without offering better

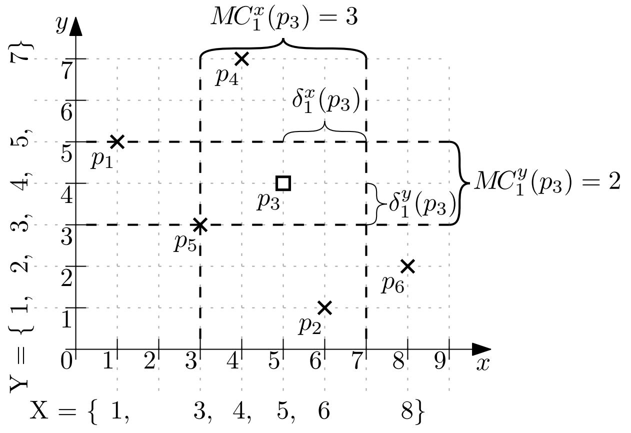

Figure 2: Illustration of terms used for the KSG.

results [15, 23]. While both scale quadratically in the number of attributes, their approach is also quadratic in the number of points. The complexity of the KSG in turn is $\Theta(n \log n)$ [32]. Additionally, it does not expose any parameter to modify the result quality. Consequently, there would not be any benefit of a direct experimental comparison with IMIE.

3 FUNDAMENTALS

We first cover the background of MI and its estimation.

Mutual Information. Shannon has introduced the notion of *entropy* [28] to quantify the expected information gained from observing a value of a random variable. $H(X)$ stands for the entropy of a random variable X. The expected information of observing two random variables X and Y is the *joint entropy* $H(X, Y)$. *Mutual Information* quantifies the amount of information that is shared or redundant between the two variables. It is defined as

$$I(X; Y) = H(X) + H(Y) - H(X; Y). \tag{1}$$

With the definition of entropy for continuous variables [6], the MI of two continuous random variables is

$$I(X; Y) = \int_X \int_Y p_{XY}(x, y) \, \log \left(\frac{p_{XY}(x, y)}{p_X(x) p_Y(y)} \right) dx \, dy, \tag{2}$$

where p_X, p_Y and p_{XY} are the marginal and joint probability density functions of X and Y. The type of logarithm used in Equation 2 determines the unit of measurement. In this work we use the natural logarithm. This means that MI is measured in the *natural unit of information* (nat).

Estimation. One can perceive many sources of data, e.g., smart meters or market prices, as random variables with unknown distribution. Since Equation 2 requires probability density functions, we cannot compute the MI of such sources exactly. Instead, we can only estimate the MI based on available samples. The popular estimator that will serve as foundation of our work is the one by Kraskov, Stögbauer and Grassberger [19], which we call KSG. It is based on the estimator for probability densities by Loftsgaarden and Quesenberry [21], which Kozachenko and Leonenko have studied further in the context of entropy [17]. In the following, we briefly review the terms and computation of the KSG.

Let $P = \{p_1 = (x_{p_1}, y_{p_1}), \ldots, p_n = (x_{p_n}, y_{p_n})\} \subseteq \mathbb{R}^2$ be a sample from a random variable with two attributes. Figure 2 illustrates the notions that we define in the following using the sample $P = \{(1, 5), (6, 1), (5, 4), (4, 7), (3, 3), (8, 2)\}$. Let $X = \{x_{p_1}, \ldots, x_{p_n}\}$ and $Y = \{y_{p_1}, \ldots, y_{p_n}\}$ be the set of values per attribute. For each point $p \in P$, its $k \in \mathbb{N}^+$ nearest neighbors in P using the maximum distance form the set $kNN(p)$. More formally, it is

$$kNN(p) = \underset{S \subseteq (P \setminus \{p\}) \; s.t. \; |S|=k}{\arg\min} \; \max_{s \in S} \|p, s\|_\infty, \tag{3}$$

with $\|p, s\|_\infty = \max(|x_p - x_s|, |y_p - y_s|)$. We define the largest distance between x_p and any x-value among the k nearest neighbors of p as $\delta_k^x(p) = \max_{s \in kNN(p)} |x_p - x_s|$. We use this distance $\delta_k^x(p)$ to define the *x-marginal count*

$$MC_k^x(p) = |\{x \in (X \setminus x_p) : |x - x_p| \leq \delta_k^x(p)\}|, \tag{4}$$

which is the number of points whose x-value is "close to p". In Figure 2, vertical dashed lines mark the area of points whose x-values are at least as close as the nearest neighbor of p_3. Since this area contains three points excluding p_3, it is $M_1^x(p_3) = 3$. The distance $\delta_k^y(p)$ and the *y-marginal count* $MC_k^x(p)$ are defined analogously. Note that $\delta_k^x(p)$ and $\delta_k^y(p)$ may differ, which results in differently sized areas for the marginal counts, as seen in Figure 2. Using these counts, the KSG estimate is defined as

$$\widehat{I}(P) = \psi(n) + \psi(k) - \frac{1}{k} - \frac{1}{n} \sum_{i=1}^{n} \psi\left(MC_k^x(p_i)\right) + \psi\left(MC_k^y(p_i)\right), \tag{5}$$

where ψ is the digamma function. This is $\psi(z) = -C + \sum_{t=1}^{z-1} \frac{1}{t}$ for $z \in \mathbb{N}^+$ and $C \approx 0.577$ being the Euler-Mascheroni constant.

While k is a parameter of this estimator, it is generally recommended [15, 16, 19] to use a small k, that is $k \leq 10$. Gao et al. [9] have proven that the KSG is a consistent estimator for fixed k, that is, it converges towards the true value with increasing sample size.

4 ITERATIVE ESTIMATION

In this section we present IMIE, our iterative estimator for MI. The core concept of our approach is considering the KSG estimate itself as the mean of a random variable with a finite population. Using subsamples of this population for early estimates offers beneficial properties such as an expected value equal to the KSG estimate and convergence to the KSG for large sample sizes.

We first present IMIE and its underlying data structure as well as the algorithms for the initialization and for subsequent iterations. Then we describe our approach for nearest neighbor search, which is better for iterative algorithms than the standard procedures. Finally, we describe the statistical bounds that IMIE provides with its estimates.

4.1 IMIE

For brevity, we introduce some notation in addition to the one from Section 3. For a point $p \in P$, we define the *pointwise estimate*

$$\Psi(p) = \psi\left(MC_k^x(p)\right) + \psi\left(MC_k^y(p)\right). \tag{6}$$

The set of all pointwise estimates is $\rho = \{\Psi(p_1), \ldots, \Psi(p_n)\}$. Seeing ρ as a finite population of size n with mean μ_ρ, Equation 5 can be rewritten as

$$\widehat{I}(P) = \psi(n) + \psi(k) - \frac{1}{k} - \mu_\rho. \tag{7}$$

Using a (random) subsample $\varrho \subseteq \rho$, its mean μ_ϱ is an (unbiased) estimation of μ_ρ. This in turn yields an (unbiased) estimate of $\widehat{I}(P)$,

$$\widehat{I_\varrho}(P) = \psi(n) + \psi(k) - \frac{1}{k} - \mu_\varrho. \tag{8}$$

Data Structure 1: IMIE

```
struct {
    Point[] $P$
    Real $Mean$, $Var$
    Int $k, m$
    Int[] $Order_R$, $Order_x$, $Order_y$
    Real $Offset$
};
```

Algorithm 2: Init (P, k)

```
Persist $k$ and $P$                                         $O(n)$
$Mean, Var, m \leftarrow 0$                                 $O(1)$
$Order_R, Order_x, Order_y \leftarrow (0, 1, \dots, |P|-1)$ $O(n)$
Sort $Order_x$ and $Order_y$                                $O(n \log n)$
$Offset \leftarrow \psi(|P|) + \psi(k) - \frac{1}{k}$       $O(1)$
```

Algorithm 3: Iterate

```
1  $ID \leftarrow$ Draw random integer from $[m, n-1]$                      $O(1)$
2  Swap values of $Order_R[m]$ and $Order_R[ID]$                            $O(1)$
3  $p \leftarrow P[Order_R[m]]$                                             $O(1)$
4  $kNN(p) \leftarrow$ NNSearch$(p)$          (see Algorithm 4)             $O(\sqrt{n})$
5  Compute $\delta^x_k(p)$, $\delta^y_k(p)$                                 $O(1)$
6  Compute $MC^x_k(p)$, $MC^y_k(p)$                                         $O(\log n)$
7  $\Psi(p) \leftarrow \psi\big(MC^x_k(p)\big) + \psi\big(MC^y_k(p)\big)$  $O(1)$
8  $m \leftarrow m + 1$                                                     $O(1)$
9  $Diff_{\text{old}} \leftarrow \Psi(p) - Mean$                            $O(1)$
10 $Mean \leftarrow Mean + \frac{Diff_{\text{old}}}{m}$                     $O(1)$
11 $Diff_{\text{new}} \leftarrow \Psi(p) - Mean$                            $O(1)$
12 $Var \leftarrow \frac{Var\cdot(m-1)+Diff_{\text{old}}\cdot Diff_{\text{new}}}{m}$   $O(1)$
```

The variance σ^2_ϱ of our subsample serves as a quality indicator of this approximation, which we further discuss in Section 4.3. The idea of IMIE is to maintain a subsample ϱ and use $\widehat{I_\varrho}(P)$ to estimate $\widehat{I}(P)$. Each iteration then increases the sample size of ϱ by one, to improve the estimate. Starting with an empty set, this means there are exactly $|P|$ iterations before IMIE yields exactly the same result as the KSG, i.e., $\widehat{I_\varrho}(P) = \widehat{I}(P)$.

Data Structure. IMIE uses and stores P and k as well as some additional information listed in Data Structure 1. In the following we use the zero-indexed array notation $P[i] = p_{i+1}$. Contrary to the original data sample P, we do not store ϱ explicitly. Instead we store its mean *Mean*, its variance *Var* and size, which is the number of performed iterations m. To maintain the current variance efficiently, we use the online algorithm by Welford [34]. To ensure that ϱ is a random subsample of ρ, we need to draw without replacement. To this end, IMIE maintains an array of indices $Order_R$, where index i at position j means that $\Psi(p_i)$ is added to ϱ in the j-th iteration. The positions of this array are randomly swapped during iterations to perform the random selection. This enables a fast selection of a random element without replacement in each iteration. In addition, we maintain two arrays $Order_x$ and $Order_y$ containing references to all points in P ordered by their x- and y-value, respectively. For instance, index i at $Order_x[0]$ means that p_i has the smallest x-value in P, i.e., $p_i = \arg\min_{p \in P} x_p$. These ordered arrays are used to find nearest neighbors, as described in Section 4.2. Finally, we store the $Offset = \psi(n) + \psi(k) - \frac{1}{k}$. With this, the (preliminary) MI estimate is available as $\widehat{I_\varrho}(P) = Offset - Mean$.

Methods. We now present the two methods Init and Iterate. See Algorithms 2 and 3, together with amortized time complexities, derived in Section 5. Init ensures the proper state of Data Structure 1 before the first iteration, i.e., preparing all variables assuming that $|\varrho| = 0$. Observe that Init is a straightforward method for the simple case of static data with two attributes. For other scenarios, such as high-dimensional or streaming data, some adjustments to the initialization may be appropriate, as discussed in Section 5.3.

Iterate increases the size of sample ϱ by one. This requires computing $\Psi(p)$ for a random $p \in P$ with $\Psi(p) \notin \varrho$. Iterate consists of three phases. In the first one (Lines 1–3), we select a random point p of P that has not been selected earlier. After $m-1$ iterations, we swap the index at position m of $Order_R$ with the index at a random position behind $m-1$. This ensures that we do not use any index twice, since positions before m are not considered, and that each unused index has the same probability of being selected. This random swap is one step of the Fisher-Yates Shuffle in the version of Durstenfeld [8], which fully randomizes the order of a sequence. The second phase (Lines 4–7) computes $\Psi(p)$ using the ordered lists $Order_x$ and $Order_y$. The last phase (Lines 8–12) performs the online algorithm [34] to maintain mean and variance of a sample, in our case ϱ.

Example 4.1. Disregarding the dashed lines for now, Figure 3 illustrates the state of Data Structure 1 after initialization and before the first iteration. For the first iteration, we draw an integer ID from $\{0, \dots, n-1\}$. Suppose that we drew 5. We swap the content of $Order_R[0]$ and $Order_R[5]$. $Order_R[0]$ now contains 6. This means that this iteration adds $\Psi(p_6)$ to our implicit sample ϱ. We then determine its nearest neighbor $1NN(p_6) = \{p_{15}\}$, the distances $\delta^x_1(p_6)$ and $\delta^y_1(p_6)$ as well as the marginal counts $MC^x_1(p_6) = 1$ and $MC^y_1(p_6) = 3$. The dashed lines in Figure 3 illustrate the area of counted points in x and y-direction, respectively, identically to Figure 2. It follows that $\Psi(p_6) = \psi(1)+\psi(3) = 0.346$. Substituting the appropriate variables, the remaining values are set accordingly, i.e., $m = 0 + 1 = 1$, $Mean = 0 + \frac{0.346}{1} = 0.346$ and $Var = \frac{0\cdot 0+0\cdot 0.346}{1} = 0$. The second iteration is analogous, drawing $ID = 6$ at random from $\{1, \dots, n-1\}$, thus choosing p_7. Its nearest neighbor is p_8, and the marginal counts are $MC^x_1(p_7) = 1$ and $MC^y_1(p_7) = 6$, cf. the dashed lines in Figure 4. As a result, it is $\Psi(p_7) = \psi(1)+\psi(6) = 1.129$. Analogously to the first iteration, the remaining values are $m = 1+1 = 2$, $Mean = 0.346 + \frac{0.783}{2} = 0.738$ and $Var = \frac{0\cdot 1+0.783\cdot 0.391}{2} = 0.153$. Figure 4 graphs the state of Data Structure 1 after both iterations, and the new MI estimate is $1.164 - 0.738 = 0.426$.

4.2 Nearest-Neighbor Search

A computation-intensive step in Iterate is the computation of nearest neighbors, which also is a key step for static estimation with the KSG. The classic solution [19, 31] is using space-partitioning trees, which are optimal in terms of computational complexity [32]. This efficiency is achieved because the slow tree construction is performed once, and each nearest-neighbor search afterwards is fast. Contrary to the traditional KSG estimation, it is not known beforehand how many nearest-neighbor searches IMIE performs. Constructing such a tree for IMIE would

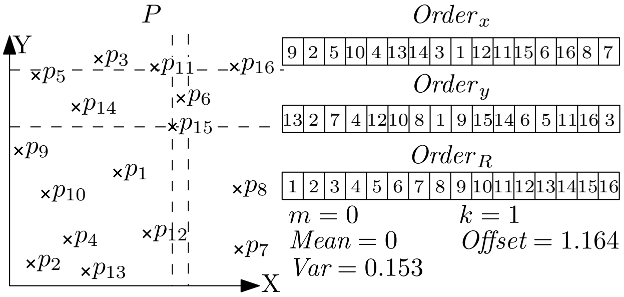

Figure 3: State of IMIE after initialization.

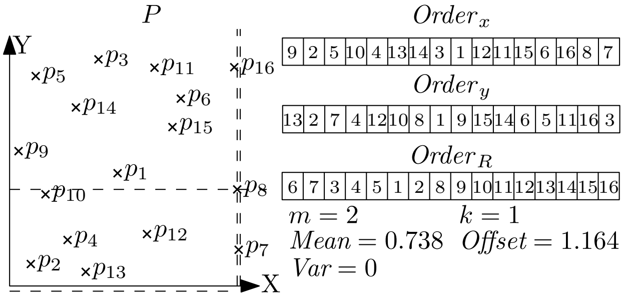

Figure 4: State of IMIE after two iterations ($\Psi(p_6)$ and $\Psi(p_7)$).

not only delay the first estimate, but may also be an inefficient choice overall if only few iterations take place. The opposite, i.e., searching nearest neighbors without any preparation, is a linear search. Each iteration would then require time linear in the number of data points. Since IMIE should offer both fast iterations and preliminary estimates after a short time, our approach is a compromise between these two options. The general idea is to use sorted arrays to perform a "guided" linear search that offers a good amortized time complexity (cf. Section 5). In the following, we elaborate on our NNSearch approach.

Let p be the point whose nearest neighbor we are searching for and q the nearest neighbor we have found so far. Then any point r with $|x_p - x_r| > \|p-q\|_\infty$ cannot be a nearest neighbor with the maximum norm. This means that we only have to consider the interval $[x_p - \|p-q\|_\infty, x_p + \|p-q\|_\infty]$ in the sorted array $Order_x$. When we find a closer point during the search, this interval gets smaller, and fewer points need to be considered. For the y-values, this is analogous. To reduce the number of worst-case scenarios, we perform this search simultaneously in both directions and terminate when either one terminates. See Algorithm 4 for an algorithmic description of NNSearch.

Example 4.2. Figure 5 illustrates an exemplary run of this procedure for $k = 1$. The figure shows four states corresponding to the variables of NNSearch(p) after $0, \ldots, 3$ loops. The query point p is the filled square, and a projection of the points to their x- and y-coordinates is shown at the bottom and the left side, respectively. These projections indicate the order of points in $Order_x$ and $Order_y$, respectively. Each state after the first loop also illustrates the variables of NNSearch. The nearest neighbor found so far is marked with a circle and is labeled NN, and the distance $\delta_{\max} = \|p - NN\|_\infty$ is used for the dashed lines that highlight the remaining area of nearest neighbor candidates. Points accessed via $Order_x$ in a previous iteration are marked with a diagonal stripe from the upper left to the lower right. This is done analogously for $Order_y$. Each loop considers the next unmarked point in both directions for both $Order_x$ and $Order_y$. Additionally, the small arrows illustrate the minimal distances $\Delta_{\circ\pm}$ for any further point accessed when iterating over $Order_x$ or $Order_y$ in the respective direction. After the third loop, the arrows of Δ_{y+} and Δ_{y-} both exceed the area of the remaining candidates, represented by the dashed lines. This means that all relevant candidates have been considered via $Order_y$, and that the current nearest neighbor is correct.

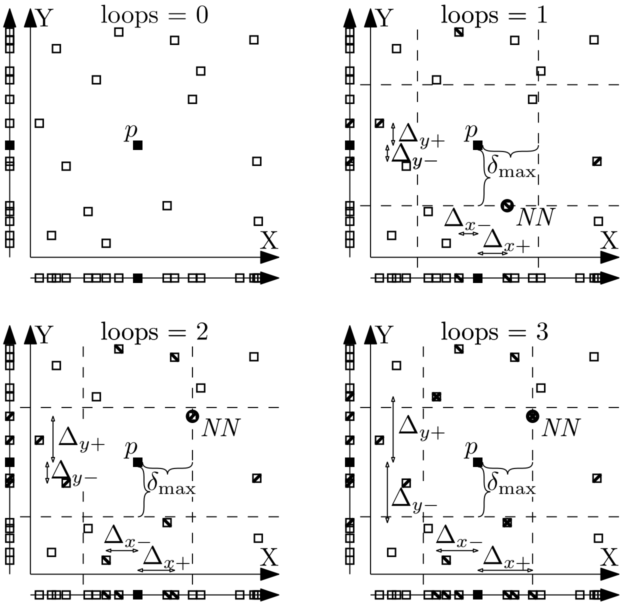

Figure 5: Illustration of Algorithm 4 for each loop.

4.3 Statistical Quality Indicators

Finally we present statistical guarantees for early estimates by IMIE. Since ϱ is a subsample of ρ, statistical tests with μ_ϱ and σ_ϱ^2 yield statistically significant assertions regarding μ_ρ. Equations 7 and 8 give way to analogous assertions for $\widehat{I}(P)$.

Theorem 4.3 ([27]). *Let ρ be a finite population of size n with mean μ_ρ and a variance σ_ρ^2. When drawing an i.i.d. sample ϱ of size m from ρ, the sample mean μ_ϱ has an expected value of $\mathbb{E}(\mu_\varrho) = \mu_\rho$ and a variance of $\sigma_{\mu_\varrho}^2 = \frac{\sigma_\rho^2}{m}\left(\frac{n-m}{n-1}\right)$.*

Proof. See [27]. □

While the classic version of the Central Limit Theorem is not formulated for finite populations, it has been proven that some variations are applicable, and that μ_ϱ is approximately normally distributed [27]. In other words, drawing a sample of size m with a sample mean μ is as likely as drawing μ from $\mathcal{N}(\mu_\rho, \sigma_{\mu_\varrho})$ with $\sigma_{\mu_\varrho} = \sqrt{\sigma_{\mu_\varrho}^2}$. So we can estimate the probability that a sample mean μ_ϱ is off by more than a specified value $\epsilon > 0$ by using the cumulative distribution function Φ of the standard normal distribution $\mathcal{N}(0, 1)$. This is illustrated in Figure 6 and is formally described as

$$\Pr[|\mu_\varrho - \mu_\rho| \geq \epsilon] = 2 \cdot \Phi\left(\frac{-\epsilon}{\sigma_{\mu_\varrho}}\right). \tag{9}$$

Algorithm 4: NNSearch(p)

```

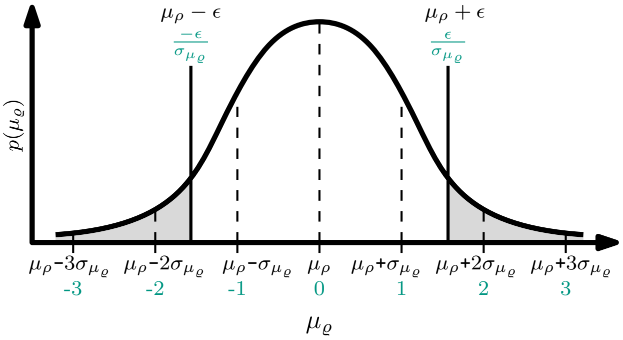

Figure 6: Illustration of the normal distributions $\mathcal{N}(\mu_\rho, \sigma_{\mu_\varrho})$ (upper labels) and $\mathcal{N}(0,1)$ (lower labels).

Alternatively, one can specify a tolerated error probability α and obtain a confidence interval. Let Φ^{-1} be the inverse cumulative distribution function of the standard normal distribution, i.e., $\Phi(\Phi^{-1}(\alpha)) = \alpha$. Then the mean of a sample deviates with probability $1 - \alpha$ by at most $|\Phi^{-1}(\frac{\alpha}{2})| \cdot \sigma_{\mu_\varrho}$ from μ_ρ. This is because both tails of the distributions have to be considered. More formally, it is

$$Pr\left[\mu_\varrho - \left|\Phi^{-1}\left(\frac{\alpha}{2}\right)\right| \sigma_{\mu_\varrho} \leq \mu_\rho \leq \mu_\varrho + \left|\Phi^{-1}\left(\frac{\alpha}{2}\right)\right| \sigma_{\mu_\varrho}\right] \approx 1 - \alpha. \qquad (10)$$

Lastly, there are two more considerations necessary to obtain these statistical guarantees from IMIE. One is that the variance σ_ρ^2, which is used to determine $\sigma_{\mu_\varrho}^2$ in Theorem 4.3, is not known. Using the approximation $\sigma_\rho^2 \approx \sigma_\varrho^2 \frac{m(n-1)}{(m-1)n}$ yields the unbiased approximation $\sigma_{\mu_\varrho}^2 \approx \frac{\sigma_\varrho^2(n-m)}{(m-1)n}$, see [27]. The other point is the *multiple testing problem.* The probabilities for errors only hold for individual tests. But when performing multiple tests to obtain a statistically significant result, the chance of an erroneous result in one test is higher. For instance, this occurs when the response to a statistically insignificant test result is to perform another test, evaluating the result without considering the first, inconclusive result. We illustrate this effect with an example.

Example 4.4. Consider an instance of IMIE that has performed some iterations so far. We use the current mean and var to perform a statistical test whether $\hat{I}(P)$ is above a threshold t. We accept an error chance of 10%. Let us assume that the result of the first test is not significant enough, i.e., the probability is less than 90% based on the current sample. We iterate our estimate a few times and perform a second test, which achieves the desired probability of 90%. However, if $\hat{I}(P)$ is below t, the likelihood that a test reports false certainty based on an unlikely sample increases with each sample. For two tests, the probability of obtaining false certainty is then $Pr[\hat{I}(P) < t] = 1 - (1 - 0.1)^2 = 0.19$.

To account for this problem, we use the correction due to Šidák [29]: To obtain an overall error chance of α, the error chance allowed for the c-th test is $\alpha_{\text{test}} = 1 - (1 - \alpha)^{\frac{1}{c}}$.

To summarize this section, we present the full formula for the c-th statistical test whether $\widehat{I}(P)$ is greater than a threshold t, using variables from IMIE.

$$\Pr[\widehat{I}(P) > t] \approx 1 - \left(1 - \Phi\left(\frac{Offset - Mean - t}{\sqrt{\frac{Var\cdot(|P|-m)}{(m-1)|P|}}}\right)\right)^c \qquad (11)$$

Since we approximate σ_ρ^2, this equation is not exact. On the other hand, the Šidák-correction is very conservative in our case. Namely, when iterating IMIE, the new sample is a superset of the previous sample. This means that the tests based on these samples are dependent, and that the effect of the multiple testing problem is less pronounced. Ultimately, we do not have any formal result to which degree these effects do cancel each other out. In all our experiments in Section 6 however, the error rate never exceeds the bounds established in this section.

5 TIME COMPLEXITY

Now we derive the time complexity of IMIE. First, we do so for our nearest-neighbor search. We then use this result to derive the complexity for initializing and iterating IMIE. Finally, we discuss potential improvements for specific scenarios.

5.1 Nearest-Neighbor Search

We establish the time complexity of Algorithm 4. Each call of UpdateNN(q) takes time in $O(k)$ to compute the (arg) $\max_{r \in NN}$ $\|r - p\|_\infty$. Additionally, let $\mathbb{I}(p)$ be the number of loops performed by NNSearch(p) before terminating. Then the time complexity is in $O(\log n + \mathbb{I}(p) \cdot k)$. Namely, the only other step that is not an elementary assignment is computing the indices of p in $Order_x$ and $Order_y$ with binary search, in $O(\log n)$. However, $\mathbb{I}(p)$ is linear in n for the worst case. Figure 7 shows such a degenerative case, where all points except for p and q are equally distributed among

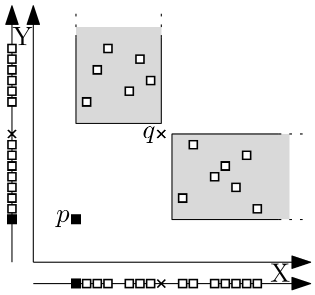

Figure 7: A degenerative case for NNSearch.

the two grey areas. In this case, NNSearch(p) cannot discover the nearest neighbor q via $Order_x$ or $Order_y$ with fewer than $\frac{n-2}{2}$ loops. However, we prove the nontrivial bound $\sum_{p\in P}\mathbb{I}(p) \le (4\cdot\sqrt{n\cdot k}+1)\cdot n$ below.

To prove this bound, we first introduce some additional notation and properties for the several executions of Algorithm 4. For each point $p \in P$, let $V_x(p)$ and $V_y(p)$ be the set of positions of $Order_x$ and $Order_y$, respectively, accessed by NNSearch(p). Additionally, let Pos_x^p be the position of $Order_x$ containing the reference to a point p, i.e., $P[Order_x[Pos_x^p]] = p$. The set of points that access this position during NNSearch(q) is $R_x(p) = \{q \in P : Pos_x^p \in V_x(q)\}$. Pos_y^p and $R_y(p)$ are defined analogously using $Order_y$ instead of $Order_x$. By definition, it is

$$\sum_{p\in P}|V_x(p)| = \sum_{p\in P}|R_x(p)|, \tag{12}$$

as both count the total number of accesses of $Order_x$ across all searches.

Note that NNSearch(q) for points $q \in R_x(p)$ often performs several loops before accessing Pos_x^p. In particular, there are only two points q^+ and q^- such that NNSearch(q^+) and NNSearch(q^-) access Pos_x^p during their first loop. These two points are the points corresponding to the neighboring positions of Pos_x^p, i.e., $q^+/q^- = P[Order_x[Pos_x^p \pm 1]]$. More specifically, for each $c \in \mathbb{N}_0$, there exist at most two points whose positions are exactly c steps away. This is because $Order_x$ is a linear order of a finite set of elements. As a result, $R_x(p)$ defines a lower bound for $\sum_{q\in R_x(p)}\mathbb{I}(q)$. Formally, for each $p \in P$ it is

$$2\cdot\sum_{i=1}^{\frac{R_x(p)-1}{2}} i \le 0+0+1+1+\cdots+\left\lfloor\frac{R_x(p)-1}{2}\right\rfloor \le \sum_{q\in R_x(p)}\mathbb{I}(q). \tag{13}$$

Next, we also consider the properties of $V_y(\cdot)$ and $R_y(\cdot)$. During each loop of a search NNSearch(p), it is $\min(\Delta_{y-},\Delta_{y+}) < \delta_{\max}$. This means that NNSearch(p) accesses at least one new position of $Order_y$ in Line 14 or Line 17. It follows that

$$\mathbb{I}(p) \le |V_y(p)| \tag{14}$$

and with Equation 13, it is

$$2\cdot\sum_{i=1}^{\frac{R_x(p)-1}{2}} i \le \sum_{q\in R_x(p)}|V_y(q)|. \tag{15}$$

Now, we use the fact that NNSearch stops accessing new positions in a certain direction when this direction cannot offer a closer nearest neighbor. In the following lemma, we use this pattern to limit the number of points p where NNSearch(p) accesses certain positions of $Order_x$ and $Order_y$. That is, for each combination of a position of $Order_x$ and $Order_y$, there is only a small number of points whose nearest neighbor search accesses both.

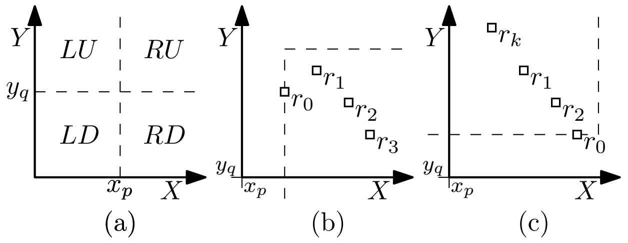

Figure 8: Illustration of arrangements in Claim 5.1. (a) Partitioning of $\mathbb{R}^2$ based on (x_p, y_p). (b),(c) Two cases of layouts of RU.

Lemma 5.1. *For any two points $p, q \in P$, it is $|R_x(p) \cap R_y(q)| \le 4\cdot k$.*

Proof. We consider a partitioning of $\mathbb{R}^2$ into four axis-aligned quadrants RU, RD, LD and LU centered at (x_p, y_q), as illustrated in Figure 8a. To ensure that any point $r \in P \setminus \{p, q\}$ is in exactly one partition, equalities such as $x_r = x_p$ and $y_r = y_q$ are resolved by their ordering in $order_x$ and $order_y$, respectively. For the sake of contradiction, suppose that there are $k+1$ points $\{r_0,\ldots,r_k\} = R_{RU} \subseteq R_x(p) \cap R_y(q)$ in the area RU. We discern between two cases regarding the arrangement of these points.

In the first case, it is $\max_{r,s\in R_{RU}}|x_r - x_s| \ge \max_{r,s\in R_{RU}}|y_r - y_s|$. That is, the largest difference in x-values among points in RU is at least as large as any difference in y-values among RU. For all r in R_{RU}, it is $Pos_x^r > Pos_x^p$. Without loss of generality, let r_0 be the point closest to p and r_k the furthest from p in $Order_x$, respectively. Formally, $r_0 = \arg\min_{r\in R_{RU}} Pos_x^r$ and $r_k = \arg\max_{r\in R_{RU}} Pos_x^r$. This implies that $|x_{r_k} - x_{r_0}| \ge \|r_k - r\|$ for all $r \in R_{RU}$. As illustrated in Figure 8b, NNSearch(r_k) accesses Pos_x^r for all $r \in R_{RU}\setminus\{r_k\}$ before accessing Pos_x^p. After accessing $Pos_x^{r_0}$ and calling UpdateNN(r_0), it holds for the variables in NNSearch(r_k) that $\delta_{\max} = \Delta_{x-}$. The dashed line in Figure 8b illustrates this. This means that NNSearch(r_k) does not access further positions of $Order_x$ in this direction, and thus there is a contradiction to $r_k \in R_x(p)$.

The second case, $\max_{r,s\in R_{RU}}|x_r - x_s| < \max_{r,s\in R_{RU}}|y_r - y_s|$, is symmetric to the first one using $Order_y$ instead of $Order_x$. With r_0 and r_k being the closest and furthest point from q in $Order_y$, NNSearch(r_k) also accesses all positions corresponding to other points in R_{RU} before Pos_y^q. Analogously, it is $\delta_{\max} = \Delta_{y-}$ after calling UpdateNN(r_0), as illustrated in Figure 8c. Thus NNSearch(r_k) does not access the position Pos_y^q, which contradicts $r_k \in R_y(q)$.

As a result there are at most k points from $R_x(p) \cap R_y(q)$ in RU. By symmetry, the same is true for RD, LD, LU. This yields the lemma. □

Combining this lemma with other equations introduced in this section yields the following limit for the total number of iterations performed by all searches.

Lemma 5.2. *For a set $P \subseteq R^2$ of points, the total number of iterations performed by NNSearch(p) for all $p \in P$ is bounded as $\sum_{p\in P}\mathbb{I}(p) \le (4\cdot\sqrt{n\cdot k}+1)\cdot n$.*

Proof. Following Lemma 5.1, each position of $Order_y$ is accessed at most $4 \cdot k$ times by searches accessing one specific position of $Order_x$. More formally, with Equation 15, it is for each $p \in P$

$$\begin{aligned} 4 \cdot k \cdot n \geq \sum_{q \in R_x(p)} |V_y(q)| &\geq 2 \cdot \sum_{i=1}^{\frac{R_x(p)-1}{2}} i \\ &= 2 \cdot \frac{\frac{R_x(p)-1}{2}\left(\frac{R_x(p)-1}{2}+1\right)}{2} \geq \left(\frac{R_x(p)-1}{2}\right)^2 \\ 2\sqrt{k \cdot n} &\geq \frac{R_x(p)-1}{2} \\ 4 \cdot \sqrt{k \cdot n} &\geq R_x(p) - 1 \qquad (16) \end{aligned}$$

Combining Equations 12, 14 and 16 yields

$$\sum_{p \in P} \mathbb{I}(p) \leq \sum_{p \in P} |V_x(p)| = \sum_{p \in P} |R_x(p)| \leq (4 \cdot \sqrt{k \cdot n} + 1) \cdot n. \quad (17)$$

□

Because k is a small constant, the time complexity of performing NNSearch for all points is in $O(n \cdot \sqrt{n})$. So the complexity for each individual search is in amortized $O(\sqrt{n})$.

Theorem 5.3. *NNSearch has an amortized time complexity of* $O(\sqrt{n})$.

5.2 Init and Iterate

We derive the time complexity for initializing and iterating IMIE.

In Init, most operations are assignments, of constant size (Lines 2, 4) or of linear size (Lines 1, 3). The only exception is sorting $Order_x$ and $Order_y$, which is $O(n \log n)$. So the overall runtime of Init is $O(n \log n)$. However, we show in the following section that more efficient variants are possible for scenarios encompassing more than one estimation task. Furthermore, our experiments in Section 6 indicate that the actual runtime of Init often is negligible in comparison to Iterate.

As for the runtime of Iterate, there are only two steps that are not elementary assignments of constant size. One step is computing the marginal counts $MC_k^x(p)$ and $MC_k^y(p)$ (Line 6). It can take place in $O(\log n)$, with binary searches on the sorted arrays as follows. Let i be the smallest integer in $\{0, \ldots, |P| - 1\}$ with $x_{P[Order_x[i]]} \geq x_p - \delta_k^x(p)$. Similarly, let j be the largest integer in $\{0, \ldots, |P| - 1\}$ with $x_{P[Order_x[j]]} \leq x_p + \delta_k^x(p)$. Because $Order_x$ contains all points sorted by x-coordinate, it is $MC_k^x(p) = j - i$. The other marginal count $MC_k^y(p)$ is available analogously, using $Order_y, y_p$ and $\delta_k^y(p)$ instead. The other step is the nearest neighbor search (Line 4), which has an amortized time complexity of $O(\sqrt{n})$ by Theorem 5.3. As a result, Iterate also has an amortized time complexity of $O(\sqrt{n})$. Since P and thus ρ contain n elements, IMIE requires time in $O(n\sqrt{n})$ to reach the final estimate, the one equal to the KSG estimate. This means that IMIE is only slightly slower in reaching the final result than the lower bound $O(n \log n)$ for algorithms without preliminary results [32].

5.3 Scenario-specific Improvements

The initialization procedure presented in Section 4 explains the core concept and properties. Init has been described in a way that is always applicable. However, in many scenarios a user has more than one estimation task based on the same or similar data. Think of estimating the MI for overlapping attribute pairs when searching for strongly dependent attributes. In such a case, it may not be necessary for each instance of IMIE to sort the arrays from scratch, which is the primary computational burden of Init. In this section we present the improvements possible for IMIE in scenarios with high-dimensional data as in Scenario 1 and with streaming data as in Scenario 2. We consider benefits over both the naïve initialization of IMIE as well as the non-iterative estimation.

High Dimensional Data. The number of attribute pairs grows quadratically with the number of attributes. If the data has d attributes, the number of pairs is $\frac{d \cdot (d-1)}{2}$. We now consider using one instance of IMIE for each pair to obtain the pairwise MI estimates. A naïve initialization of these instances would require time in $O(d^2 \cdot n \log n)$. However, we only need to sort the points once per attribute to use the respective sorted arrays for several attribute pairs. This reduces the time complexity for initialization to $O(d \cdot n \log n)$.

Non-iterative estimators for the KSG use two-dimensional space-partitioning trees [19, 31, 32]. This means that each attribute pair requires a different tree, which prohibits a similar improvement. In addition, non-iterative estimators must commit the computation time beforehand. IMIE in contrast can budget computation time between different pairs of attributes, depending on which pairs a user finds interesting, based on the preliminary estimates.

Data streams. With data streams, new data is arriving continuously, and computation time is limited. We consider estimating the current MI using all points whenever new data arrives. This means that most data points remain unchanged. When maintaining up-to-date MI estimates, IMIE can reuse the instance of Data Structure 1 used for the previous estimate instead of another initialization. Considering Data Structure 1, only the adjustment of $Order_x$, $Order_y$ and $Order_R$ does not incur constant costs when a new data point arrives. Adjusting $Order_x$ and $Order_y$ to accommodate new data can take place in $O(\log n)$.[1] Since $Order_R$ is shuffled randomly during the estimation, IMIE can also start off with a (partially) shuffled order and only needs the addition of new indices for new data items. This means that initialization of a new estimator on a data stream can take place in $O(\log n)$ instead of $O(n \log n)$.

Additionally, if the delays between items from the data streams are irregular in length, IMIE automatically offers the best estimate for the time available. Previous work regarding efficient, non-iterative MI estimation on streams [4, 14, 32] imposes a fixed computation time, and there is no easy adjustment if items arrive faster.

Takeaway. While the time complexity of Init may appear prohibitively large in the previous section, we have demonstrated in this section that concrete settings can allow for more efficient solutions. Note that the improvements described are not mutually exclusive. This means that both improvements can be combined when dealing with high-dimensional data in the form of streams. Table 1 summarizes the impact of these techniques on the initialization of IMIE for pairwise MI estimation between d data streams.

[1] From a technical perspective, this time complexity requires $Order_x$ and $Order_y$ to be implemented as binary search trees. For simplicity we keep calling them sorted arrays.

Optimization	Time Complexity
Naïve application	$O(d^2 \cdot n \log n)$
Reuse previous data structure	$O(d^2 \cdot \log n)$
Reuse sorted dimensions	$O(d \cdot n \log n)$
Both	$O(d \cdot \log n)$

Table 1: Impact of optimization techniques for initializing IMIE for pairwise MI of d data streams.

6 EXPERIMENTS

In this section we investigate the performance of IMIE in terms of runtime and estimation quality. We also perform experiments to test the potential benefits from the statistical guarantees and the anytime property of IMIE.

As reference for the performance of IMIE we use the KSG (see Equation 5), because it offers high-quality estimations, and it is the basis of IMIE. To ensure competitive runtime of the KSG we use KD-Trees for its nearest-neighbor search, resulting in the optimal computation complexity of $O(n \log n)$ [32]. As a reference point for faster estimates with lower estimation quality, we use the KSG on subsamples of the data. Since the number of points subsampled can be expressed as a percentile of all points or as an absolute number, we introduce a notation for both. Using a random sample of p% from all data points to compute the KSG is denoted as *KSG%p*. Subsampling exactly q points at random from all data points to compute the KSG on this subsample is denoted as *KSG@q*.

Setup. All approaches and experiments are implemented in C++ and compiled using the Microsoft® C/C++ Optimizing Compiler Version 19.00. We use the non-commercial ALGLIB[2] implementation of KD-Trees for the KSG. We also use the non-commercial ALGLIB[2] implementation of the cumulative density function of the standard normal distribution Φ and its inverse Φ^{-1} when computing our statistical guarantees. All experiments are conducted on Windows 10 using a single core of an Intel® Core™ i5-6300U processor clocked at 2.4 GHz and 20GB RAM.

6.1 Data

In our experiments we use both synthetic and real-world data. As synthetic data, we use dependent distributions with noise used to compare MI estimators, see [15], uniform distributions used to compare MI with the maximal coefficient, see [16], as well as independent uniform and normal distributions. As real data, we use smart meter readings from an industrial plant (HIPE) [3], recorded smart phone sensors to recognize human activities (HAR) [7], and physical quantities for condition monitoring of hydraulic systems (HYDRAULIC) [12]. As proposed by the inventors of the KSG [19], we prevent duplicate points in real-world data by adding noise with minimal intensity. Beginning with real-world data, we now briefly describe the data specifics.

HIPE. This data set, available online[3], contains high-resolution smart meter data from 10 production machines over 3 months. This data has over 2000 attributes total and over 1.5 million data points. We consider a reduced data set containing the first 1000 data points of the machines “PickAndPlaceUNIT”, “ScreenPrinter” and “VacuumPump2” with a grand total of 333 attributes.

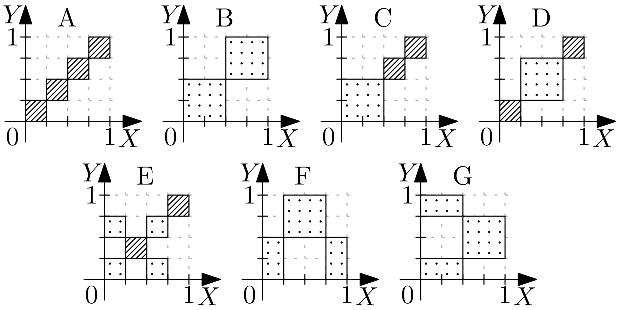

Figure 9: An overview of the uniform distributions used.

HAR. This data set, available at the UCI ML repository[4], features accelerometer and gyroscope sensor readings from smartphones to classify the activity of the human carrying the phone. The data set contains 561 attributes and a total of 5744 data points.

HYDRAULIC. This data set, available at the UCI ML repository[5], features recordings of several physical quantities such as temperature, vibrations and efficiency factors at different sampling rates. For our experiments we use all quantities with a sampling rate of 10 Hz. As a result, each of the 2205 data points has 480 attributes.

For synthetic data, we use the following distributions with known MI values [16, 23]. For distributions with a noise parameter σ_r, we vary σ_r between 0.1 and 1.0.

Linear To construct the point $p_i \in P$, we draw the value x_i from the normal distribution $N(0, 1)$. Additionally, we draw some noise r_i from the normal distribution $N(0, \sigma_r)$, where σ_r is the noise parameter of the distribution. This yields the point $p_i = (x_i, x_i + r_i)$.

Quadratic This distribution is generated analogously to the linear distribution, except that the point is $p_i = (x_i, x_i^2 + r_i)$.

Periodic For each point $p_i \in P$, we draw the value x_i from the uniform distribution $U[-\pi, \pi]$. Additionally, we draw some noise r_i from the normal distribution $N(0, \sigma_r)$, where σ_r is the noise parameter. This yields the point $p_i = (x_i, \sin(x_i) + r_i)$.

Uniform The uniform distributions A to G we use are illustrated in Figure 9. Note that the striped areas contain twice as many points as the dotted areas. For these distributions, each striped area with size $0.25 \cdot 0.25$ contains 25% of all points, while dotted areas of the same size contain 12.5% of all points.

Independent Lastly, we use the distributions U_{IND} and N_{IND}, where each point consists of two values drawn independently from $U[0, 1]$ and $N(0, 1)$, respectively.

6.2 Synthetic Benchmarks

We first evaluate the concrete runtimes of IMIE. While we have established in Section 5 that the time complexity is competitive, actual runtimes may have constant factors that time complexity does not capture. We also look at the estimation quality offered by IMIE after a variable number of iterations. Since the true MI value of real data is unknown, we perform these experiments using

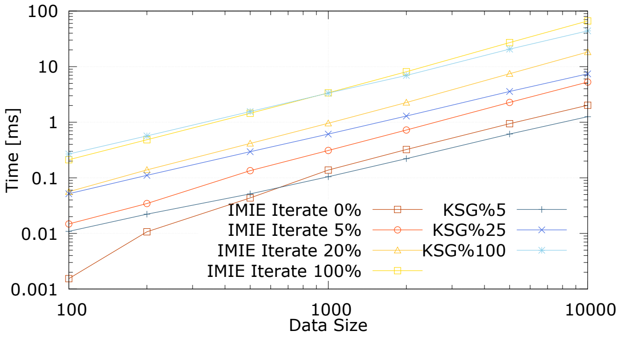

Figure 10: Average runtime depending on the data size for IMIE and subsampling variants.

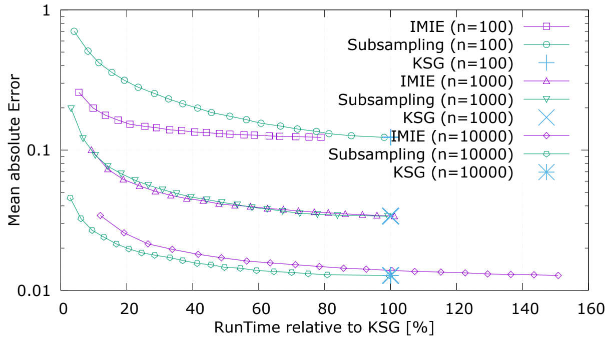

Figure 11: MAE of IMIE and subsampling depending on the runtime relative to KSG for the same data.

synthetic data. Each synthetic data set corresponds to one pair of attributes, for which we produce samples of varying sizes. For each pair, sample size and estimator, we perform 100 estimates and average the runtime and mean absolute error (MAE).

Figure 10 shows the average runtime of IMIE with various numbers of iterations and the KSG with various subsampling settings. Note that the concrete performance of IMIE when iterating until convergence and *KSG%*100 is very similar. This means that computing the exact KSG in the conventional way with a KD-tree and without preliminary results is not faster than using IMIE. Another point to observe is the difference in runtime between IMIE with only the initialization and IMIE that has performed some iterations. Even with only 5% of the iterations, IMIE already consumes more than double the time used for initialization. This shows that the time used for iterations quickly dominates the time required for initialization, even though Init has a high time complexity.

Figure 11 graphs the MAE of subsampling and IMIE depending on the runtime. The plot shows curves per estimator corresponding to a specific sample size, and the time is measured relative to the runtime of the naive KSG estimation for this size. Each point corresponds to the average runtime and absolute error of 100 estimations with the same number of iterations or subsampling size, respectively. In other words, the leftmost point corresponds to subsampling 5% or iterating 5% respectively, while the rightmost point uses all points or iterates until convergence, respectively. The result is that IMIE and KSG with subsampling offer the same time-quality-tradeoff for data of size 1000, with IMIE being somewhat faster for smaller data and somewhat slower for larger data. However, this assumes “optimal” subsampling, in the sense that it is known beforehand which subsampling size is desired. In cases where it is not clear how much time is available or how much time an estimate for a given subsample size takes, this is not given. The time spent finding a good subsampling size is discussed in Section 6.4.

6.3 Statistical Quality Indicators

Next, we investigate the practical relevance of the statistical guarantees. The scenario considered is high-dimensional data. A common information need for high-dimensional data is finding highly dependent attributes. In our experiments we want to know for each of the $\frac{d\cdot(d-1)}{2}$ pairs of attributes whether it is above or below a threshold τ. For IMIE we keep iterating the estimate and perform the test from Equation 11. To be precise, one test is performed for $I(P) > \tau$, and one test is performed for $I(P) < \tau$. To reduce the necessary Šidák-correction for our significance level α_{test} we perform these two tests only every 10 iterations. We start with a minimum sample size of 30 to reduce effects of minimal sample sizes. The exact choice of initial iterations and iterations between tests is arbitrary as long as they are not extreme, e.g., performing statistical tests with sample size one or iterating $\frac{|P|}{4}$ times between tests. Regarding the target significance level, we test different values $\alpha \in \{0.1, 0.05, 0.01, 0\}$. We use fixed percentile subsamples for comparison, i.e., *KSG%5*, *KSG%25* and *KSG%50*.

Figure 12 shows the results for the three real-world data sets with τ varying between 0 and 1. The figure contains two plots per data set. The “Error Rate” shows the number of pairs falsely classified over or under τ as a relative count of all pairs (left axis) and as absolute count (right axis). The “Run Time” shows the total execution time relative to the "naïve" estimation using the KSG (left axis) and as absolute time (right axis). The behavior depending on τ is different per data set. This is because the dependencies in the data are distributed differently. The closer τ is to the actual MI value, the easier it is for an approximate result to be above the threshold while the actual value is below, or vice versa. So it is harder to obtain statistical certainty that the actual value is above or below. To illustrate, the attributes in HIPE are largely independent. This yields MI values close to zero, resulting in high error rates for subsampling approaches and longer execution times for IMIE. Conversely, the attributes of HYDRAULIC are highly dependent. This in turn increases error rates and computation times, for subsampling and IMIE respectively, for higher threshold values.

Nevertheless, there are several common patterns. One is that IMIE does offer better time-quality-tradeoffs than subsampling. I.e., for each subsampling rate there is an α such that IMIE yields fewer errors using less time. A second pattern is that IMIE does adapt to “tough threshold values” by increasing the computation time used. Subsampling in turn makes more false claims. A third interesting pattern is that IMIE with $\alpha = 0$ is almost always faster than the naïve KSG estimation. IMIE can speed up such queries significantly with essentially no risk of error.[6]

6.4 Anytime Experiments

Now we test the performance of IMIE as anytime algorithm. In other words, the available time is not known beforehand. To

[6] Technically there could still be errors due to rounding, numerical evaluation of Φ^{-1} and the approximation in Section 4.3. However, no such error has occurred in any of our experiments.

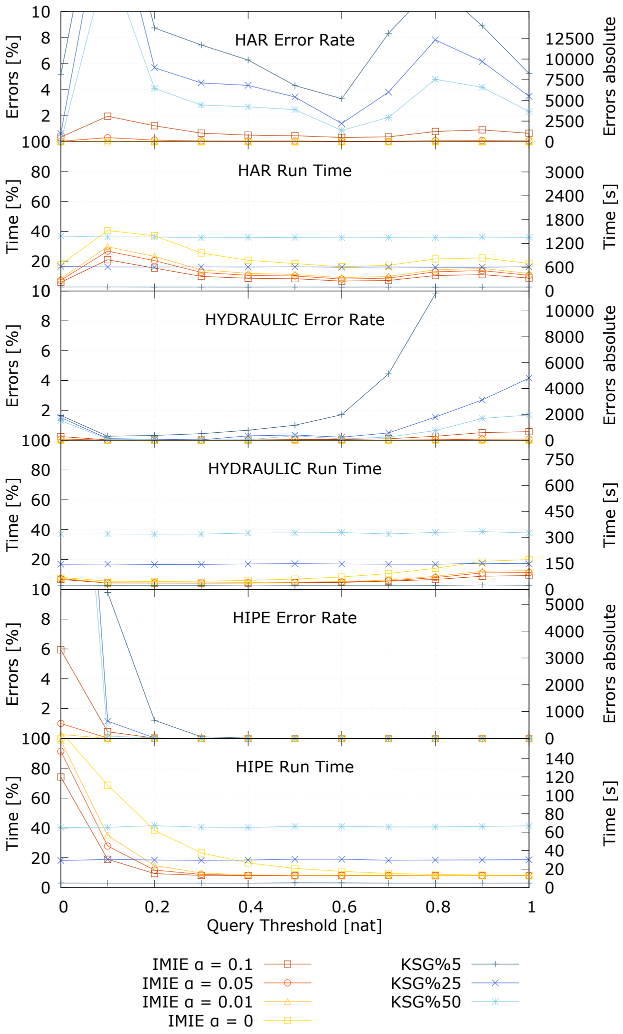

Figure 12: Time and error rate of IMIE and subsampling variants, depending on the chosen threshold τ.

mimic the behaviour of IMIE to improve the estimate with additional time, we also examine two strategies based on subsampling. KSG_{Lin} consecutively computes *KSG%10*, *KSG%20*, . . . , *KSG%100* as long as time is available. We also consider KSG_{Exp}, which computes *KSG@10*, *KSG@20*, *KSG@40*, *KSG@80*, etc. until no time is left.

For this experiment we randomly select 100 pairs of attributes from each real-world data set and estimate MI using IMIE, KSG_{Lin} and KSG_{Exp}. After some time the estimate is interrupted, and the most recent result is used. Since IMIE and subsampling appear most comparable in our synthetic benchmarks for data size $n = 1000$, we use the first 1000 data points of each attribute pair. Given the small scale of time per estimate (cf. Figure 10), we use 1000 estimators in parallel for each pair. One "iteration" then performs the next computation sequentially for each of these estimators.

Figure 13 shows the mean absolute error compared to a KSG estimate using 1000 points as well as the mean standard deviation of estimates for the same attribute pair. Additionally, for each estimate from IMIE we use the statistical quality indicator to determine the distance ϵ. Additionally, the plot displays the average value ϵ such that our preliminary estimate is wrong by at most ϵ with a confidence of 95%. This value is obtained for each estimate using Equation 10. Note that KSG_{Lin} does not consistently produce estimates with time less than 0.3 ms per estimate, and IMIE does not consistently finish the first iteration in 0.1 ms.

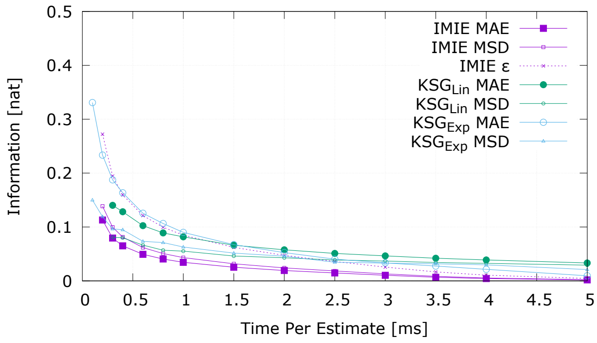

Figure 13: Mean absolute error (MAE) and mean standard deviation (MSD) of anytime approaches as well as the mean ϵ of IMIE.

A result of this experiment is that IMIE has smaller errors on average than the subsampling approaches, even though they are comparable in Figure 11. This is because the subsampling strategies are not efficient for iterative estimation. Estimates from previous iterations are discarded without further benefit, and iteration steps are less granular. This means that only a part of the overall time available is spent on the estimate that is ultimately presented.

6.5 Discussion

To summarize this section, IMIE offers a time-quality tradeoff similar to the one when estimating the KSG with varying subsampling settings. The time necessary for IMIE to converge towards the KSG result is slightly lower for small data and slightly higher for larger data, compared to the naive KSG estimation. But IMIE also offers preliminary results and achieves this time-quality tradeoff even if the time available is not known beforehand. This means that IMIE offers significant benefits for tasks that use these features, such as threshold queries or irregular data-stream processing, without notable drawbacks for regular tasks.

7 CONCLUSIONS

In this work, we have studied the iterative estimation of Mutual Information (MI). The goal has been to provide an estimator that offers a first estimate quickly and improves the estimation with additional time. It should also use the available time efficiently, even if the time available is not known beforehand. To this end, we have proposed IMIE.

By design, IMIE converges towards the same result as the popular MI estimator (KSG) by Kraskov et al. [19] after sufficiently many iterations. Before convergence, the preliminary results of IMIE also offer helpful statistical quality indicators which one can use to infer information regarding the final estimate, i.e., the KSG result. This can take the form of confidence intervals or the probability of surpassing a certain threshold. In addition to these formal results on estimation quality, we also have studied the time complexity of IMIE both in general and when tailored towards specific use cases. One result is that this complexity when computing the exact KSG estimate is only slightly larger than an optimal implementation to compute the KSG that does not offer any preliminary result.

Using extensive experiments, we have evaluated the practical performance of IMIE in terms of concrete runtimes and quality on real data. Among other results, IMIE remains competitive with its estimation quality per time, even when being compared to approaches without preliminary results. The experiments also demonstrate a significant runtime improvement when searching for attribute pairs with high MI in high-dimensional data.

ABSTRACT

We introduce *Functional Geometric Monitoring (FGM)*, a substantial theoretical and practical improvement on the core ideas of Geometric Monitoring. Instead of a binary constraint, each site is provided with a non-linear function, which, applied to its local summary vector, projects it to a real number. The sites collectively monitor the sum of these one-dimensional projections and as long as the global sum is subzero, the monitoring bounds are guaranteed. We demonstrate that FGM is as generally applicable as Geometric Monitoring, and provides substantial benefits in terms of performance, scalability, and robustness. In addition, in FGM it is possible to prove worst-case results, under standard monotonicity assumptions on the monitoring problem. In terms of performance, the salient quality of FGM is that it can adapt naturally to adverse changes in the monitored problem, such as lack of monotonicity or very tight monitoring bounds, where no method can deliver asymptotically good performance. We provide formal proofs for many of the properties of FGM, and present an extensive empirical performance evaluation under adverse conditions, on real data.

KEYWORDS

distributed functional monitoring, geometric monitoring, distributed streaming

1 INTRODUCTION

The explosion in the amount of data generated online is entering its next phase, as the Internet of Things (IoT) is set to increase the number of networked data sources by orders of magnitude in the near future. Thus, there is a clear need for ever more scalable techniques for *distributed* stream processing, where the tsunami of data generated by networked nodes is filtered and summarized in near-real time at (or, near) the source, drastically reducing the required communication costs.

Motivated by such needs, there has been significant research effort on the distributed functional monitoring problem, over the past decade. Much effort has concentrated on worst-case communication complexity for particular types of important queries, such as frequency moments, heavy hitters, percentiles, distinct elements etc. Early on, it became apparent that many of these problems can have very bad worst-case performance, unless certain assumptions were made, in particular with respect to monotonicity, about the input streams and/or the monitored functions.

A problem not yet addressed by previous work on monitoring algorithms, is that it can be a challenge to *integrate* them into large stream processing frameworks, such as STORM and Spark, or even more targeted systems such as Gorilla and InfluxDB. Indeed, while such frameworks are a staple of modern information systems, the algorithmic work on distributed functional monitoring has not yet found practical adoption in them. Part of the reason is, we believe, lack of uniformity; each distributed monitoring algorithm imposes different requirements on the system architecture and its communication patterns. Historically, this was also the case with databases, until adoption of the relational model (its limitations notwithstanding) created a vibrant industrial and research ecosphere.

A technique—to our knowledge, the only one—intended to be applicable to *arbitraty continuous queries* is Geometric Monitoring (GM) [27]. A strong appeal of GM is that it separates the complexities of the monitored query operator, from the communication protocol that executes the monitoring. Unfortunately, although it can be very successful at reducing the communcation cost in real-world applications, its performance can degenerate under certain circumstances, such as high stream variability, or skew between the relative rates of local streams. On the theoretical side, the GM is not known to provide any cost guarantees, even under monotonicity assumptions.

Related Work. After the introduction of (centralized) streaming algorithms in the mid '90s, several works proposed *distributed streaming* techniques for particular important problems, such as linear functions [16, 17, 23], top-*k* queries [3, 24], ratio thresholding queries [15], and polynomials of scalar variables [26]. Of particular importance is the problem of tracking sketch synopses [7] of local streams, which can be applied to the approximation of self-join and join aggregates [5, 6].

The first (and, to our knowledge, only) general-purpose technique, Geometric Monitoring (GM), was first proposed in [27, 28]. This paper ignited a rich line of work, part of which related to improving the basic method [14, 18–22], and also utilizing it in important applications (e.g., [4, 11, 12, 25] to name but a few). Interestingly, despite the rich mathematical techniques employed in this body of work, to date there have been no analytical results on the *communication cost* of the method, even under strict assumptions.

Starting with the fundamental results of Cormode et al. [9], the problem of continuous query tracking over distributed streams has also been studied in a theoretical setting in recent years, within the broad framework of communication complexity; the minimum amount of bits that needs to be exchanged between a group of communicating parties, each party observing incrementally a local dataset, so that a global function on the union of the data possessed by all players can be *continuously* tracked with some bounded error. Much of the work has concentrated on the hardness of the problem. It has been shown [1] that the worst-case communication cost of distributed function monitoring can hardly improve upon the baseline method of centralizing all local data, unless restrictive assumptions are made; this is true even for the trivial problem of maintaining a distributed counter. Despite the general negative results, there are also positive results for particular problems of interest, e.g., [1, 9, 29, 30] to name but a few.

Series ISSN: 2367-2005

10.5441/002/edbt.2019.09

In particular, [9] provides optimal results on the communication complexity of monitoring a linear monotone function, while subsequent papers [1, 29] prove strong lower-bounds showing that guaranteeing better than linear worst-case communication costs is probably impossible for complex, non-linear query functions.

Our Contributions. We propose *Functional Geometric Monitoring (FGM)*, a technique which can conceptually be applied to any monitoring problem, in order to perform distributed monitoring with communication costs that are lower (often by orders of magnitude) compared to centralizing all data to a coordinator. The FGM comprises of a distributed algorithm which is independent of the monitoring problem. In order to perform a monitoring task, the FGM must be parameterized by a problem-specific family of functions (termed safe functions later in the paper); to this end, the FGM draws on and can utilize the extensive previous work on distributed monitoring, where such functions have been proposed for a large variety of monitoring problems [11, 13, 21]. Combined with these previous results, FGM is a technique that is ready to be utilized to real distributed monitoring applications.

The strict separation of concerns between distributed systems issues and the monitoring problem, is critically important to anyone wishing to implement distributed monitoring on a general-purpose middleware platform. In addition, despite this strict separation, the FGM offers significant improvements to the communication cost of distributed monitoring, compared to previous monitoring techniques, notably the GM. In particular, FGM has provably better performance than GM, regardless of the monitoring problem. In fact, under FGM it is possible to provide good worst-case guarantees on the communication cost of specific monitoring problems, comparable to the best known theoretical results on distributed functional monitoring. By contrast, no such results are known for GM. In this paper, we provide such worst case analytical results for monitoring frequency norms.

Another issue that has not been treated uniformly—and has often been ignored—by previous techniques, is the detection and response of the monitoring algorithm to circumstances where the monitored constraints (thresholds) are too “tight”; in such occasions, any distributed monitoring algorithm would be unable to do better than to naively centralize all data to a coordinator. Such situations occur frequently in practice, and practical monitoring algorithms should be able to smoothly transition their operation for handling such loads. An important fetaure of FGM is that it can adapt to these high variability situations seamlessly; that is, in a problem-independent manner, and within the logic of the basic protocol.

In addition, FGM’s performance is resilient to the presense of skew in the distribution of data among distributed nodes, as well as in the relative rates of local streams; its performance is fundamentally determined by the characteristics of the global stream (i.e., the union of all distributed streams). Again, this is a novel feature; the performance of previous techniques, notably of GM, is adversely affected in the presense of skew. We have performed extensive experiments that demonstrate and quantify the resilience of FGM both in adverse streaming conditions of high variability, and in the presense of skew.

2 FUNCTIONAL GEOMETRIC MONITORING

The focus of this section is to present the basic principles and protocol of Functional Geometric Monitoring (FGM). Our discussion employs standard notation and terminology from functional analysis: Vectors are denoted by boldface letters, and sets of vectors are added by Minkowski addition:

$$A + B = \{\boldsymbol{x} + \boldsymbol{y} \mid \boldsymbol{x} \in A, \boldsymbol{y} \in B\}.$$

We write $\boldsymbol{x} + A$ instead of $\{\boldsymbol{x}\} + A$; also, $\lambda A = \{\lambda \boldsymbol{x} | \boldsymbol{x} \in A\}$. Finally, in some proofs, we assume some familiarity with the properties of convex functions and sets; in particular, the biconjugate (convex hull of a function), norms and semi-norms, gauge functions and convex cones. The convex hull of A is $\operatorname{conv} A$.

2.1 Background: Approximate Query Monitoring

We adopt the standard data model for distributed data streams. Assume that there are k distributed sites, and that at each site, a local stream is generated or collected, denoted as a (very high-dimensional) vector in vector space $\mathbb{R}^D$. This vector can be the frequency vector of the stream records, or a linear sketch thereof, and changes as stream updates arrive. Let $\boldsymbol{S}_i(t)$, $i = 1 \dots k$ denote the local state vectors. Every site communicates with a coordinator, where users pose queries on the global stream. Without loss of generality, assume that the global stream state is the average of the local stream states, i.e., $\boldsymbol{S}(t) = \frac{1}{k}\sum_{i=1}^{k} \boldsymbol{S}_i(t)$. (Other linear formulas, e.g., sum, can be treated by multiplying local state vectors with scalars as needed.)

We consider two types of queries on this model. In the *one-shot* query, the coordinator needs to monitor for the event $Q(\boldsymbol{S}(t)) \le T$, where Q is a query function and T a threshold. On the other hand, for a *continuous* query, the coordinator needs to maintain at all times a close estimate $Q(\boldsymbol{E}(t))$ of the true value of the query $Q(\boldsymbol{S}(t)$, so that

$$Q(\boldsymbol{S}(t)) \in (1 \pm \varepsilon) Q(\boldsymbol{E}(t)). \tag{1}$$

This guarantee is maintained by the local sites periodically flushing the updates received to their local streams. In particular, the coordinator maintains, for each site i, an estimated state vector $\boldsymbol{E}_i$. When a flush occurs, the site transmits its *drift vector* $\boldsymbol{X}_i(t) = \boldsymbol{S}_i(t) - \boldsymbol{E}_i$, and the coordinator updates $\boldsymbol{E}_i$ by adding $\boldsymbol{X}_i$ to it, while the site resets $\boldsymbol{X}_i$ to 0. Then, the coordinator updates the global estimate $\boldsymbol{E} = \frac{1}{k}\sum_{i=1}^{k} \boldsymbol{E}_i$.

Note that a site can transmit its drift $\boldsymbol{X}_i$ either as a vector of size D, or as a list of the records that arrived since the previous flush (whichever is smaller), therefore the total communication cost for flushing is never worse than tranmitting all data to the coordinator.

In geometric monitoring, the correctness criterion is described as a geometric constraint, of the form $\boldsymbol{S} \in A$, where $A \subseteq \mathbb{R}^D$ is the *admissible region*, that is, the set of global stream states where the constraint holds. That is,

$$A = \left\{ \boldsymbol{x} \in \mathbb{R}^D \mid Q(\boldsymbol{x}) \le T \right\} \qquad \text{one-shot queries} \tag{2}$$

$$A = \left\{ \boldsymbol{x} \in \mathbb{R}^D \mid Q(\boldsymbol{x}) \in (1 \pm \varepsilon) Q(\boldsymbol{E}) \right\} \qquad \text{continuous queries} \tag{3}$$

2.2 Communication costs

We assume that each message consists of a sequence of *words*, of sufficient size. In particular, we assume that each word can store a real number; all our protocols are robust against finite precision, so this is not an unrealistic assumption.

We distinguish two directions in communication. *Downstream communication* consists of messages from local nodes to the coordinator, while *upstream communication* consists of messages from the coordinator to local nodes. We do not consider a multicast capability, although our work can be adapted to such settings.

2.3 Safe functions

Our starting point relates to the representation of a safe *configuration*, in a monitoring algorithm. The *configuration* of the system of k sites is a is a (kD)-dimensional vector consisting of the *concatenation* of the k local drift vectors, $\boldsymbol{X}_i$. The system is in a safe state as long as $\boldsymbol{E} + \frac{\sum_{i=1}^{k} \boldsymbol{X}_i}{k} = \boldsymbol{S} \in A$.

To guarantee that a configuration is safe, FGM employs a real function $\phi : \mathbb{R}^D \to \mathbb{R}$, depending on A, $\boldsymbol{E}$ and k. Each site tracks its ϕ-value, $\phi(\boldsymbol{X}_i)$, as $\boldsymbol{X}_i$ is updated. System safety is guaranteed by tracking the sign of the *sum* $\psi = \sum_{i=1}^{k} \phi(\boldsymbol{X}_i)$. In particular, we need to guarantee that $\psi \leq 0$ implies $\boldsymbol{S} \in A$.

Definition 2.1 (($A, \boldsymbol{E}, k$)-safe function). A function $\phi : \mathbb{R}^D \to \mathbb{R}$ is *safe* for admissible region $A \subseteq \mathbb{R}^D$, vector $\boldsymbol{E} \in \mathbb{R}^D$, and $k \geq 1$, if, $\phi(\boldsymbol{0}) < 0$ and, for all $\boldsymbol{X}_i \in \mathbb{R}^D$, $i = 1, \ldots, k$,

$$\sum_{i=1}^{k} \phi(\boldsymbol{X}_i) \leq 0 \implies \boldsymbol{E} + \frac{\sum_{i=1}^{k} \boldsymbol{X}_i}{k} \in A.$$

Much of previous work on distributed monitoring has proposed safe functions for specific problems. Since we indend to explore the FGM in terms of its generality, we are interested in properties of safe functions as a class.

First, note that safety is preserved under common pointwise operations: positive scaling, addition and pointwise supremum. Consequently, $(A, \boldsymbol{E}, k)$ safety is monotone under pointwise dominance, i.e., if ϕ is $(A, \boldsymbol{E}, k)$-safe and $\forall \boldsymbol{x}, \phi(\boldsymbol{x}) \leq \phi'(\boldsymbol{x})$, then ϕ' is also $(A, \boldsymbol{E}, k)$-safe.

In fact, more can be said about addition and pointwise supremum of safe functions; they can be employed to *compose* safe functions for an admissible region A, defined by a set-algebraic expression over some family of admissible regions $\{A_i\}$, when a safe function ϕ_i for each A_i is available.

Theorem 2.2. *Let ϕ_i be $(A_i, \boldsymbol{E}, k)$-safe, for each $i \in I$ respectively. Then,*

- $\sup_{i \in I} \phi_i$ *is* $(\bigcap_{i \in I} A_i, \boldsymbol{E}, k)$*-safe, and*
- $\sum_{i \in I} \phi_i$ *is* $(\bigcup_{i \in I} A_i, \boldsymbol{E}, k)$*-safe, provided that I is finite.*

On the dependence on k, note that, for any divisor k' of k, a k-safe function is also k'-safe , and 1-safe in particular. Therefore a necessary condition for k-safety is that the 0-sublevel $L(\phi) = \{\boldsymbol{x} | \phi(\boldsymbol{x}) \leq 0\}$, shifted by $\boldsymbol{E}$, be a subset of A:

$$\boldsymbol{E} + L(\phi) \subseteq A.$$

2.3.1 Safe functions and convexity. Intuitively, we can "improve" a safe function ϕ by finding a function $\phi' \leq \phi$ that is still safe; ϕ' is improved in the sense that the set of configurations where $\psi \leq 0$ is larger for ϕ' than for ϕ.

In this respect, of particular interest are functions that are safe for all k (and fixed A, $\boldsymbol{E}$). We denote such functions as $(A, \boldsymbol{E})$-safe. The salient property of $(A, \boldsymbol{E})$-safe functions is that they can always be "improved" into dominated, *convex* safe functions.

Theorem 2.3. *If a function ϕ is $(A, \boldsymbol{E})$-safe, there exists a* ***convex*** *function $\zeta \leq \phi$ which is also $(A, \boldsymbol{E})$-safe.*

Proof. Ommitted due to space constraints. □

Convex safe functions are appealing because they admit a very simple criterion for $(A, \boldsymbol{E})$-safety.

Lemma 2.4. *A convex function ζ with $\zeta(\boldsymbol{0}) < 0$ is $(A, \boldsymbol{E})$-safe, if and only if, $\boldsymbol{E} + L(\zeta) \subseteq A$.*

Proof. We have already seen that $\boldsymbol{E}+L(\zeta) \subseteq A$ is necessary for safety. Sufficiency follows directly from the convexity of ζ. □

2.3.2 Quality of safe functions. Consider the set $C \subseteq \mathbb{R}^{kD}$ of safe configurations of a monitoring problem

$$C = \left\{(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k) \mid \boldsymbol{E} + \frac{1}{k}\sum_{i=1}^{k} \boldsymbol{X}_i \in A\right\} \tag{4}$$

The FGM protocol under-approximates this set by the set of configurations, where $\psi \leq 0$. Call this the *quiescent region* $\boldsymbol{Q}_\phi$, which is determined by the choice of safe function ϕ. We would like to characterize ϕ so that $\boldsymbol{Q}_\phi$ is as large (inclusion-wise) as possible, in order to improve the approximation of C. Such a characterization is possible if we restrict our attention to $(A, \boldsymbol{E})$-safe (and by virtue of the above theorem, convex) functions.

Intuitively, the issue that we examine can be presented with an example: assume that $A = \{\boldsymbol{x} | \|\boldsymbol{x}\| \leq 1\}$ is the unit ball, and take $\boldsymbol{E} = \boldsymbol{0}$. It is easy to see that both convex functions $\|\boldsymbol{x}\| - 1$ and $\|\boldsymbol{x}\|^2 - 1$ are suitable safe functions. However, the former choice is superior to the latter, when the size of the quiescent region is taken into account. To see this, note that $(1/2)(\|\boldsymbol{x}\|^2 - 1)$ strictly dominates $\|\boldsymbol{x}\| - 1$; therefore, a configuration say, $(\boldsymbol{0}, \boldsymbol{p})$ with $\|\boldsymbol{p}\| = \sqrt{3}$ is quiescent for $\|\boldsymbol{x}\| - 1$ but not for $\|\boldsymbol{x}\|^2 - 1$.

It turns out that safe functions that are best, are those that are *level-minimal*, that is, they do not strictly dominate any function with equal level set.

Theorem 2.5. *A $(A, \boldsymbol{E})$-safe function ϕ has maximal quiescent region, among all $(A, \boldsymbol{E})$-safe functions, for every k, iff,*

- *ϕ is convex*
- *$L(\phi)$ is a maximal convex subset of A, and*
- *ϕ is level-minimal*

Proof. Ommitted due to space constraints. □

The above results highlight the centrality of convexity in the monitoring problem; starting from very broad principles, we have shown that convexity enters in a natural way from the definition of safety, and furthermore, we have formally identified the requirement of level minimality, in order to maximize the quiescent region in FGM.

We will return to the issue of safe functions, with respect to the communication costs they entail, after we present the FGM distributed protocol.

2.4 The basic FGM protocol

The FGM protocol works in rounds. Monitoring the threshold condition

$$\sum_{i=1}^{k} \phi(\boldsymbol{X}_i) \leq 0, \tag{5}$$

over the duration of the round is performed along the lines of the algorithm in [9].

At the beginning of a round, the coordinator knows the current state of the system $\boldsymbol{E} = \boldsymbol{S}$. It selects an $(A, \boldsymbol{E}, k)$-safe function ϕ. At each point in time, let $\psi = \sum_{i=1}^{k} \phi(\boldsymbol{X}_i)$. The round's steps are:

(1) At the beginning of a round, the coordinator ships ϕ to every site (it is sufficient to ship vector $\boldsymbol{E}$, since A can then be determined from it). Local sites initialize their drift vectors to $\boldsymbol{0}$. With these settings, initially it is $\psi = k\phi(\boldsymbol{0})$.

(2) Then, the coordinator initiates a number of subrounds, to be described below. At the end of all subrounds, $\psi > \epsilon_\psi k\phi(\mathbf{0})$, for some small ϵ_ψ (Note that ϵ_ψ is not related to the desired accuracy for the monitored query, ε, but only to the desired quantization for monitoring ψ. We have used $\epsilon_\psi = 0.01$ in our experiments).
(3) Finally, the coordinator ends the round by collecting all drift vectors and updating $\boldsymbol{E}$.

2.4.1 Execution of subrounds. The goal of each subround is to monitor the condition $\psi \leq 0$ coarsely, with a precision of roughly θ, performing as little communication as possible. Subrounds are executed as follows:

(1) At the beginning of a subround, the coordinator knows the value of ψ. It computes the subround's *quantum* $\theta = -\psi/(2k)$, and ships θ to each local site. Also, the coordinator initializes a counter $c = 0$. Each local site records its initial value $z_i = \phi(\boldsymbol{X_i})$, where $2k\theta = -\sum_{i=0}^{k} z_i$. Also, each local site initializes a counter $c_i = 0$.
(2) Each local site i maintains its local drift vector $\boldsymbol{X}_i$, as it processes stream updates. When $\boldsymbol{X_i}$ is updated, site i updates its counter

$$c_i := \max\{c_i, \lfloor \frac{\phi(\boldsymbol{X}_i) - z_i}{\theta} \rfloor\}.$$

If this update increases the counter, the local site sends a message to the coordinator, with the increase to c_i.
(3) When the coordinator receives a message with a counter increment from some site, it adds the increment to its global counter c. If the global counter c exceeds k, the coordinator finishes the subround by collecting all $\phi(\boldsymbol{X}_i)$ from all local sites, recomputing ψ. If $\psi \geq \epsilon_\psi k\phi(\mathbf{0})$, the subrounds end, else another subround begins.

The following simple statement guarantees the correctness of the protocol.

Proposition 2.6. *During the execution of a subround, if $c \leq k$ then $\sum_{i=1}^{k} \phi(\boldsymbol{X}_i) < 0$.*

Proof. At each point in time and for any site, it must be

$$\frac{\phi(\boldsymbol{X}_i) - z_i}{\theta} - 1 < \lfloor \frac{\phi(\boldsymbol{X}_i) - z_i}{\theta} \rfloor \leq c_i.$$

Summing both sides, we get $\frac{1}{\theta}\left(\psi + 2k\theta\right) - k < c$, which simplifies to $\sum_{i=1}^{k} \phi(\boldsymbol{X}_i) < (c-k)\theta \leq 0$. □

2.5 Performance analysis

Apart from the communication incurred during the subrounds of the FGM protocol, the communication cost of a round consists of two parts; an upstream cost $\Theta(kD)$ for shipping $\boldsymbol{E}$ to all sites at the beginning of a round, and a downstream cost $O(\min\{kD, \tau\})$, for shipping drift vectors to the coordinator at the end of the round. Here, τ stands for the total number of stream updates processed by all sites during a round—as mentioned before, sites that received few stream updates during a round, can ship them verbatim to the coordinator.

2.5.1 The cost of subrounds. Each subround itself costs only $3k + 1$ one-word messages: k messages to broadcast quantum θ, k messages to collect ζ-values at the end of a subround, and up to $k + 1$ downstream messages carrying counter updates.

The problem of monitoring $\psi \leq 0$ is of course an instance of the non-monotone distributed counting problem. As shown in [9], if ψ is an increasing function of time, then the number of subrounds is at most $\log_2 \frac{1}{\epsilon_\psi}$.

In general, there is no guarantee that ψ will be increasing; therefore we also provide an analysis within the framework of *variability*, as set out in [10]. In this framework, the cost of tracking a non-monotone counter $f(t)$ within accuracy ε is shown to take $O(\frac{k}{\varepsilon}V_f)$ messages, where $V_f(t) = \sum_{\tau=0}^{t} \min\{1, \frac{|\delta f(t)|}{|f(t)|}\}$. They provide space-plus-time lower bounds for the tracking problem that match the communication cost.

In our setting, we are not interested in *tracking* the value of ψ. Still, the definition of variability during a round can be given as follows: let the sequence ψ_n represent the value of ψ at the end of the n-th subround. Also, define the set of values that $\phi(\boldsymbol{X}_i)$ takes, during subround n, as

$$\Phi_{i,n} = \{\phi(\boldsymbol{X}_i(t)) \mid \forall t \text{ during subround } n\}$$

Then the change $\Delta\psi_n$ is

$$\Delta\psi_n = \sum_{i=1}^{k} \sup \Phi_{i,n} - \inf \Phi_{i,n}$$

Finally, the ψ-variability over a round with q subrounds is

$$V = \sum_{n=1}^{q} \frac{|\Delta\psi_n|}{|\psi_n|}.$$

Theorem 2.7. *The communication cost of all subrounds of a round is $O(kV)$ words.*

Proof. Consider the n-th subround, with quantum $\theta = -\psi_{n-1}/2k$. If the counter of site i is c_i, then, at some point during this subround we had

$$\lfloor \frac{\phi(\boldsymbol{X}_i) - z_i}{\theta} \rfloor = c_i.$$

We conclude that, since $c > k$,

$$\Delta\psi_n \geq (k+1)\theta = \frac{k+1}{2k}|\psi_{n-1}| \geq \frac{|\psi_{n-1}|}{2}.$$

On the other hand, $|\psi_n - \psi_{n-1}| \leq \Delta\psi_n$, thus the variability has increased by at least $1/3$ during this subround. Therefore, the total cost of all subrounds is at most $(9k + 3)V$ words. □

At this point, we should report that in our extensive experiments with complex non-monotone functions over sketches and streams created from real data with deletions (using windows), the number of subrounds per round q was always at most 10, and almost always $7 \approx \log_2 \frac{1}{0.01}$. In fact, the total cost $O(kq)$ of all subrounds in a round, was dominated by several orders of magnitude, by the upstream cost $\Theta(kD)$. This good fortune is possibly due to tight monitoring bounds in our experiments, but still, it is an interesting observation, considering how bad the worst-case costs are.

An interesting open question is to relate ψ-variability to the variability of the query function Q, and in particular derive lower bounds based on this concept.

We should also discuss the role of ϵ_ψ. Note that this bound is unrelated to the approximation bound ε of the monitored query Q. It is simply a threshold of accuracy, with which the value of ψ is approximated. In practice, a fixed value of 0.01 seemed to suffice. The choice of ϵ_ψ can be understood as the precision to which $\phi(\boldsymbol{X}_i)$ are evaluated; their values are quantized to $\epsilon_\psi\phi(\mathbf{0})$ absolute error. Selecting a different value depends on the geometry of a particular problem; we omit the details.

2.5.2 Comparison to classic geometric monitoring. Both the FGM protocol and the standard protocol of geometric monitoring (GM) are generally applicable. The two protocols can be rendered comparable; when FGM is used together with convex safe functions, the condition $\phi(\boldsymbol{x}) \leq 0$ is akin to testing membersip in a convex Safe Zone [22]. However, the GM protocol adopts a much stricter safeness condition, equivalent to

$$\max_{i=1,\ldots,k} \phi(\boldsymbol{X}_i) < 0. \tag{6}$$

When the above condition is violated, the GM protocol performs substantial communication (either a partial, or a full synchronization, by flushing the local state vectors). By contrast, the FGM is much more patient; in fact, it is easy to see that, if the two protocols start from the same estimate $\boldsymbol{E}$ at the beginning of a round, as long as safeness condition (6) holds, the first subround of FGM has not yet finished.

Proof. As long as $\phi(\boldsymbol{X}_i) < 0$, it is $1 - \phi(\boldsymbol{X}_i)/\phi(\boldsymbol{0}) < 1$. The quantum of the first FGM subround is $\theta = -\phi(\boldsymbol{0})/2$, therefore, for each site i, it is

$$\lfloor \frac{\phi(\boldsymbol{X}_i) - \phi(\boldsymbol{0})}{-\phi(\boldsymbol{0})/2} \rfloor = \lfloor 2(1 - \frac{\phi(\boldsymbol{X}_i)}{\phi(\boldsymbol{0})}) \rfloor \leq 1,$$

and thus the coordinator has received at most k bits. □

The advantage of FGM over GM becomes more apparent by considering the size of the quiescent regions for these protocols. Each protocol will synchronize (flush local sites) as soon as the system escapes the quiescent region. It is therefore advantageous to admit a quiescent region that better approximates the set of safe configurations C.

Fig. 1 depicts the situation for $D = 1$ and $k = 2$. Without loss of generality, we are assuming $A = [-1, 1]$. The quiescent region for GM is simply $A \times A$, whereas for FGM the region depends on the choice of ϕ. Choosing $\phi(x) = |x|^p - 1$ will be correct for every $p \geq 1$, but naturally the best function is the level-maximal function $|x| - 1$ (i.e., $p = 1$). In fact, it can be seen in Fig. 1 that as p grows, the benefit of FGM over GM decreases; however, FGM will never be inferior to GM.

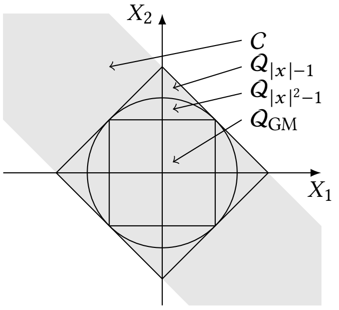

Figure 1: Configuration space for $A = [-1, 1] \subseteq \mathbb{R}$ and $k = 2$, depicting the set of safe configurations C, the FGM quiescent regions $Q_{|x|^p-1}$ for $p = 1, 2$ and the GM quiescent region $Q_{\mathbf{GM}}$.

3 COMPLEXITY RESULTS FOR F_p MOMENTS

We now turn to an analysis of the worst-case communication cost of FGM for F_p moments. In this analysis, it is necessary to introduce monotonicity assumptions about the studied problems; otherwise, even the simplest problems can have very bad worst case complexity. In particular, we assume that all local state vectors and drifts are frequency vectors with nonnegative coefficients; this assumption is compatible with an insert-only stream.

Similar complexity results were obtained by [9], by an algorithm which is similar to FGM; under monotonicity, each round of their algorithm is essentially a round similar to ours, but with carefully selected thresholds. Here, we will strive for a simpler approach.

Since the functions to be monitored are convex, and in fact the $F_p(\boldsymbol{x})$ moment of a frequency vector $\boldsymbol{x}$ is just the norm $\|\boldsymbol{x}\|_p^p$, we use safe functions of the form $\|\boldsymbol{x}+\boldsymbol{E}\|_p - T$. Note that selecting not to raise the norm to p yields better quiescent regions, although it does not make much difference to the asymptotic results under monotonicity.

We begin by examining the effect of a single FGM round. In such a round, we start from some global state $\boldsymbol{E}$ and we allow the protocol to proceed to termination, under an admissible region of the form $\{\boldsymbol{x} | \|\boldsymbol{x}\|_p \leq T\}$, where T depends on whether we are interested in an one-shot query or a continuous one.

Lemma 3.1. *Assume the problem of monitoring admissible region $A = \{\boldsymbol{x} | \|\boldsymbol{x}\|_p \leq T\}$ for $p \geq 1$, starting at some $\boldsymbol{E} \in A$.*

Under monotonicity assumptions, at the end of a single FGM round with safe function $\phi = \|\boldsymbol{x} + \boldsymbol{E}\|_p - T$, the final stream state $\boldsymbol{S}$ will have

$$\|\boldsymbol{S}\|_p^p \geq (1 - \frac{1}{k^{p-1}})\|\boldsymbol{E}\|_p^p + \frac{1}{k^{p-1}}\tilde{T}^p,$$

where $\tilde{T} = T(1 - \epsilon_\psi) + \epsilon_\psi \|\boldsymbol{E}\|_p \approx T$.

Proof. At the end of the round, the value of ψ has become greater than $\epsilon_\psi k \phi(0)$. Therefore, under our safe function, at the end of the round, the coordinator collected drift vectors $\boldsymbol{X}_i$, with

$$\tilde{T} \leq \frac{1}{k} \sum_{i=1}^{k} \|\boldsymbol{X}_i + \boldsymbol{E}\|_p.$$

From Hölder's inequality (thinking of the sum as an inner product with vector $\mathbf{1} = (1, 1, \ldots, 1)$), we get

$$\sum_{i=1}^{k} \|\boldsymbol{X}_i + \boldsymbol{E}\|_p \leq \|\mathbf{1}\|_q \Big(\sum_{i=1}^{k} \|\boldsymbol{X}_i + \boldsymbol{E}\|_p^p \Big)^{1/p},$$

where $q = p/(p-1)$ is the Hölder conjugate of p. Combining the above inequalities by raising to p, and noting that $\|\mathbf{1}\|_q^p = k^{p-1}$, we get

$$\sum_{i=1}^{k} \|\boldsymbol{X}_i + \boldsymbol{E}\|_p^p \geq k\tilde{T}^p. \tag{7}$$

To proceed, first observe that $k\boldsymbol{S} = k\boldsymbol{E} + \sum_{i=1}^{k} \boldsymbol{X}_i$. Consider the following real inequality (over nonnegative numbers):

$$(ke + \sum_{i=1}^{k} x_i)^p = (\sum_{i=1}^{k} (x_i + e))^p \geq \sum_{i=1}^{k} (x_i + e)^p + (k^p - k)e^p.$$

When applied to each coordinate of $\boldsymbol{E}$ and $\boldsymbol{X}_i$, it follows from 7 that

$$k^p \|\boldsymbol{S}\|_p^p \geq k\tilde{T}^p + (k^p - k)\|\boldsymbol{E}\|_p^p.$$

Dividing both sides with k^p finishes the proof. □

Observe from the above lemma that the effect of ϵ_ψ is localized in reducing slightly the threshold T in each round; however, as $\|\boldsymbol{E}\|_p \rightarrow T$, the effect dissappears; this case makes apparent that ϵ_ψ does not affect the accuracy of the monitoring; it only increases (slightly) the number of rounds. We do not discuss ϵ_ψ any further.

We can consider two scenaria for monitoring the F_p norm.

3.0.1 One-shot query. In this scenario, which is exactly the framework of ditributed functional monitoring, we set an initial T and we estimate the number of rounds needed until $\|\boldsymbol{S}\|_p$ exceeds $(1-\varepsilon)T$, starting at $\boldsymbol{E} = \boldsymbol{0}$. By solving a simple linear recurrence, we get the following

THEOREM 3.2. *For safe function $\|\boldsymbol{x}\|_p - T$, the FGM protocol can monitor the F_p moment of a monotone stream in $O(k^{p-1}\log\frac{1}{\varepsilon})$ rounds.*

For the actual communication cost, when using sketches or other summaries for F_p norms, we refer to the discussion of [9].

3.0.2 Continuous query. In this case, the threshold T given to the FGM protocol at each round is set to $(1+\varepsilon)\|\boldsymbol{E}\|_p$, that is, it changes with each round. To describe the communication cost in the continuous setting, we express the number n of rounds as a function of a starting query value Q_0 and an ending query value Q_n. Ommitting the easy details, we have

THEOREM 3.3. *For safe function $\|\boldsymbol{x}\|_p - T$, the FGM protocol can monitor continuously the F_p moment of a monotone stream, as it transitions from value O_0 to Q_n in $O(\frac{k^{p-1}}{\varepsilon}\log\frac{Q_n}{Q_0})$ rounds.*

3.0.3 Discussion. The above complexity results match those of the original paper by Cormode et al. [9]. Our proofs show that they can be obtained without resorting to a special-purpose protocol like the one proposed in [9]. By contrast, the FGM protocol is built along the lines of greedy relaxation: setting a safe zone and letting the protocol iterate to completion. Naturally, there is nothing to forbid a clever coordinator algorithm to set more precise targets, in order to achieve better results.

The real limitation of FGM comes from the fact that in FGM, local nodes are memoryless; once a local drift is transmitted, the node has no memory of its past state. It should not come as a surpsise that better communication complexity can be achieved with stateful nodes. In particular, the results of [29] on very good upper bounds for frequency moments require nodes to retain much information for a long time. On the other hand, this may be quite undesirable from an implementation point of view. Thus, such results are important in the context of communication complexity with unrestricted parties, but arguably not immediately practical.

Another point compares the implementation cost of algorithms; arguably, the algorithms presented in [9] and elsewhere, are harder to adapt to more general setting. To illustrate the point, consider the problem of monitoring, say, the F_2 moment, in a stream allowing deletions as well as insertions. With FGM, it suffices to augment the safe function: starting at state $\boldsymbol{E}$, a good safe function for admissible region $A = \{\boldsymbol{x} | \|\boldsymbol{x}\|_2 \geq (1-\varepsilon)\|\boldsymbol{E}\|\}$ is defined as a half space, tangent to ball A at the projection of $\boldsymbol{E}$ onto A. Then, the safe functions for upper and lower bound of the F_2 moment can be combined via the pointwise-max operation:

$$\phi(\boldsymbol{x}) = \max\{-\varepsilon\|\boldsymbol{E}\| - \boldsymbol{x}\frac{\boldsymbol{E}}{\|\boldsymbol{E}\|}, \|\boldsymbol{x}+\boldsymbol{E}\| - (1+\varepsilon)\|\boldsymbol{E}\|\}.$$

If the above function is employed in an insertion-only setting, it will retain the cost guarantees proved above.

4 ROBUSTNESS UNDER ADVERSE CONDITIONS

We now turn our attention to features of the FGM that allow it to handle gracefully adverse streaming conditions. These conditions can arise from a number of factors, such as:

- Setting the monitoring accuracy ε to a very low value, resulting in tight thresholds for monitoring.
- In the absense of monotonicity, handling local streams which tend to cancel each other (this is a multidimensional version of the problem of non-monotone counter).
- Handling cases where the local stream rates are very uneven (e.g., following a power-law distribution).

To handle the above situations, the FGM protocol offers a number of enhancements; the effect of these enhancements is quite apparent in our experiments, but to our knowledge they do not provide asymptotic improvements in communication cost.

The guiding intuition in the following is the observation that, under a greedy view, it is preferable to have FGM rounds last longer (consuming more stream updates), since then, not only the streams are better summarized in local state vectors, but also, the upstream overhead of shipping $\boldsymbol{E}$ to local sites at the the beginning of a round is paid less often.

4.1 Rebalancing

Our starting point is the observation that $\sum_{i=1}^{k}\phi(\boldsymbol{X}_i) > 0$ does not generally imply that $\phi(\frac{1}{k}\sum_{i=1}^{k}\boldsymbol{X}_i)$ is also positive, or even much different than $\phi(\boldsymbol{0})$, i.e., often, at the end of a round, the global stream state $\boldsymbol{S}$ has not moved significantly far from $\boldsymbol{E}$. Therefore, the current safe function ϕ may still be quite useful, and we would like to avoid the overhead of shipping a new safe function to the sites.

Rebalancing is an important technique in classic Geometric Monitoring. The idea in GM is to flush a subset of the local sites, and then ship them the average of their previous drifts. A straightforward adaptation of the rebalancing method of GM, could benefit FGM. Unfortunately, the method is highly uncertain as to the benefit it provides, versus the added upstream communication overhead (which is a multiple of $O(D)$).

A simple approach to rebalancing, that incurs negligibly small additional upstream communication cost, is to ship to the sites a scaling factor, with which to scale their local drifts. We restrict the discussion to convex safe functions.

In our rebalancing scheme, the coordinator holds an extra state vector, the *balance vector* $\boldsymbol{B}$, which is used to aggregate drift vectors from local sites, without ending the round. At the beginning of a round, the balance vector is set to $\boldsymbol{0}$. During the round, sites update their drift vectors as local stream updates arrive. However, with rebalancing allowed, it is possible for a site to flush its current drift vector to the coordinator, during the round. When a flush occurs, the coordinator updates the balance, by adding $\boldsymbol{X}_i$ to it. After drift vector $\boldsymbol{X}_i$ is flushed, it is reset to $\boldsymbol{0}$.

Therefore, the global drift is always equal to

$$\boldsymbol{B}/k + \frac{1}{k}\sum_{i=1}^{k}\boldsymbol{X}_i. \tag{8}$$

This can be rewritten as

$$\mu \frac{\boldsymbol{B}}{\mu k} + \frac{\lambda}{k} \sum_{i=1}^{k} \frac{\boldsymbol{X}_i}{\lambda} \tag{9}$$

for some $\lambda > 0$, $\mu \geq 0$, with $\lambda + \mu = 1$ (note that we allow $\mu = 0$ when $\boldsymbol{B} = \boldsymbol{0}$, namely at the beginning of a round).

If ϕ is a convex $(A, \boldsymbol{E})$-safe function, known to the sites, we can adapt the safety condition by applying ϕ to Eq. 9. Define

$$\psi = \sum_{i=0}^{k} \lambda \phi(\frac{\boldsymbol{X}_i}{\lambda}) \qquad \text{and} \qquad \psi_B = \begin{cases} (1-\lambda)k\phi(\frac{B}{(1-\lambda)k}) & \lambda < 1, \\ 0 & \lambda = 1. \end{cases}$$

Theorem 4.1. *If ϕ is convex $(A, \boldsymbol{E})$-safe, then, for any $\lambda \in (0, 1]$,*

$$\psi + \psi_B \leq 0 \implies \boldsymbol{E} + \frac{\boldsymbol{B} + \sum_{i=1}^{k} \boldsymbol{X}_i}{k} \in A.$$

Proof. Let $\mu = 1 - \lambda$. By convexity,

$$k\phi(\frac{\boldsymbol{B} + \sum_{i=1}^{k} \boldsymbol{X}_i}{k}) \leq \mu k \phi(\frac{\boldsymbol{B}}{\mu k}) + \lambda k \phi(\frac{\sum_{i=1}^{k} \boldsymbol{X}_i}{\lambda k}) \leq \psi_B + \psi.$$

Since $k\phi$ is $(A, \boldsymbol{E})$-safe, and dominated by $\psi + \psi_B$, the claim follows. □

To monitor condition $\psi + \psi_B \leq 0$, the only modification needed to the FGM algorithm during subrounds, is in the selection of a suitable quantum θ at the beginning of each subround, so that

$$2k\theta = -(\psi + \psi_B). \tag{10}$$

4.1.1 Rebalancing FGM protocol. The extended protocol begins exactly as described in §2.4, with $\lambda = 1$. At the end of all subrounds, it is $\psi > \epsilon_\psi k \phi(\boldsymbol{0})$. Where the basic protocol would start a new round, the rebalancing protocol restores the invariant $\psi + \psi_B \leq 0$ as follows:

1. The coordinator asks some or all of the sites to flush their local drift vectors, and updates $\boldsymbol{B}$. There are many possible heuristics that can be employed to do this as conservatively as possible, dealying flushes and thus giving the opportunity to local streams to summarize their results better.
2. When all drift vectors have been received, the coordinator recomputes ψ_B and ψ, choosing a new value for λ, or failing. The choice of λ is discussed below.
3. If condition $\psi + \psi_B \leq \epsilon_\psi k \phi(\boldsymbol{0})$ is restored, a new subround is started with quantum $\theta = -(\psi + \psi_B)/(2k)$,
4. else, the round finishes and a new round starts by computing the new $\boldsymbol{E}$ and shipping it to all sites.

4.1.2 Selection of λ. The choice of a good λ is a generally dependent on the statistics of the monitored streams. Consider the "ideal" case, where $\boldsymbol{B}$ was shipped back to the sites; then, the sites could instead monitor function $\phi(\boldsymbol{x} + \boldsymbol{B}/k)$ (we would have $\psi_B = 0$). This is "ideal" in the sense that for any $\lambda > 0$,

$$\sum_{i=1}^{k} \phi(\boldsymbol{X}_i + \boldsymbol{B}/k) \leq \sum_{i=1}^{k} \lambda \phi(\boldsymbol{X}_i/\lambda) + \mu k \phi(\boldsymbol{B}/(\mu k)) = \psi + \psi_B. \tag{11}$$

Scaling the input streams. Let $Z = L(\phi)$. Geometrically, the level set of $\phi(\boldsymbol{x} + \boldsymbol{B}/k)$ is $Z - \boldsymbol{B}/k$, that is, it is a shift of Z along the $\boldsymbol{B}$-direction. The new safe zone, by our choice of λ has to be a subset of this set. We could then "scale down" Z to λZ, so that $\lambda Z \subseteq Z - \boldsymbol{B}/k$, and their boundaries touch at a point along the axis of the shift, that is, at $\boldsymbol{B}/(\mu^* k)$, where

$$\mu^* = \inf\{\mu > 0 \mid \phi(\boldsymbol{B}/(\mu k)) = 0\}.$$

This value of μ^* can easily be found iteratively by bisection. Then, $\lambda = 1 - \mu^*$. This heuristic is well-behaved in practice and is the one we have used in our experiments.

4.1.3 Discussion. To assess the effect of rebalancing on round duration, assume that the statistics of the *global stream* are such that the global state vector $\boldsymbol{S}$ maintains a rougly constant "velocity" over the stream data. Under this "statistical inertia" assumption, which is often a realistic approximation of stream statistics, our rebalancing protocol achieves a round duration at least 1/2 of the ideal maximum: if τ stream updates were processed, then processing another τ updates would lead the total drift outside the safety bounds (i.e., outside $L(\phi)$). In such conditions, rebalancing ameliorates the presence of *skew* in the trends and rates of *local* streams.

4.2 Adaptively shipping safe zones to local sites

In order to amortize the upstream cost of a round with communication benefits, it is necessary for a round to last for at least twice this many updates totally; that is, the round must last for at least $2kD$ updates, if the total communication cost of the round is to be better than the naive method. This minimum duration of a round (in terms of local stream updates) may not be not be achievable when overall variability is high.

Another practical issue, even with low variability, is the case where the stream rates of individual sites are highly unequal, e.g., they follow a 98-2 power law. Then, the cost of shipping safe zones to 98% of the sites is probably wasteful; those sites could just forward their local streams to the coordinator, and a protocol should try to save communication on those 2% of the sites which provide 98% of the stream updates.

Many previous protocols for distributed monitoring, including much of the previous work on Geometric Monitoring, do not adapt well to such problematic situations. In this section, we introduce an enhancement the FGM protocol, where such situations are handled within the protocol's basic logic. There are two subproblems addressed by our solution; (a) a systematic way to eliminate the upstream cost of shipping $\boldsymbol{E}$ to selected sites at the beginning of a round, and (b) a cost-based way to select those sites.

4.2.1 Reducing the upstream costs. One simplistic way to avoid shipping $\boldsymbol{E}$ to a site at the beginning of a round, is to put this site into "promiscuous mode", that is, to let it ship all local stream updates to the coordinator, which can then "simulate" the local node, and otherwise execute the protocol as is.

Naturally, this simplistic method will create many small messages, which we would like to avoid. This can be done if we ship to the site a cheaper safe function, such as some function of the form $b(\boldsymbol{x}) = \|\boldsymbol{x}\|_p^q + a$, which takes only 3 words (carrying p, q, a) to tramsmit. To maintain correctness, it is sufficient to guarantee simply that $\phi \leq b$. Given such a function, a site can participate normally in the FGM protocol. Naturally, the fact that this site is not equipped with the full function ϕ may cause it to end subrounds prematurely (sending many bits rapidly) and thus interfering with other sites. Although this is certainly possible, our experiments revealed that, under adverse monitoring conditions, the coordinator will often decide to ship the cheap safe function to *every* site, in which case the interference problem vanishes.

Selecting a function $b \geq \phi$ depends on the analytic properties of ϕ, and can in general be done easily. In general, we should avoid higher-degree functions, as they grow too quickly; this is possible if the degree of ϕ itself is small (which, is important for achieving better quiescent region for ϕ, as discussed previously). In order to keep our exposition simple, we do not discuss this issue in full analytic generality. Instead, we note that a 1-degree requirement can be met, if the safe zone function ϕ is nonexpansive:

$$\forall \boldsymbol{x}, \boldsymbol{y} \in V,\ |\phi(\boldsymbol{x}) - \phi(\boldsymbol{y})| \leq \|\boldsymbol{x} - \boldsymbol{y}\|. \tag{12}$$

This property is well-known in functional analysis, and is also known as *Lipschitz continuity*. It is easy to see that, in this case,

$$|\phi(\boldsymbol{x}) - \phi(\boldsymbol{0})| \leq \|\boldsymbol{x}\|,$$

which implies that

$$\phi(\boldsymbol{x}) \leq \|\boldsymbol{x}\| + \phi(0).$$

An important class of safe functions that are non-expansive are the Signed Distance Functions of convex sets. Also, the gauge functions with bounded level-set (including all norms and semi-norms) can be scaled to be nonexpansive.

Selecting the sites which will use the "cheap" function b is crucial. We propose a solution based on a cost model and some collected statistics, much in the spirit of database query optimization. In the rest of this section, we will ignore the FGM rebalancing protocol, and instead focus on the basic FGM protocol. This is done for the sake of keeping our optimization algorithm simple. However, once the "plan" for a round is selected, the full FGM protocol with rebalancing can be executed for the round.

4.2.2 Modeling the communication cost of a round. Assume that the coordinator is at the beginning of a round, with current estimate $\boldsymbol{E}$ and has selected a non-expansive safe function ϕ. Let $d_i, i = 1, \ldots, k$ be indicator variables; d_i is equal to 1 when the full safe function ϕ is to be shipped to local site i, and 0 if the cheap safe function is to be used. In other words, d_i encodes the optimized "query plan" for the upcoming round. Let $\boldsymbol{d}$ denote the vector of d_i values. Our goal is to select the plan $\boldsymbol{d}$ that maximizes the gain of the round.

Assume that, based on the decision $\boldsymbol{d}$, the length of the next round is going to be τ. Furthermore, assume that a fraction $\gamma_i \tau$ of these updates arrives at local stream i. The benefit of the round in terms of summarizing τ updates in the local state vectors, is

$$g_0 = \tau - \sum_{i=1}^{k} \min\{\gamma_i \tau, D\}, \tag{13}$$

where $\min\{\gamma_i \tau, D\}$ reflects the downstream cost of site i, which will ship $\gamma_i \tau$ raw updates, instead of the D-dimensional drift vector, if $\gamma_i \tau < D$. In addition, the upstream cost of the round is $D \sum_{i=1}^{k} d_i$ (where we assume that the difference in the cost of shipping ϕ vs. b is D). Therefore, we must select $\boldsymbol{d}$ so as maximize the round's *gain*,

$$g = \tau - \sum_{i=1}^{k} \min\{\gamma_i \tau, D\} - D \sum_{i=1}^{k} d_i. \tag{14}$$

The challenge is to predict $\tau(\boldsymbol{d})$, given a choice for $\boldsymbol{d}$. To this end, consider ψ as function of "time" (updates):

$$\psi(t) = \sum_{d_i=1} \phi(\boldsymbol{X_i}(t)) + \sum_{d_i=0} \|\boldsymbol{X}_i(t)\| - \phi(\boldsymbol{0}) \tag{15}$$

The current round can be seen as the transition of the system from a state where $\psi = k\phi(\boldsymbol{0})$ to a state where $\psi = 0$. Of course, this transition will in general follow a complicated, non-linear trajectory in the quiescent region. However, we adopt a simplistic linear estimate. In particular, we model the behaviour of each local stream i by two rates, α_i and β_i, assuming simplistically that

$$\begin{aligned} \phi(\boldsymbol{X}_i(t)) &\approx \phi(\boldsymbol{0}) + |\phi(\boldsymbol{0})|\alpha_i t \quad (16) \\ \|\boldsymbol{X}_i(t)\| + \phi(\boldsymbol{0}) &\approx \phi(\boldsymbol{0}) + |\phi(\boldsymbol{0})|\beta_i t \quad (17) \end{aligned}$$

We shall assume that $0 < \alpha_i < \beta_i$.

Based on this simple-minded model, the prediction of a round's length τ, as a function of $\boldsymbol{d}$, based on Eq. 15, is

$$\tau = \frac{k}{\beta_{\text{tot}} - \boldsymbol{d} \cdot \boldsymbol{\theta}}, \tag{18}$$

where $\beta_{\text{tot}} = \sum_{i=1}^{k} \beta_i$ and $\boldsymbol{\theta}$ is the vector of values $\theta_i = \beta_i - \alpha_i$.

4.2.3 Maximizing the gain of a round. It is required to find the value of $\boldsymbol{d}$ that maximizes the gain g (Eq. 14). An exhaustive search of the solution space would require time $O(2^k)$, which would not scale well to large k. Thankfully, it turns out that a simple greedy algorithm is sufficient to maximize g. The key observation is that $g_0(\tau)$ (from Eq. 13) is non-decreasing in τ. Fix some number $0 \leq n \leq k$. We wish to find a feasible solution $\boldsymbol{d}^*$, with $\sum_i d_i^* = n$, which maximizes g among all solutions $\boldsymbol{d'}$ with $\sum_i d'_i = n$. But since $g(\boldsymbol{d}^*) = g_0(\tau(\boldsymbol{d}^*)) - nD$, and g_0 is non-decreasing in τ, it suffices to maximize $\tau(\boldsymbol{d}^*)$. To do this, simply set $d_i^* = 1$, iff θ_i is among the n largest coordinates of $\boldsymbol{\theta}$ (ties are broken arbitrarily). Now, g can be optimized by comparing among $k+1$ solutions, one for each value of n. Furthermore, since an optimal solution for $n+1$ subsumes an optimal solution for n, the whole computation can be performed in $O(k \log k)$ steps (essentially for sorting vector $\boldsymbol{\theta}$).

4.2.4 Obtaining estimates for local streams. It remains to discuss the estimation of α_i, β_i and γ_i in each round. In this paper, we explored the simplest possible alternative: simply use the data collected at the end of the previous round, to obtain fresh estimates of all three parameters. Since at the end of a round the coordinator has received each drift $\boldsymbol{X}_i$, together with a count of updates to each local stream during the round, all three parameters can be computed directly, more or less from Eqs. 16 and 17.

Some care must be taken, to ensure $0 < \alpha_i < \beta_i$; in particular, Eq. 16 may yield a non-positive value. If this occurs, then simply set α_i to a small positive value (so that θ_i is minimum among the components of vector $\boldsymbol{\theta}$. Also, when $\beta_i = 0$ or $\gamma_i = 0$ (there were no updates to the site in the previous round), simply set $d_i = 0$ and ignore this site in the optimization process.

4.2.5 Discussion. Our estimates for modeling local streams are simple to acquire in practice, but may yield estimates which may not represent well the evolution of the system. After all, predictions are hard, especially about the future! Thankfully, our approach, of estimating τ in order to decide on the next round's plan, is relatively insensitive to the exact value of τ, as it is essentially a based of thresholds, determined by local stream rate predictions, which can be predicted much more accurately.

In practice the algorithm managed to perform quite well, making the FGM protocol quite robust in adverse situations of very high variability, compared to executions that shipped a safe function to every site. Most of the time, the selection of $\boldsymbol{d}$ values either resulted in almost all 1s (when variability was low) or in almost all 0s (during high variability). Also, during periods of medium variability, the algorithm would alternate between these two decisions for a few rounds.

Improving on this algorithm is certainly an interesting problem. On the prediction side, higher-order polynomial models in place of Eqs. (16–17) can in principle be constructed. Whether these more elaborate modeling would benefit the final communication cost in real data settings, remains to be seen.

5 EXPERIMENTAL EVALUATION

We performed an extensive experimental study of the FGM protocol, over a variety of datasets and streaming parameters, with emphasis on validating our claims of resilience to adverse situations. For lack of space, we only present results from the WorldCup dataset [2], which contains log traces of all requests sent to the 1998 World Cup web site, consisting of 33 mirrors spread around the globe and receiving 1.3 billion http requests. Our experiments used only data from day 46, during which 50.3 million requests where received by 27 mirror sites. From this data, we constructed stream records over the schema R(CID, TYPE), where CID is the (anonymized) client address of the http request, and TYPE is the type of file requested (HTML, image etc).

On this stream, we approximately monitored two continuous queries. Both queries operate on Fast-AGMS sketches [8] on the input streams. A Fast-AGMS sketch $\boldsymbol{S}$ is stored as a $d \times w$ matrix $\boldsymbol{S}$ of integer counters, and can be used to estimate join and self-join sizes within accuracy $\Theta(1/\sqrt{w})$ with probability at least $1-2^{-\Theta(d)}$. Each stream update changes the sketch by modifying one cell in each row vector $\boldsymbol{S}[i]$ (totally, d cells) by ±1, according to certain hash functions.

The first query monitors the self-join size of $R \bowtie_{\text{CID}} R$. To estimate this query, an AGMS sketch is used as the state vector to summarize all records. The query function is the self-join size estimate,

$$Q_1(\boldsymbol{S}) = \underset{i=1,\ldots,d}{\text{median}}\{\sum_{j=1}^{w} \boldsymbol{S}[i,j]^2\} = \underset{i=1,\ldots,d}{\text{median}}\{\boldsymbol{S}[i]^2\}.$$

The second query monitors the join size of

$$\sigma_{\text{TYPE=HTML}}(R) \ \bowtie_{\text{CID}} \ \sigma_{\text{TYPE}\neq\text{HTML}}(R).$$

For this query, the state vector consisted of the concatenation of two sketches, $\boldsymbol{S}_1$ and $\boldsymbol{S}_2$. The monitored query function is

$$Q_2(\boldsymbol{S_1 S_2}) = \underset{i=1,\ldots,d}{\text{median}}\{\sum_{j=1}^{w} \boldsymbol{S}_1[i,j]\boldsymbol{S}_2[i,j]\} = \underset{i=1,\ldots,d}{\text{median}}\{\boldsymbol{S}_1[i]\boldsymbol{S}_2[i]\}.$$

Note that query function Q_2 is much more challenging than query Q_1 in terms of variability.

5.1 Experimental setup

We explored the space of four parameters: AGMS sketch size, size of sliding window over the streams, monitoring accuracy ε and the number of sites k.

We evaluated queries Q_1 and Q_2 both in the cash-register model (each record was inserted one at a time), and also in the turnstile model, where we used a time-based sliding window (ranging from 1hr to 4hrs) to generate record deletions. Naturally, the variability of our queries decreases as the time window increases. Also, time-based windows yield higher variability than fixed-size ones. We allowed the monitoring accuracy to vary as $\varepsilon \in [0.02, 0.1]$.

Finally, in order to study the effect of k (the number of sites) on performance, we created synthetic streams by hashing the original 27 local site ids to fewer site ids, for $k \in [2:20]$. Naturally, we also used the original (real) data, for $k = 27$.

Note that, in all experiments presented, the "global" stream was identical, and we simply changed the distribution of the data in time (by sliding windows), and among local streams.

5.1.1 Safe functions employed.

We implemented nonexpansive, convex safe functions for queries Q_1 and Q_2 following the technique of [13]. To monitor query Q_1 for estimate sketch $\boldsymbol{E}$ we need to ensure that $(1-\varepsilon)|Q_1(\boldsymbol{E})| \leq Q_1(\boldsymbol{S}) \leq (1+\varepsilon)|Q_1(\boldsymbol{E})|$.

We can rewrite it compactly (applying properties of the median) as

$$\pm\big(Q_1(\boldsymbol{S}) - T^{\pm}\big) = \underset{i=1,\ldots,d}{\text{median}}\{\pm(\boldsymbol{S}[i]^2 - T^{\pm})\} \leq 0.$$

where, for $\pm \in \{+,-\}$, $T^{\pm} = (1 \pm \varepsilon)|Q_1(\boldsymbol{E})|$, respectively.

The safe function $\phi(\boldsymbol{X})$ we used is *composed* as

$$\phi(\boldsymbol{X}) = \max\big(\phi^{-}(\boldsymbol{X}), \phi^{+}(\boldsymbol{X})\big),$$

where $\phi^{\pm}$ is safe for condition $\pm\big(Q_1(\boldsymbol{S}) - T^{\pm}\big) \leq 0$ respectively. Following the methodology of [13] for the median, we used

$$\phi^{\pm}(\boldsymbol{X}) = \max_{I \in \binom{D^{\pm}}{|D^{\pm}|-(d-1)/2}} \frac{\sum_{i\in I} |\phi_i^{\pm}(\boldsymbol{0})| \cdot \phi_i^{\pm}(\boldsymbol{X}[i])}{\sqrt{\sum_{i\in I} |\phi_i^{\pm}(\boldsymbol{0})|^2}},$$

where $D^{\pm} = \{i \mid 1 \leq i \leq d \text{ and } \pm(\boldsymbol{E}[i]^2 - T^{\pm}) < 0\}$. Note that the notation $I \in \binom{D}{n}$ means "I ranges over all n-subsets of D".

Functions $\phi_i^{\pm}(\boldsymbol{x}), i = 1,\ldots,d$, must be safe for conditions $\pm(\boldsymbol{S}[i]^2 - T^{\pm}) \leq 0$ respectively. We used

$$\phi_i^{+}(\boldsymbol{x}) = \|\boldsymbol{x}+\boldsymbol{E}[i]\|-\sqrt{T^{+}} \quad \text{and} \quad \phi_i^{-}(\boldsymbol{x}) = \sqrt{T^{-}}-\frac{\boldsymbol{E}[i]}{\|\boldsymbol{E}[i]\|}(\boldsymbol{E}[i]+\boldsymbol{x}).$$

The same methodology was applied to derive the safe functions for the Q_2 query; the derivation is very similar to the above, however, the actual formulas for $\phi_i^{\pm}$ for conditions $\pm(\boldsymbol{S}_1[i]\boldsymbol{S}_2[i] - T^{\pm}) \leq 0$ are a bit involved and are omitted due to space constraints; we refer the reader to [13] (Section 6.3) for details, as well as for the justification of the above steps.

5.1.2 Tested protocols.

In order to compare the performance of the FGM protocol to previous work, we implemented a well-studied version of the GM protocol, based on Safe Zones [22], with a rebalancing policy along the lines of [28]. The Safe Zones used where defined using the safe functions of the FGM described above, so as to fairly contrast the inherent communication costs of the GM and FGM protocols.

To study the effect of our cost-based optimizer, we ran versions of FGM with and without it. Overall, the acronyms of the 3 protocols tested are as follows:

Acronym	Protocol
GM	classic GM protocol with rebalancing.
FGM	FGM protocol without cost-based optimizer.
FGM/O	FGM protocol with cost-based optimizer.

5.2 Performance in typical workloads

Our first set of experiments concerns the behaviour of the protocols in a non-adverse scenario (using a 4ht window over the data), monitoring accuracy $\varepsilon = 0.1$, and sketch sizes, $D = 7000$. The results depicted in Figs. 2 and 3 (corresponding to semi-join and join queries) depict this cost as a function of k, both in the turnstile and in the cash-register model.

With respect to communication cost, observe that, as k grows, the FGM protocols exhibit 2–3 times lower communication cost

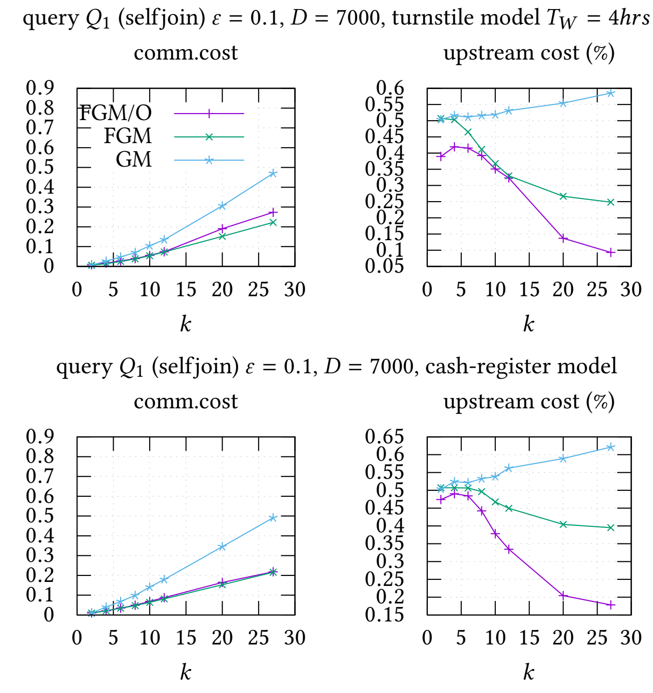

Figure 2: Performance of the GM and FGM protocols, monitoring a self-join query, over k. The top row shows the cost in the tunrstile model (with a window over the streams) and the bottom row show the cost in the cash-register model.

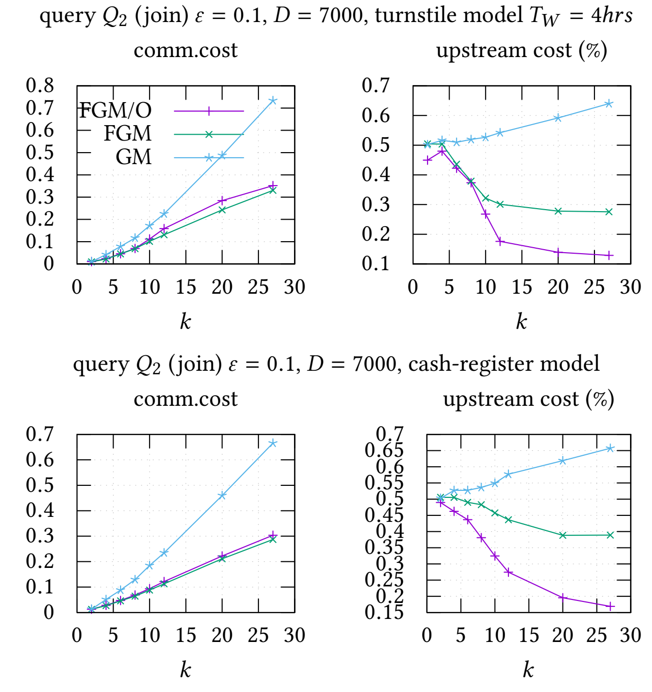

Figure 3: Performance of the GM and FGM protocols, monitoring a join query, over k. The top row shows the cost in the tunrstile model (with a window over the streams) and the bottom row show the cost in the cash-register model.

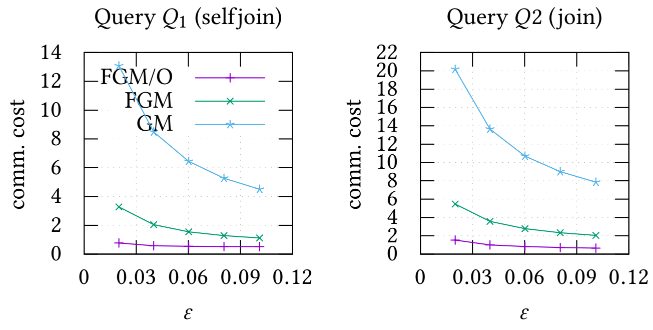

Figure 4: Communication cost for queries Q_1, Q_2, under a difficult workload. Observe that, except for FGM/*O, all protocols exhibit much higher communication cost that the size of the streamed data. Here, $k = 27$, $D = 35000$, $T_W = 1hr$.

than the GM protocols. On the other hand, for small values of k, the difference is not as pronounced.

The graphs on the right side, depicting upsteam communication costs as a percentage of total communication cost, reveals the cause of this behaviour. It is shown that the upstream cost of the standard geometric method grows as a percent of total, as the number of sites increases. This is due to two causes: first, as more sites partake in the monitoring, the strictness of the GM's monitoring condition causes frequent violations of the safety invariant of GM, while most of these violations are false positives. The rebalancing strategy of GM algorithms is unable to overcome this increase (note that, without rebalancing, the GM algorithm's total cost increases even faster, as each false violation would cause a full synchronization).

By contrast, the upstream cost of FGM *decreases* (as a percent of total communication). This is the case both with and without the cost-based optimizer. When k is small, upstream and downstream costs are roughly similar, which is true for the GM as well. As k increases however, the total cost (which increases with k naturally) is dominated by the downstream cost, of shipping data to the coordinator. This is both due to the improved safety condition of FGM, but also to the ovehead-free rebalancing performed.

Note finally the effect of cost-based optimization, which tries to aggressively minimize the upstream cost, even at the expense of downstream cost. Although total cost does not change much, the upstream percentage reduces much further. This is because the cost-based optimizer will decide not to ship safe functions to the sites in many rounds. This choice worsens the quality of summarization at the local nodes, increasing downstream costs, but manages to keep upstream costs low, while achieving good total cost.

5.3 Performance in adverse conditions

We now evaluate the performance of FGM and GM protocols under an adverse scenario, on the real WorldCup dataset, where $k = 27$. We have a large $D = 35,000$, and the stream's window is 1hr, leading to high variability. Fig. 4.

Under these conditions, round lengths are too short to amortize the cost of shipping safe zones to the sites. Therefore, all methods except for FGM/O incur excessive communication costs, in fact several times over the size of the streamed data. This

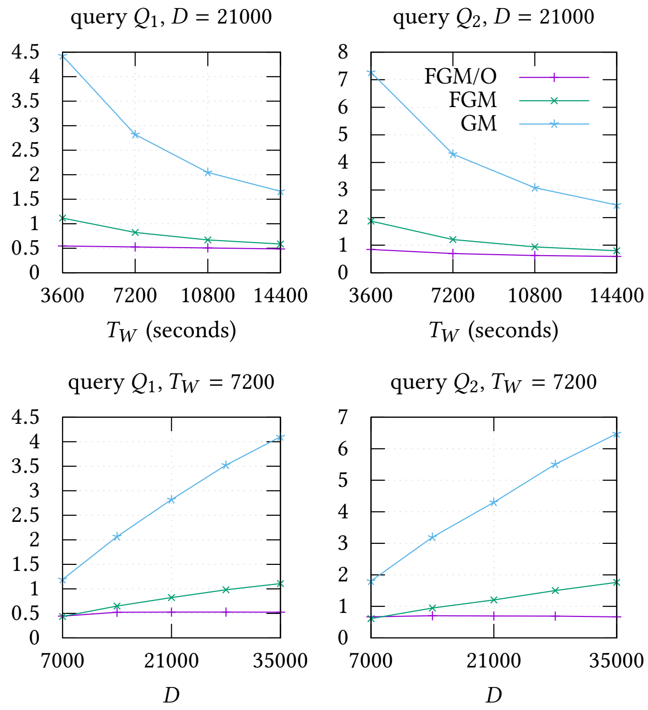

Figure 5: Communication cost for queries Q_1 (left column) and Q_2 (right column), over varying sliding windows (T_w, top row) and sketch size (D, bottom row). In all cases, it was $k = 27$ and $\varepsilon = 0.06$.

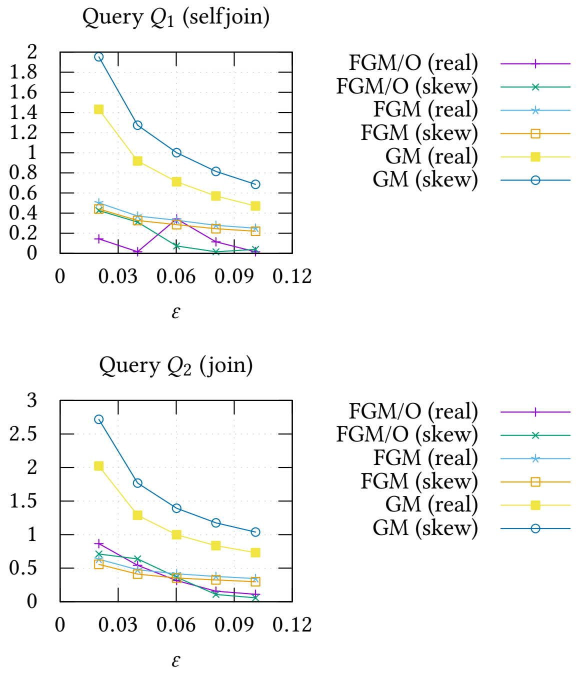

Figure 6: Communication cost for queries Q_1 (top) and Q_2 (bottom), over varying accuracy ε. For each protocol, two curves are shown, one for the real dataset and one for the skewed dataset. For both plots: $k = 27$, $D = 7000$, turnstile model (T_W=4hrs)

is not unexpected; consider that, shipping safe zones to all 27 sites, transmits roughly 3.8 Mbytes of data. Combined with short rounds due to high variability and low values of ε results in excessive overhead.

By contrast, the cost-based optimizer, although it did not deliver significant gains compared to the size of the streamed data, managed to keep the total cost quite low. This was achieved by selecting to avoid the overhead of shipping safe functions in most of the rounds.

5.3.1 Dependence on size of state vectors and on variability. The effect of variability, which decreases as the time window sliding over the stream becomes wider, is quite strong on performance. The top row of plots in Fig. 5 demonstrates this for turnstile queries, where the time window T_W changed from 1 hour to 4 hours. In particular, for the Q_2 function, using the cost model improved performance by two times over FGM (and by 4 over the GM methods), when T_W=1hr.

Similarly strong is the effect of D on performance, as depicted in the bottom row of plots of Fig. 5. In fact, the cost grows linearly with D, except for the case of FGM/O, where the cost-based optimizer switched to the cheap safe functions, achieving a small amount of compression.

5.4 The effect of skew

In order to evaluate the behaviour of our protocols under the presense of skew, we contrast the change in communication when the (real) dataset becomes more skewed. To introduce skew, we constructed a new dataset as follows: we selected 8 sites (out of a total of 27), namely those with local streams of greatest size. Then, we replaced the local stream of one of these sites—which will be referred to as the *hot site*—by the union of all 8 local streams, while the 7 remaining sites received empty local streams. In this *skewed* dataset, one local stream now provides almost half the data to the system, while 7 out of 27 local streams provide no data. However, at each point in time, the *global stream* of the skewed dataset is identical to the global stream of the real dataset.

Fig. 6 depicts the effect of skew on the communication cost. Each protocol was run with both the real and the skewed dataset. Unsuprisingly, the GM protocol's communication cost increases as skew is introduced; this is a well-known weakness of the classic geometric method. The source of the increased cost is a substantial increase in the upstream cost, because of frequent local violations at the hot site.

The FGM prococol without the cost-based optimizer on the other hand, shows resilience in the presence of skew; in fact, the communication cost improves slightly under skew. The key reason is that the ψ-value of the system under the real dataset, is always equal to the ψ-value of the system under the skewed dataset. Therefore, the coordinators in the two systems will perform the exact same number of rounds. The slight improvement is due to a reduction in the downstream cost among the 8 sites; the downstream cost of the hot site has not increased substantially (since the number of rounds remains the same), but the downstream costs of the 7 sites whose local stream vanished has decreased to almost 0 (since these sites will not ship local vectors to the coordinator).

The introduction of the cost-based optimizer is again largely beneficial to the performance. In previous experiments under adverse conditions (e.g., Fig. 4), the benefit of the optimizer was in keeping the upstream cost from becoming too large. In this scenario where skew is introduced, the benefit of the cost-based optimizer materializes more consistently when $\varepsilon \geq 0.05$, where significant benefit to the upstream cost of a round accrues, since the coordinator will undoubtedly choose the cheap safe functions for the 7 sites with empty local streams. Note that, in this scenario, the ψ-values of the constrasted systems are no longer equal (since different optimizer choices affect the actual ψ).

In this experiment, one can also observe the somewhat erratic effect of the cost-based optimizer, due to the crudeness of modeling local stream behaviour (interestingly, in the presense of skew, the behaviour is less erratic). The erratic behaviour is observed in the transition between the two extremes of small and large values of ε; for values of ε around 0.05, it seems that the cost-based optimizer will often be fooled into making sub-optimal choices. However, this is preferable to not using it at all.

Overall, our experimental results demonstrate that the FGM protocol manages to ameliorate the shortcomings of classic GM protocols, both under adverse conditions as well as in the presense of skew in the distributed stream.

6 CONCLUSIONS AND IMPLICATIONS FOR PRACTICE

We have proposed Functional Geometric Monitoring, a novel method for distributed stream monitoring, which offers significant improvements over previous techniques in terms of performance, scalability and robustness. FGM is generally applicable, it can provide worst-case guarantees for problems that were hitherto provided only by problem-specific algorithms, and it is robust in high variability and skew situations, curing an important shortcoming of previous general techniques.

Real-world stream-processing engines are typically customized by providing data-handling code (e.g., mapper/reducer functions in Hadoop, spouts and bolts in STORM, etc), which is independent of distributed execution concerns. The engine orchestrates the distributed execution of this code on a distributed platform, applying complex execution policies (resource allocation, load balancing, networking patterns, failure tolerance, etc).

The salient practical feature of FGM is that it fits this pattern extremely well, as it strictly encapsulates the specifics of monitored queries into data-handling code, namely, routines and data structures—such as sketches—to summarize local streams, and safe function implementations on these summaries. This code is platform-agnostic and an FGM implementation can deploy it on a distributed platform and execute it in a black-box fashion, under any desired execution policy.

Other aspects of FGM are alse important in practice. Although high-quality safe functions for complex query operators can be hard to derive, safe function composition can ease the burden many cases. Furthermore, the FGM protocol is resilient to loss of precision due to computational round-off errors. In addition, since local nodes are memoryless from one round to the next, the FGM protocol is compatible with relatively simple and cheap failure recovery policies.

ABSTRACT

Window aggregation is a core operation in data stream processing. Existing aggregation techniques focus on reducing latency, eliminating redundant computations, and minimizing memory usage. However, each technique operates under different assumptions with respect to workload characteristics such as properties of aggregation functions (e.g., invertible, associative), window types (e.g., sliding, sessions), windowing measures (e.g., time- or count-based), and stream (dis)order. Violating the assumptions of a technique can deem it unusable or drastically reduce its performance.

In this paper, we present the first general stream slicing technique for window aggregation. General stream slicing automatically adapts to workload characteristics to improve performance without sacrificing its general applicability. As a prerequisite, we identify workload characteristics which affect the performance and applicability of aggregation techniques. Our experiments show that general stream slicing outperforms alternative concepts by up to one order of magnitude.

1 INTRODUCTION

The need for real-time analysis shifts an increasing number of data analysis tasks from batch to stream processing. To be able to process queries over unbounded data streams, users typically formulate queries that compute aggregates over bounded subsets of a stream, called windows. Examples of such queries on windows are average vehicle speeds per minute, monthly revenue aggregations, or statistics of user behavior for online sessions.

Large computation overlaps caused by sliding windows and multiple concurrent queries lead to redundant computations and inefficiency. Consequently, there is an urgent need for *general* and *efficient* window aggregation in industry [7, 41, 50]. In this paper, we contribute a general solution which not only improves performance but also widens the applicability with respect to window types, time domains, aggregate functions, and out-of-order processing. Our solution is generally applicable to all data flow systems which adopt a tuple-at-a-time processing model (e.g., Apache Storm, Apache Flink, and other Apache Beam-based systems).

To calculate aggregates of overlapping windows, the database community has been working on *aggregation techniques* such as B-Int [3], Pairs [28], Panes [30], RA [42] and Cutty [10]. These techniques compute partial aggregates for overlapping parts of windows and reuse these partial aggregates to compute final aggregates for overlapping windows. We believe that these techniques are not widely adopted in open-source streaming systems for two main reasons: first, the literature on streaming window aggregation is fragmented and, second, every technique has its own assumptions and limitations. As a consequence, it is not clear for researchers and practitioners under which conditions which streaming window aggregation techniques should be used.

General purpose streaming systems require a window operator which is applicable to many types of aggregation workloads. At the same time, the operator should be as efficient as specialized techniques which support selected workloads only.

As our first contribution we identify the workload characteristics which may or may not be supported by existing specialized window aggregation techniques. Those characteristics are: i) *window types* (e.g., sliding, session, tumbling), ii) *windowing measures* (e.g., time or tuple-count), iii) *aggregate functions* (e.g., associative, holistic), and iv) *stream order*. We then conduct an extensive literature survey and classify existing techniques with respect to their underlying concepts and their applicability.

We identify stream slicing as a common denominator on top of which window aggregation can be implemented efficiently. Consequently, our second main contribution is *a general stream slicing technique*. Existing slicing-based techniques do not support complex window types such as session windows [28, 30], do not consider out-of-order processing [10], or limit the type of aggregation functions [10, 28, 30]. With general stream slicing, we provide a single, generally applicable, and highly efficient solution for streaming window aggregation. Our solution inherits the performance of specialized techniques, which use stream slicing, and generalizes stream slicing to support diverse workloads. Because we integrate all workloads into one general solution, we enable computation sharing among all queries with different window types (sliding, sessions, user-defined, etc.) and window measures (e.g., tuple-count or time). General stream slicing is available open source and can be integrated into streaming systems directly as a library[1].

General stream slicing breaks down slicing into three operations on slices, namely `merge`, `split`, and `update`. Specific workload characteristics influence what each operation costs and how often operations are performed. By taking into account the workload characteristics, our slicing technique i) stores the tuples themselves only when it is required which saves memory and ii) minimizes the number of slices that are created, stored, and recomputed. One can extend our techniques with additional aggregations and window types without changing the three core slicing operations. Thus, these core operations may be tuned by system experts while users can still implement custom windows and aggregations.

The contributions of this paper are as follows:

(1) We identify the workload characteristics which impact the applicability and performance limitations of existing aggregation techniques (Section 4).
(2) We contribute *general stream slicing*, a generally applicable and highly efficient solution for streaming window aggregation in dataflow systems (Section 5).
(3) We evaluate the performance implications of different usecase characteristics and show that stream slicing is generally applicable while offering better performance than existing approaches (Section 6).

The remainder of this paper is structured as follows: We first provide background information in Section 2 and present concepts of aggregation techniques in Section 3. We then present our contributions in Section 4, 5, and 6 and discuss related work in Section 7.

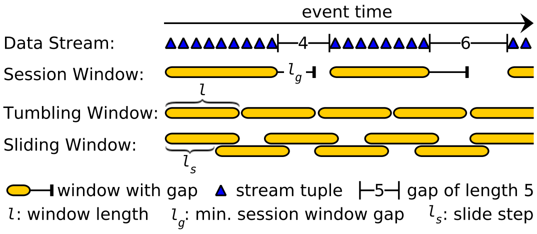

Figure 1: Common Window Types.

2 PRELIMINARIES

Streaming window aggregation involves special terminology with respect to window types, timing, stream order, and data expiration. This section revisits terms and definitions, which are required for the remainder of this paper.

Window Types. A window type refers to the logic based on which systems derive finite windows from a continuous stream. There exist diverse window types ranging from common sliding windows to more complex data-driven windows [17]. We address the diversity of window types with a classification in Section 4.4. For now, we limit the discussion to *tumbling* (or *fixed*), *sliding*, and *session* windows (Figure 1) which we use in subsequent examples. A *tumbling* window splits the time into segments of equal length l. The end of one window marks the beginning of the next window. *Sliding* windows, in addition to the length l, also define a slide step of length l_s. This length determines how often a new window starts. Consecutive windows overlap when $l_s < l$. In this case, tuples may belong to multiple windows. A *session* window typically covers a period of activity followed by a period of inactivity [1]. Thus, a session window times out (ends) if no tuple arrives for some time gap l_g. Typical examples of sessions are taxi trips, browser sessions, and ATM interactions.

Notion of Time. One can define windows on different measures such as times and tuple-counts. The *event-time* of a tuple is the time when an event was captured and the *processing-time* is the time when an operator processes a tuple [1, 9]. Technically, an event-time is a timestamp stored in the tuple and processing-time refers to a system clock. If not indicated otherwise, we refer to event-time windows in our examples because applications typically define windows on event-time.

Stream Order. Input tuples of a stream are in-order if they arrive chronologically with respect to their event-times, otherwise, they are out-of-order [1, 33]. In practice, streams regularly contain out-of-order tuples because of transmission latencies, network failures, or temporary sensor outages. We differentiate in-order tuples from out-of-order tuples and in-order streams from out-of-order streams. Let a stream S consist of tuples $s_1, s_2, s_3, \ldots$ where the subscripts denote the order in which an operator processes the tuples. Let the event-time of any tuple s_x be $t_e(s_x)$.

- A tuple s_x is *in-order* if $t_e(s_x) \geq t_e(s_y)\ \forall\, y < x$.
- A stream is in-order iff all its tuples are in-order tuples.

Punctuations, Watermarks, and Allowed Lateness. *Punctuations* are annotations embedded in a data stream [47]. Systems use punctuations for different purposes: *low-watermarks* (in short *watermarks*) indicate that no tuple will arrive with a timestamp smaller than the watermark's timestamp [1]. Many systems use watermarks to control how long they wait for out-of-order tuples before they output a window aggregate [2]. *Window punctuations* mark window starts and endings in the stream [14, 20]. The *allowed lateness*, specifies how long systems store window aggregates. If an out-of-order tuple arrives after the watermark, but in the allowed lateness, we output updated aggregates.

Partial Aggregates and Aggregate Sharing. The key idea of partial aggregation is to compute aggregates for subsets of the stream as intermediate results. These intermediate results are *shared* among overlapping windows to prevent repeated computation [3, 28, 51]. In addition, one can compute partial aggregates incrementally when tuples arrive [42]. This reduces the memory footprint if a technique stores few partial aggregates instead of all stream tuples in the allowed lateness. It also reduces the latency because aggregates are pre-computed when windows end.

	Memory Usage	Example
1. Tuple Buffer	|▲|·size(▲)	
2. Aggregate Tree	|▲|·size(▲) +(|▲|−1)·size(●)	3. Agg. Buckets	|win|·size(●) +|win|·size(␣)	4. Tuple Buckets	|win|·[avg(▲ per win.) ·size(▲) +size(␣)]	5. Lazy Slicing	|⬬|·size(⬬)	6. Eager Slicing	|⬬|·size(⬬) +(|⬬|−1)·size(●)	7. Lazy Slicing on tuples	|▲|·size(▲) +|⬬|·size(⬬)	8. Eager Slicing on tuples	|▲| · size(▲) +|⬬|·size(⬬) +(|⬬|−1)·size(●)

3 WINDOW AGGREGATION CONCEPTS

In this section, we survey concepts for streaming window aggregation and give an intuition for each solution's memory usage, throughput, and latency. We provide a detailed comparison of all concepts in our experiments. Techniques which support out-of-order streams store values for an *allowed lateness* (see above). In the following discussion, we refer to allowed lateness only. Techniques which do not process out-of-order tuples, store values for the duration of the longest window.

Table 1 provides an overview of all techniques we discuss in the following subsections. We write |▲| for the number of values (i.e., tuples), |⬬| for the number of slices, and |win| for the number of windows in the allowed lateness.

3.1 Tuple Buffer

A tuple buffer (Table 1, Row 1) is a straightforward solution which does not share partial aggregates.

The *throughput* of a tuple buffer is fair as long as there are few or no concurrent windows (i.e., no window overlaps), and there are few or no out-of-order tuples. Window overlaps decrease the throughput because of repeated aggregate computations. Out-of-order tuples decrease the throughput because of memory copy operations which are required for inserting values in the middle of a sorted ring buffer.

The *latency* of a tuple buffer is high because aggregates are computed lazily when windows end. Thus, all aggregate computations contribute to the latency at the window end.

A tuple buffer stores all tuples for the allowed lateness, which is |▲|·size(▲). Thus, the more tuples we process per time, the higher the memory consumption and the higher the memory copy overhead for out-of-order tuples.

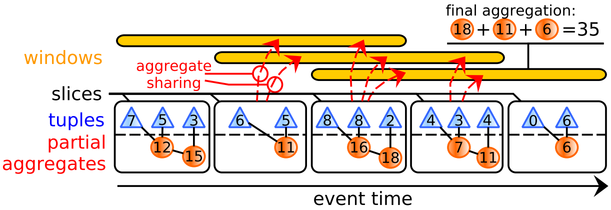

Figure 2: Example Aggregation with Stream Slicing.

3.2 Aggregate Trees

Aggregate trees such as FlatFAT [42] and B-INT [3] store partial aggregates in a tree structure and share them among overlapping windows (Table 1, Row 2). FlatFAT stores a binary tree of partial aggregates on top of stream tuples (leaves) which roughly doubles the memory consumption.

In-order tuples require $\log(|▲|)$ updates of partial aggregates in the tree. Thus, the *throughput* is decreased logarithmically when the number of tuples in the allowed lateness increases. Out-of-order tuples decrease the throughput drastically: they require the same memory copy operation as in tuple buffers. In addition, they cause a rebalancing of the aggregate tree and the respective aggregate updates.

The *latency* of aggregate trees is much lower than for tuple buffers because they can compute final aggregates for windows from pre-computed partial aggregates. Thus, only a few final aggregation steps remain when windows end [39].

3.3 Buckets

Li et al. introduce *Window-ID* (WID) [31–33], a bucket-per-window approach which is adopted by many systems with support for out-of-order processing [1, 2, 9]. Each window is represented by an independent bucket. A system assigns tuples to buckets (i.e., windows) based on event-times, independently from the order in which tuples arrive [33]. Buckets do not utilize aggregate sharing. Instead, they compute aggregates for each bucket independently.

Systems can compute aggregates for buckets incrementally [42]. This leads to very low *latencies* because the final window aggregate is pre-computed when windows end.

We consider two versions of buckets. *Tuple buckets* keep individual tuples in buckets (Table 1, Row 4). This leads to data replication for overlapping buckets. *Aggregate buckets* store partial aggregates in buckets plus some overhead (e.g., start and end times), but no tuples (Table 1, Row 3).

We prefer to store aggregates only in order to save memory. However, some use-cases (e.g., holistic aggregates over count-based windows) require us to keep individual tuples.

Buckets process in-order tuples as fast as out-of-order tuples for most use-cases: they assign the tuple to buckets and incrementally compute the aggregate of these buckets. The throughput bottleneck for buckets are overlapping windows. For example, one sliding window with $l = 20s$ and $l_s = 2s$ results in 10 overlapping windows (i.e., buckets) at any time. This causes 10 aggregation operations for each input tuple.

3.4 Stream Slicing

Slicing techniques divide (i.e., *slice*) a data stream into non-overlapping chunks of data (i.e., *slices*) [28, 30]. The system computes a partial aggregate for each slice. When windows end, the system computes window aggregates from slices.

We show stream slicing with an example in Figure 2. Slicing techniques compute partial aggregates incrementally when tuples arrive (bottom of Figure 2). We show multiple intermediate aggregates per slice to illustrate the workflow.

Partial aggregates (i.e., slices) are shared among overlapping windows which avoids redundant computations. In Figure 2, dashed arrows mark multiple uses of slices. In contrast to aggregate trees and buckets, slicing techniques require just one aggregation operation per tuple because each tuple belongs to exactly one slice. This results in a high *throughput*.

Similar to aggregate trees, the *latency* of stream slicing techniques is low because only a few final aggregation steps are required when a window ends. We consider a lazy and an eager version of stream slicing. The lazy version of stream slicing stores slices including partial aggregates (Table 1, Row 5). The eager version stores a tree of partial aggregates on top of slices to further reduce latencies (Table 1, Row 6). Both variants compute aggregates of slices incrementally when tuples arrive. The term *lazy* refers to the lazy computation of aggregates for combinations of slices.

There are usually many tuples per slice ($|●| \ll |▲|$) which leads to huge memory savings compared to aggregate trees and tuple buffers. Some use-cases such as holistic aggregates over count-based windows require us to keep individual tuples in addition to aggregates (Table 1, Row 7 and 8). In these cases, stream slicing requires more memory than tuple buffers, but saves memory compared to buckets and aggregate trees.

In this paper, we focus on stream slicing because it offers a good combination of high throughputs, low latencies, and memory savings. Moreover, our experiments show that slicing techniques scale to many concurrent windows, high ingestion rates, and high fractions of out-of-order tuples.

4 WORKLOAD CHARACTERIZATION

In this section, we identify workload characteristics which either limit the applicability of aggregation techniques or impact their performance. These characteristics are the basis for subsequent sections in which we generalize stream slicing.

4.1 Characteristic 1: Stream Order

Out-of-order streams increase the complexity of window aggregation because out-of-order tuples can require changes in the past. For example, tuple buffers and aggregate trees process in-order tuples efficiently using a ring buffer (FIFO principle) [42]. Out-of-order tuples break the FIFO principle and require memory copy operations in buffers.

We differentiate whether or not out-of-order processing is required for a use-case. For techniques which support out-of-order processing, we study how the fraction of out-of-order tuples and the delay of such tuples affect the performance.

4.2 Characteristic 2: Aggregation Function

We classify aggregation functions with respect to their algebraic properties. Our notation splits the aggregation in incremental steps and is consistent with related works [10, 42]. We write input values as lower case letters, the operation which adds a value to an aggregate as $\oplus$, and the operation which removes a value from an aggregate as $\ominus$. We first adopt three algebraic properties used by Tangwongsan et al. [42]. These properties focus on the incremental computation of aggregates:

(1) Associativity: $(x \oplus y) \oplus z = x \oplus (y \oplus z) \ \ \forall \, x, y, z$
(2) Invertibility: $(x \oplus y) \ominus y = x \ \ \forall \, x, y$
(3) Commutativity: $x \oplus y = y \oplus x \ \ \forall \, x, y$

Stream slicing requires *associative* aggregate functions because it computes partial aggregates per slice which are shared among windows. This requirement is inherent for all techniques which share partial aggregates [3, 10, 28, 30, 42]. Our general slicing approach does not require invertibility or commutativity, but exploits these properties if possible to increase performance.

We further adopt the classification of aggregations in *distributive*, *algebraic*, and *holistic* [16]. Aggregations such as `sum`, `min`, and `max` are *distributive*. Their partial aggregates equal the final aggregates of partials and have a constant size. An aggregation is *algebraic* if its partial aggregates can be summarized in an intermediate result of fixed size. The final aggregate is computed from this intermediate result. The remainder of aggregations, which have an unbounded size of partial aggregates, is *holistic*.

4.3 Characteristic 3: Windowing Measure

Windows can be specified using different measures (also called *time domains* [8] or `WATTR` [31]). For example, a tumbling window can have a length of 5 minutes (time-measure), or a length of 10 tuples (count-measure). To simplify the presentation, we refer to *timestamps* in the rest of the paper. However, bear in mind that a timestamp can actually be a point in time, a tuple count, or any other monotonically increasing measure [10]:

- **Time-Based Measures:** Common time-based measures are *event-time* and *processing-time* as introduced in Section 2.
- **Arbitrary Advancing Measures** are a generalization of event-times. Typically, it is irrelevant for a stream processor if *"timestamps"* actually represent a time or another advancing measure. Examples of other advancing measures are transaction counters in a database, kilometers driven by a car, and invoice numbers.
- **Count-Based Measures** (also called *tuple-based* [31] or *tuple-driven* [8]) refer to a tuple counter. For example, a window can start at the 100th and end at the 200th tuple of a stream. Count-based measures cause challenges when combined with out-of-order processing: If tuples are ordered with respect to their event-times and a tuple arrives out-of-order, it changes the count of all other tuples which have a greater event-time. This changes the aggregates of all count-based windows which start or end after the out-of-order tuple.

If we process multiple queries which use different window-measures, timestamps are represented as vectors which contain multiple measures as dimensions. This representations allows for slicing the stream with respect to multiple dimensions (i.e., measures) while slices are still shared among all queries [10].

4.4 Characteristic 4: Window Type

We classify window types with respect to the *context* (or *state*) which is required to know where windows start and end. We adopt the classification in context free (CF), forward-context aware (FCA), and forward-context free (FCF) introduced by Li et al. [31]. Here we present those classes along with the most common window types belonging to those classes.

- **Context Free (CF).** A window type is context free if one can tell all start and end timestamps of windows without processing any tuples. Common *sliding* and *tumbling* windows are context free because we can compute all start and end timestamps a priori based on the parameters l and l_s.
- **Forward Context Free (FCF).** Windows are forward context free, if one can tell all start and end timestamps of windows up to any timestamp t, once all tuples up to this timestamp t have been processed. An example are *punctuation-based* windows where punctuations mark start and end timestamps [14]. Once we processed all tuples up to t (including out-of-order tuples), we also processed all punctuations before t and, thus, we know all start and end positions up to t.
- **Forward Context Aware (FCA).** The remaining window types are forward context aware. Such window types require us to process tuples after a timestamp t in order to know all window start and end timestamps before t. An example of such windows are *Multi-Measure Windows* which define their start and end timestamps on different measures. For example, *output the last 10 tuples (count-measure) every 5 seconds (time-measure)* is forward context aware: we need to process tuples up to a window end in order to compute the window begin.

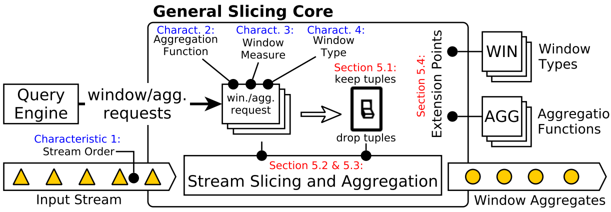

Figure 3: Architecture of General Stream Slicing

5 GENERAL STREAM SLICING

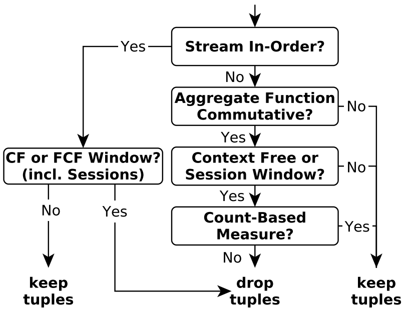
We now present our general stream slicing technique which supports high-performance aggregation for multiple queries with diverse workload characteristics. General stream slicing replaces alternative operators for window aggregation without changing their input or output semantics. Our technique minimizes the number of partial aggregates (saving memory), reduces the final aggregation steps when windows end (reducing latency), and avoids redundant computation for overlapping windows (increasing throughput). The main idea behind our technique is to exploit workload characteristics (Section 4) and to automatically adapt aggregation strategies. Such adaptivity is a highly desired feature of an aggregation framework: current non-adaptive techniques fail to support multiple window types, process in-order streams only, cannot share aggregates among windows defined on different measures, lack support for holistic aggregations, or incur dramatically reduced performance in exchange for being generally applicable.

Approach Overview. Figure 3 depicts an overview of our general slicing and aggregation technique. Users specify their queries in a high-level language such as a flavor of stream SQL or a functional API. The query translator observes the characteristics of a query (i.e., window type, aggregate function, and window measure) as well as the characteristics of input streams (in-order vs. out-of-order streams) and forwards them to our aggregator. Once those characteristics are given to our aggregator, our general slicing technique adapts automatically to the given workload characteristics.

More specifically, general slicing detects if individual tuples need to be kept in memory (to ensure generality) or if they can be dropped after computing partial aggregates (to improve performance). We further discuss this in Section 5.1. Queries can be added or removed from the aggregator and due to that, the workload characteristics can change. To this end, our aggregator adapts when one adds or removes queries. Weather we need to keep tuples in memory or not solely depends on workload characteristics. Thus, there is no need to adapt on changes in the input data streams such as a changing ratio of out-of-order tuples. When processing input tuples, the stream slicing component automatically decides when it needs to apply our three fundamental slicing operations: merge, split, and update (discussed in Section 5.2). General slicing has extension points that can be used to implement user-defined window types and aggregations (discussed in Section 5.4).

5.1 Storing Tuples vs. Partial Aggregates

General aggregation techniques [3, 42] achieve generality by storing all input tuples and by computing high-level partial aggregates. Specialized techniques, on the other hand, only store (partial) aggregates. A general slicing technique needs to decide when to store what, according to workload characteristics of each of the queries



Stream In-Order?

keep tuples
drop tuples
keep tuples

Figure 4: Decision Tree - Which workload characteristics require storing individual tuples in memory?

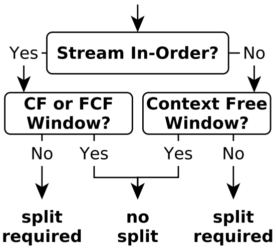

Figure 5: Decision Tree. Are splits required?

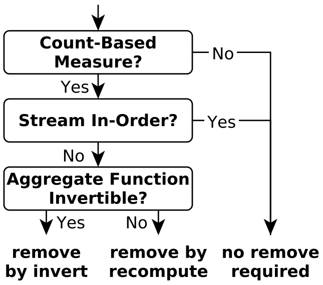

Figure 6: Decision Tree. How to remove tuples?

that it serves. In this section, we discuss how we match the performance of specialized techniques, by choosing on-the-fly whether to keep tuples for a workload or to store partial aggregates only.

For example, consider an aggregation function which is non-commutative ($\exists x, y : x \oplus y \neq y \oplus x$) defined over an unordered stream. When an out-of-order tuple arrives, we need to recompute aggregates from the source tuples in order to retain the correct order of the aggregation. Thus, one would have to store the actual tuples for possible later use. Storing all tuples for the whole duration of the allowed lateness requires more memory but allows for computing arbitrary windows from stored tuples. The decision tree in Figure 4 summarizes when storing source tuples is required depending on different workload characteristics.

In-order Streams. For in-order streams, we drop tuples for all context free and forward context free windows but must keep tuples if we process forward context aware windows. For such windows, forward context leads to additional window start or end timestamps. Thus, we must be able to compute partial aggregates for arbitrary timestamp ranges from the original stored tuples.

Out-of-order Streams. For out-of-order streams, we need to keep tuples if at least one of the following conditions is true:

(1) The aggregation function is non-commutative.
An out-of-order tuple changes the order of the incremental aggregation, which forces us to recompute the aggregate using source tuples. For in-order processing, the commutativity of aggregation functions is irrelevant because tuples are always aggregated in-order. Thus, there is no need to store source tuples in addition to partial aggregates.

(2) The window is neither context free nor a session window.
In combination with out-of-order tuples, all context aware windows require tuples to be stored. This is because out-of-order tuples change backward context which can lead to additional window start or end timestamps. Such additional start and end timestamps require to split slices and to recompute the respective partial aggregates from the original tuples. Session windows are an exception, because they are context aware, but never require recomputing aggregates [46].

(3) The query uses a count-based window measure.
An out-of-order tuple changes the count of all succeeding tuples. Thus, the last tuple of each count-based window shifts to a succeeding window.

5.2 Slice Management

Stream slicing is the fundamental concept that allows us to build partial aggregates and share them among concurrently running queries and overlapping windows. In this section, we introduce three fundamental operations which we can perform on slices.

Slice Metadata. A slice stores its start timestamp ($t_{\texttt{start}}$), its end timestamp (t_{end}), and the timestamp of the first ($t_{\texttt{first}}$) and last tuple it contains ($t_{\texttt{last}}$). Note that the timestamps of the first and last tuples do not need to conincide with the start and end timestamps of a slice. For instance, consider a slice A that starts at $t_{\texttt{start}}(A) = 1$ and ends at $t_{\text{end}}(A) = 10$ but the first (earliest) tuple contained is timestamped as $t_{\texttt{first}}(A) = 2$ and its last/latest one as $t_{\texttt{last}}(A) = 9$. We remind the reader that the *timestamp* can refer not only to actual time, but to any measure presented in Section 4.3.

We identify three fundamental operations which we perform on stream slices. These operations are *i*) *merging* of two slices into one, *ii*) *splitting* one slice into two, and *iii*) *updating* the state of a slice (i.e., aggregate and metadata updates). In the following paragraphs, we discuss `merge`, `split`, and `update` as well as the impact of our workload characteristics on each operation. We use upper case letters to name slices and corresponding lower case letters for slice aggregates.

Merge. Merging two slices A and B happens in three steps:

1. Update the end of A such that $t_{\text{end}}(A) \leftarrow t_{\text{end}}(B)$.
2. Update the aggregate of A such that $a \leftarrow a \oplus b$.
3. Delete slice B, which is now merged into A.

Steps one and three have a constant computational cost. The complexity of the second step ($a \leftarrow a \oplus b$) depends on the type of aggregate function. For instance, the cost is constant for algebraic and distributive functions such as `sum`, `min`, and `avg` because they require just a few basic arithmetic operations. Holistic functions such as quantiles can be more complex to compute. Except from the type of aggregation function, no other workload characteristics impact the complexity of the merge operation. However, stream order and window types influence when and *how often* we merge slices. We discuss this influence in Section 5.3.

Split. Splitting a slice A at timestamp t requires three steps:

1. Add slice B: $t_{\texttt{start}}(B) \leftarrow t + 1$ and $t_{\text{end}}(B) \leftarrow t_{\text{end}}(A)$.
2. Update the end of A such that $t_{\text{end}}(A) \leftarrow t$.
3. Recompute the aggregates of A and B.

Note that splitting slices is an expensive operation because it requires recomputing slice aggregates from scratch. Moreover, if splitting is required, we need to keep individual tuples in memory to enable the recomputation.

We show in Figure 5 when split operations are required. For in-order streams, only forward context aware (FCA) windows require split operations. For such windows, we split slices according to a window's start and end timestamp as soon as we process the required forward context. In out-of-order data streams, all context aware windows require split operations because out-of-order tuples possibly contain relevant backward context. We never split slices for context free windows such as tumbling and sliding ones.

Update. Updating a slice can involve adding in-order tuples, adding out-of-order tuples, removing tuples, or changing metadata ($t_{\texttt{start}}$, t_{end}, $t_{\texttt{first}}$, and $t_{\texttt{last}}$).

Metadata changes are simple assignments of new values to the existing variables. Adding a tuple to a slice requires one incremental aggregation step ($\oplus$), with the exception of processing out-of-order tuples with a non-commutative aggregation function.

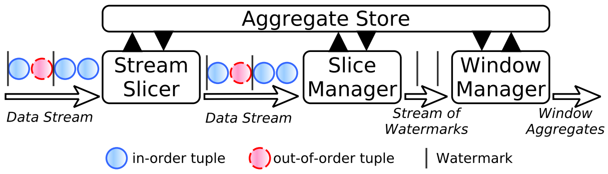

Figure 7: The Stream Slicing and Aggregation Process

For this, we recompute the aggregate of the slice from scratch to retain the order of aggregation steps.

For some workloads we need to remove tuples from slices. We show in Figure 6 when and how we remove tuples from slices. Generally, a remove operation is required only if a window is defined on a count-based measure and if we process out-of-order tuples. An out-of-order tuple changes the count of all succeeding tuples. This requires us to shift the last tuple of each slice one slice further starting at the slice of the out-of-order tuple. If the aggregation function is invertible, we exploit this property by performing an incremental update. Otherwise, we have to recompute the slice aggregate from scratch. If the out-of-order tuple has a small delay, such that it still belongs to the latest slice, we can simply add the tuple without performing a remove operation.

5.3 Processing Input Tuples

The stream slicing and aggregation logic (bottom of Figure 3) consists of four components which we show in Figure 7. The Aggregate Store is our shared data structure which is accessed by the Stream Slicer to create new slices, by the Slice Manager to update slices, and by the Window Manager to compute window aggregates.

The input stream can contain in-order tuples, out-of-order tuples, and watermarks. Note that in-order tuples can either arrive from an in-order stream (i.e., one that is guaranteed to never contain an out-of-order tuple) or from an out-of-order stream (i.e., one that does not guarantee in-order arrival). If the the stream is in-order (i.e., all tuples are in-order tuples), there is no need to ingest watermarks. Instead, we output windows directly since there is no need to wait for potentially delayed tuples.

Step 1 - The Stream Slicer. The Stream Slicer initializes new slices on-the-fly when in-order tuples arrive [28]. In an in-order stream, it is sufficient to start slices when windows start [10]. In an out-of-order stream, we also need to start slices when windows end to allow for updating the last slice of windows later on with out-of-order tuples. We always cache the timestamp of the next upcoming window edge and compare in-order tuples with this timestamp. As soon as the timestamp of a tuple exceeds the cached timestamp, we start a new slice and cache the timestamp of the next edge. This is highly efficient because the majority of tuples do not end a slice and require just one comparison of timestamps.

The Stream Slicer does not process out-of-order tuples and watermarks but forwards them directly to the Slice Manager. This is possible because the slices for out-of-order tuples have already been initialized by previous in-order tuples.

Step 2 - The Slice Manager. The Slice Manager is responsible for triggering all `split`, `merge`, and `update` operations on slices.

First, the Slice Manager checks whether a `merge` or `split` operation is required. We always merge and split slices such that all slice edges match window edges and vice versa. This guarantees that we maintain the minimum possible number of slices [10, 46].

In an out-of-order stream, context aware windows can cause `merge`s or `split`s. In an in-order stream, only forward context aware windows can cause these operations. Context free windows never require `merge` or `split` operations, as the window edges are known in advance and slices never need to change.

In-order tuples can be part of the forward context which indicates window start or end timestamps earlier in the stream. When processing forward context aware windows, we check if the new tuple changes the context such that it introduces or removes window start or end timestamps. In such case, we perform the required `merge` and `split` operation to match the new slice and window edges. Out-of-order tuples can change forward and backward context such that a `merge` operation or `split` operation are required.

If the new context causes new window edges and, thus, `merge` or `split` operations, we notify the Window Manager which outputs window aggregates up to the current watermark.

Finally, the Slice Manager adds the new tuple to its slice and updates the slice aggregate accordingly. In-order tuples always belong to the current slice and are added with an incremental aggregate update [42]. For out-of-order tuples, we look up the slice which covers the timestamp of the out-of-order tuple and add the tuple to this slice. For commutative aggregation functions, we add the new tuple with an incremental aggregate update. For non-commutative aggregation functions, we need to recompute the aggregate from individual tuples to retain the correct order.

Step 3 - The Window Manager. The Window Manager computes the final aggregates for windows from slice aggregates.

When processing an in-order stream, the Window Manager checks if the tuple it processes is the last tuple of a window. Therefore, each tuple can be seen as a watermark which has the timestamp of the tuple. If a window ended, the window manager computes and outputs the window aggregate (final aggregation step).

For out-of-order streams, we wait for the watermark (see Section 2) before we output results of windows which ended before a watermark.

The Slice Manager notifies the Windows Manager when it performs `split`, `merge`, or `update` operation on slices. Upon such notification, the Window Manager performs two operations:

(1) If an out-of-order tuple arrives within the allowed lateness but after the watermark, the tuple possibly changes aggregates of windows which were output before. Thus, the Window Manager outputs updates for these window aggregates.
(2) If a tuple changes the context of context aware windows such that new windows end before the current watermark, the window manager computes and outputs the respective aggregates.

Parallelization. We parallelize stream processing with key partitioning which is the common approach used in stream processing systems [21] such as Flink [9], Spark [4], and Storm [44]. Key partitioning enables intra-node as well as inter-node parallelism and, thus, results in good scalability. Since our generic window aggregation is a drop in replacement for the window aggregation operator, the input and output semantics of the operator remains unchanged. Thus, neither the query interface nor optimizations unrelated to window aggregations are affected.

5.4 User-Defined Windows and Aggregations

Our architecture decouples the general logic of stream slicing from the concrete implementation of window types and aggregation functions. This makes it easy to add window types and aggregation functions as no changes are required in the slicing logic. In this section, we describe how we implement aggregation functions and window types.

5.4.1 *Implementing Aggregation Functions.*

We adopt the same approach of incremental aggregation introduced by Tangwongsan et al. [42]. Each aggregation type consists of three functions: `lift`, `combine`, and `lower`. In addition, aggregations may implement an invert function. We now discuss the concept behind these functions, and refer the reader to the original paper for an overview of different aggregations and their implementation.

Lift. The lift function transforms a tuple to a partial aggregate. For example, consider an average computation. If a tuple $\langle t, v \rangle$ contains its timestamp t and a value v, the lift function will transform it to $\langle \text{sum} \leftarrow v, \text{count} \leftarrow 1 \rangle$, which is the partial aggregate of that one tuple.
Combine. The combine function ($\oplus$) computes the combined aggregate from partial aggregates. Each incremental aggregation step results in one call of the combine function.
Lower. The lower function transforms a partial aggregate to a final aggregate. In our example, the lower function computes the average from sum and count: $\langle \text{sum}, \text{count} \rangle \mapsto \text{sum/count}$.
Invert. The optional invert function removes one partial aggregate from another with an incremental operation.

In this work, we consider holistic aggregation functions which have an unbounded size of partial aggregates. A widely used holistic function is the computation of quantiles. For instance, windowed quantiles are the basis for billing models of content delivery networks and transit-ISPs [13, 23]. For quantile computations, we sort tuples in slices to speed up succeeding merge operations and apply run length encoding to save memory [37].

5.4.2 Implementing Different Window Types. We use a common interface for the in-order slicing logic of all windows. We extend this interface with additional methods for context-aware windows. One can add additional window types by implementing the respective interface.

Context Free Windows. The slicing logic for context free windows depends on in-order tuples only. When a tuple is processed, the slicing core initializes all slices up to the timestamp of that tuple. Our interface for context free windows has two methods: The first method has the signature `long getNextEdge(long timestamp)`. It receives a timestamp as parameter and returns the next window edge (begin or end timestamp) after this timestamp. We use this method to retrieve the next window edge for on-the-fly stream slicing (Step 1 in Section 5.3). For example, a tumbling window with length l would return $timestamp + l - (timestamp \bmod l)$.

The second method triggers the final window aggregation according to a watermark and has the following signature:
`void triggerWin(Callback c, long prevWM, long currWM)`.
The Window Manager calls this method when it processes a watermark. c is a callback object, prevWM is the timestamp of the previous watermark and currWM is the timestamp of the current watermark. The method reports all windows which ended between prevWM and currWM by calling `c.triggerWin(long startTime, long endTime)`. This callback to the Window Manager triggers the computation and output of the final window aggregate.
Context Aware Windows. Context aware windows use the same interface as context free windows to trigger the initialization of slices when processing in-order tuples. In addition, context aware windows require to keep a state (i.e., context) in order to derive window start and end timestamps when processing out-of-order tuples. We initialize context aware windows with a pointer to the Aggregate Store. This prevents redundancies among the state of the shared aggregator and the window state. When the Slice Manager processes a tuple, it notifies context aware windows by calling `window.notifyContext(callbackObj, tuple)`. This method can then add and remove window start and end timestamps through the callback object and the Slice Manager splits and merges slices as required to match window start and end timestamps. We detect whether or not a window is context aware based on the interface which is implemented by the window specification. We provide examples for different context free and context aware window implementations in our open source repository.

6 EVALUATION

In this section, we evaluate the performance of general stream slicing and compare stream slicing with alternative techniques introduced in Section 3.

6.1 Experimental Setup

Setup. We implement all techniques on Apache Flink v1.3. We run our experiments on a VM with 6 GB main memory and 8 processing cores with 2.6 GHz.
Metrics. In our experiments, we report throughput, latency, and memory consumption. We measure throughput as in the Yahoo Streaming Benchmark implementation for Apache Flink [12, 48]. We determine latencies with the JMH benchmarking suite [35]. JMH provides precise latency measurements on JVM-based systems. We use the *ObjectSizeCalculator* of Nashorn to determine memory footprints [36].
Baselines. We compare an eager and a lazy version of general stream slicing with non-slicing techniques from Section 3: As representative for aggregate trees, we implement FlatFAT [42]. For the buckets technique, we use the implementation of Apache Flink [9]. For tuple buffers, we use an implementation based on a ring buffer array. We also include Pairs [28] and Cutty [10] as specialized slicing techniques where possible.
Data. We replay real-world sensor data from a football match [34] and from manufacturing machines [25]. The original data sets track the position of the football with 2000 and the machine states with 100 updates per second. We generate additional tuples based on the original data to simulate higher ingestion rates. We add 5 gaps per minute to separate sessions. This is representative for the ball possession moving from one player to another. If not indicated differently, we show results for the football data. The results for other data sets are almost identical because the performance depends on workload characteristics rather than data characteristics.
Queries. We base our queries (i.e., window length, slide steps, etc.) on the workload of a live-visualization dashboard which is built for the football data we use [45]. If not indicated differently, we use the sum aggregation in Sections 6.2 and Section 6.3. In Section 6.4, we use the M4 aggregation technique [26] to compress the data stream for visualization. M4 computes four algebraic aggregates per window (i.e., minimum, maximum, first and last value of each window). We show in Section 6.3.2 how the performance differs among diverse aggregation functions. Because we do not change the input and output semantics of the window and aggregation operation, there is no impact on upstream or downstream operations. We ensure that windowing and aggregation are the bottleneck and, thus, we measure the performance of aggregation techniques.

We do not alternate between tumbling and sliding windows because they lead to identical performance: For example, 20 concurrent tumbling window queries cause 20 concurrent windows (1 window for each query at any time). This is equivalent to a single sliding window with a window length of 20 seconds and and a slide step of one second (again 20 concurrent windows). In the following, we refer to *concurrent windows* instead of *concurrent tumbling window queries. Sliding window queries* yield identical results if they imply the same number of *concurrent windows.*
Structure. We split our evaluation in three parts. First, we compare stream slicing and alternative approaches with respect to their throughput, latency, and memory footprint (Section 6.2). Second, we study the impact of each workload characteristic introduced in Section 4 (Section 6.3). Third, we integrate general slicing in

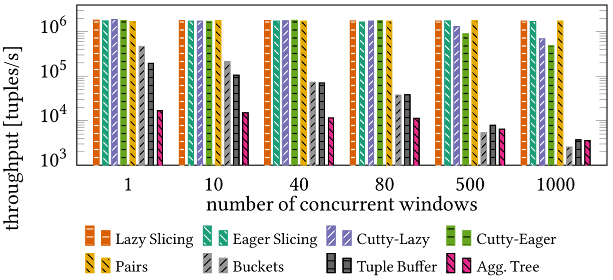

Figure 8: In-order Processing with Context Free Windows.

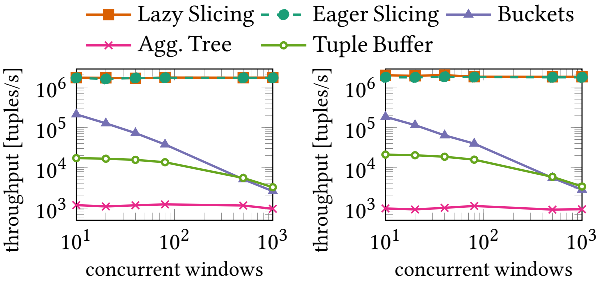


(a) Football data set [34]. **(b) Machine data set [25].**

Figure 9: Increasing the number of concurrent windows including 20% out-of-order tuples and session windows.

Apache Flink and show the performance gain for a concrete application (Section 6.4). Sections 6.2 and 6.3 focus on the performance per operator instance. Section 6.4 studies the parallelization.

6.2 Stream Slicing Compared to Alternatives

We now compare stream slicing with alternative techniques discussed in Section 3. We first study the throughput for in-order processing on context-free windows in Section 6.2.1. Our goal is to understand the performance of stream slicing compared to alternative techniques, including specialized slicing techniques. In Section 6.2.2, we evaluate how the throughput changes in the presence of out-of-order tuples and context-aware windows. In Section 6.2.3, we evaluate the memory footprint and in Section 6.2.4 the latency of different techniques.

6.2.1 Throughput.

Workload. We execute multiple concurrent tumbling window queries with equally distributed lengths from 1 to 20 seconds. These window lengths are representative of window aggregations which facilitate plotting line charts at different zoom levels (Application of Section 6.3). We chose Pairs [28] and Cutty [10] as example slicing techniques because Pairs is one of the first and most cited techniques and Cutty offers a high generality with respect to window types.

Results. We show our results in Figure 8. All three slicing techniques process millions of tuples per second and scale to large numbers of concurrent windows.

Buckets achieves orders of magnitude less throughput than Slicing techniques and does not scale to large numbers of concurrent windows. The reason is that we must assign each tuple to all concurrent buckets (i.e., windows). Thus, tuples belong to up to 1000 buckets causing 1000 redundant aggregation steps per tuple. In contrast, slicing techniques always assign tuples to exactly one slice. Similar to buckets, the tuple buffer causes redundant aggregation steps for each window as we compute each window independently. Aggregate Trees show a throughput which is orders of magnitude smaller than the one of slicing techniques. This is because each tuple requires several updates in the tree.

Summary. We observe that slicing techniques outperform alternative concepts with respect to throughput and scale to large numbers of concurrent windows.

6.2.2 Throughput under Constraints. We now analyze the throughput under constraints, i.e., including out-of-order tuples and context-aware windows.

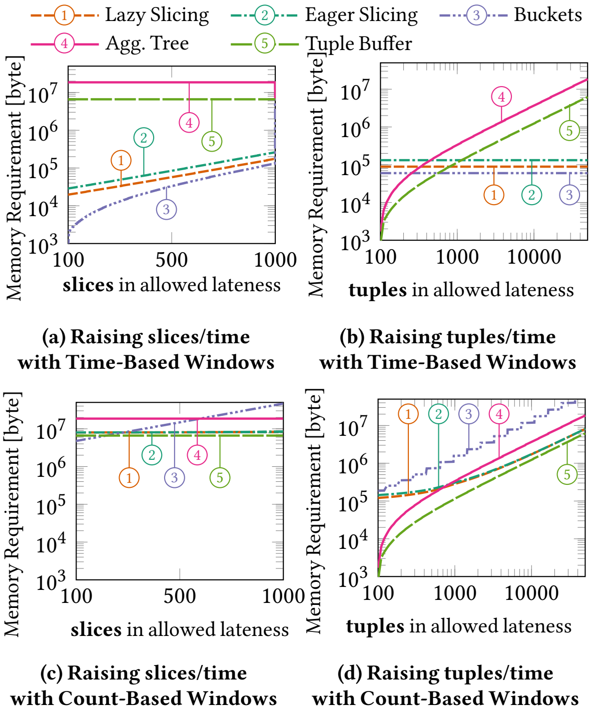
Workload. The workload remains the same as before but we add a time-based session window (l_g = 1sec.) as representative for a context-aware window. We add 20% out-of-order tuples with random delays between 0 and 2 seconds.

Results. We show the results in Figure 9. Slicing techniques achieve an order of magnitude higher throughput than alternative techniques which do not use stream slicing. Moreover, slicing scales to large numbers of concurrent windows with almost constant throughput. This is because the per-tuple complexity remains constant: we assign each tuple to exactly one slice. Lazy Slicing has the highest throughput (1.7 Million tuples/s) because it uses stream slicing and does not compute an aggregate tree. Eager Slicing achieves slightly lower throughput than Lazy Slicing. This is due to out-of-order tuples which cause updates in the aggregate tree. Buckets show the same performance decrease as in the previous experiment. The performance decrease for the Tuple Buffer is intensified due to out-of-order inserts in the ring buffer array. Aggregate Trees process less than 1500 tuples/s with 20% out-of-order tuples. This is because out-of-order tuples require expensive leaf inserts in the aggregate tree (rebalance and update of inner nodes). Eager slicing seldom faces this issue because it stores slices instead of tuples in the aggregate tree. The majority of out-of-order tuples falls in an existing slice which prevents rebalancing. We exemplary show our results on two different datasets for this experiment. Because the performance depends on workload characteristics rather than data characteristics, the results are almost identical. We omit similar results for different data sets in the following experiments and focus on the impact of workload characteristics.

Summary. For workloads including out-of-order tuples and context-aware windows, we observe that general stream slicing outperforms alternative concepts with respect to throughput and scales to large numbers of concurrent windows.

6.2.3 Memory Consumption. We now study the memory consumption of different techniques with four plots: In Figures 10a and 10c, we vary the number of slices in the allowed lateness and fix the number of tuples in the allowed lateness to 50 thousand. In Figures 10b and 10d, we vary the number of tuples and fix the number of slices to 500. We experimentally compare time-based and count-based windows. Our measurements include all memory required for storing partial aggregates and metadata such as the start and end times of slices.

Results for Time-Based Windows. Figures 10a and 10b show the memory consumption for time-based windows, which do not require to store individual tuples. For Stream Slicing and Buckets, the memory footprint increases linearly with the number of slices in the allowed lateness. The memory footprint is independent from the number of tuples. The opposite holds for Tuple Buffers and Aggregate Trees. Slicing techniques store just one partial aggregate per slice, while buckets store one partial aggregate per window. Tuple Buffers and Aggregate Trees store each tuple individually.



(a) Raising slices/time with Time-Based Windows

(b) Raising tuples/time with Time-Based Windows

(c) Raising slices/time with Count-Based Windows

(d) Raising tuples/time with Count-Based Windows

Figure 10: Memory Experiments with Unordered Streams.

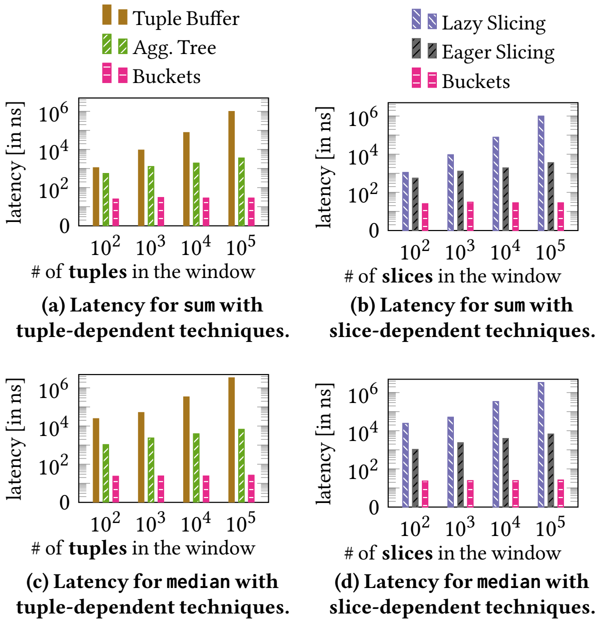
Results for Count-Based Windows. Figures 10c and 10d show the memory consumption for count-based windows, which require individual tuples to be stored. The experiment setup is the same as in Figures 10a and 10b.

The memory consumption of all techniques increases with the number of tuples in the allowed lateness because we need to store all tuples for processing count-based windows on out-of-order streams (Figure 10d). Starting from 1000 tuples in the allowed lateness, the memory consumed by tuples dominates the overall memory requirement. Accordingly, all curves become linear and parallel. Buckets show a stair shape because of the underlying hash map implementation [49]. Slicing techniques start at roughly 10^5 byte which is the space required to store 500 slices. The memory footprint of buckets also increases with the number of slices because more slices correspond to more window buckets (Figure 10c). Each bucket stores all tuples it contains which leads to duplicated tuples for overlapping buckets.

Summary. When we can drop individual tuples and store partial aggregates only (Figure 10a and 10b), the memory consumptions of slicing and buckets depends only on the number of slices in the allowed lateness. In this case, stream slicing and buckets scale to high ingestion rates with almost constant memory utilization. If we need to keep individual tuples (Figure 10c and 10d), storing tuples dominates the memory consumption.

6.2.4 Latency. The output latency for window aggregates depends on the aggregation technique, the number of entries (tuples or slices) which are stored, and the aggregation function. In Figure 11, we show the latency for different situations.

Distributive and Algebraic Aggregation. For the sum aggregation (Figure 11a), Lazy Slicing and Tuple Buffer exhibit up to 1ms latency for 10^5 entries (no matter if 10^5 tuples or 10^5 slices). Eager Slicing and Aggregate Trees show latencies below 5μs. Buckets achieve latencies below 30ns. Lazy aggregation has higher latencies because it computes final aggregates upon request. Eager Aggregation uses precomputed partial aggregates from an aggregate tree which reduces the latency. Buckets pre-compute the final aggregate of each window and store aggregates in a hash map which leads to the lowest latency.



(a) Latency for sum with tuple-dependent techniques.

(b) Latency for sum with slice-dependent techniques.

(c) Latency for median with tuple-dependent techniques.

(d) Latency for median with slice-dependent techniques.

Figure 11: Output Latency of Aggregate Stores

Holistic Aggregation. The latencies for the holistic median aggregation (Figure 11c) are in the same order of magnitude and follow the same trends. Buckets exhibit the same latencies as before because they precompute the aggregate for each bucket. Thus, a more complex holistic aggregation decreases the throughput but does not increase the latency. The latency of slicing techniques increases for the median aggregation because we combine partial aggregates to final aggregates when windows end. This combine step is more expensive for holistic aggregates than for algebraic ones.

Summary. We observe a trade-off between throughput and latency. Lazy aggregation has the highest throughput and the highest latency. Eager aggregation has a lower throughput but achieves microsecond latencies. Buckets provide latencies in the order of nanoseconds but have an order of magnitude less throughput.

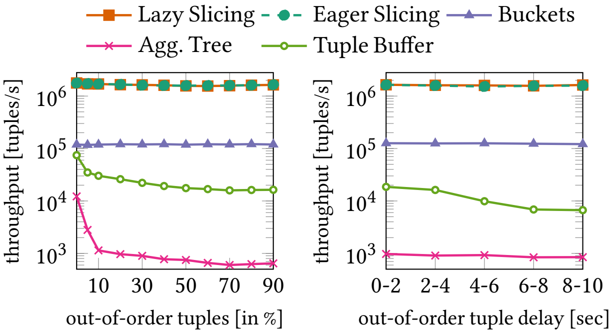
6.3 Studying Workload Characteristics

We measure the impact of the workload characteristics from Section 4 on the performance of general slicing. For comparison, we also show the best alternative techniques.

6.3.1 Impact of Stream Order. In this experiment, we investigate the impact of the amount of out-of-order tuples and the impact of the delay of out-of-order tuples on throughput (Figure 12). We use the same setup as for the throughput experiments in Section 6.2.2 with 20 concurrent windows.

Out-of-order Performance. In Figure 12a, we increase the fraction of out-of-order tuples. Slicing and Buckets process out-of-order tuples as fast as in-order tuples. The throughput of the other techniques decreases when processing more out-of-order tuples.

Slicing techniques process out-of-order tuples efficiently because they perform only one slice update per out-of-order tuple. Eager slicing also updates its aggregate tree. This update has a low overhead because there are just a few hundred slices in the allowed lateness and, accordingly, there are just a few tree levels



(a) Increasing the fraction of out-of-order tuples.

(b) Increasing the delay of out-of-order tuples.

Figure 12: Impact of Stream Order on the Throughput.

which require updates. Aggregate Trees on tuples have a much larger number of tree levels because they store tuples instead of slices as leaf nodes.

Buckets have a constant throughput as in the previous experiments. Tuple Buffers and Aggregate Trees exhibit a throughput decay when processing out-of-order tuples. Tuple Buffers require expensive out-of-order inserts in the sorted buffer array. Aggregate Trees require inserting past leaf nodes in the aggregate tree. This causes a rebalancing of the tree and the respective recomputation of aggregates. Eager Slicing seldom faces this issue (see Section 6.2.2).

Delay Robustness. In Figure 12b, we increase the delay of out-of-order tuples. We use equally distributed random delays within the ranges specified on the horizontal axis.

All techniques except Tuple Buffers are robust against increasing delays. Slicing techniques always update one slice when they process a tuple. Small delays can sightly increase the throughput compared to longer delays if out-of-order tuples still belong to the most recent slice. In this case, we require no lookup operations to find the correct slice. The throughput of Buckets is independent of the delay because Flink stores buckets in a hashmap. The throughput of the tuple buffer decreases with increasing delay of out-or-order tuples, because the lookup and update costs in the sorted buffer array increase.

Summary. Stream slicing and Buckets scale with constant throughput to large fractions of out-of-order tuples and are robust against high delays of these tuples.

6.3.2 Impact of Aggregation Functions.

We now study the throughput of different aggregation functions using the same setup as before (20 concurrent windows, 20% out-of-order tuples, delays between 0 and 2 seconds) in Figure 13. We differentiate time-based and count-based windows to show the impact of invertibility. We implement the same aggregation functions as Tangwongsang et al. [42]. The original publication provides a discussion of these functions and an overview of their algebraic properties. We additionally study the median and the 90-percentile as examples for holistic aggregation. Moreover, we study a naive version of the sum aggregation which does not use the invertibility property. This allows for making a deduction with respect to not invertible aggregations in general.

Time-Based Windows. For time-based windows, the throughput is similar for all algebraic and distributive aggregations with small differences due to different computational complexities of the aggregations. Holistic aggregations (median and 90-percentile) show a much lower throughput because they require to keep all tuples in memory and have a higher complexity.

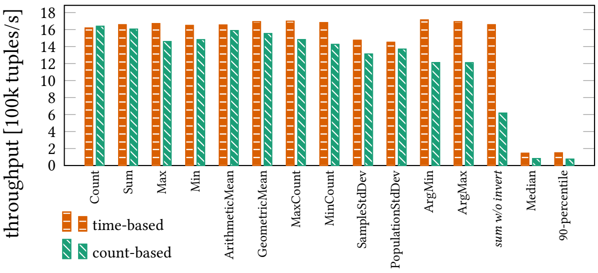


Figure 13: Impact of Aggregation Types on Throughput.

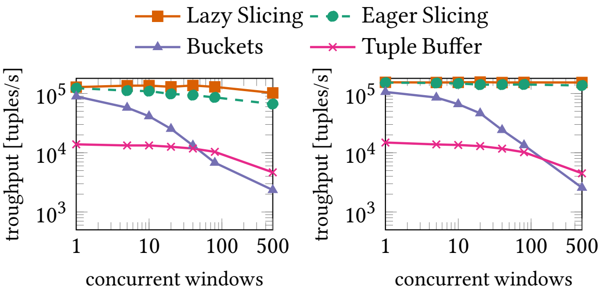

(a) Football data set [34].

(b) Machine data set [25].

Figure 14: Throughput for Median Aggregation.

Count-Based Windows. We observe lower throughputs than for time-based windows, which is because of out-of-order tuples. For count-based windows, an out-of-order tuple changes the sequence id (count) of all later tuples. Thus, we need to shift the last tuple of each slice to the next slice. This operation has low overhead for invertible aggregations because we can subtract and add tuples from aggregates. The operation is costly for not invertible aggregations because it requires the recomputation of the slice aggregate. Time-based windows do not require an invert operation because out-of-order tuples only change the sequence id (count) of later tuples but not the timestamps.

Impact of invertibility. There is a big difference between the performance for different not invertible aggregations on count-based windows. Although `Min`, `Max`, `MinCount`, `MaxCount`, `ArgMin`, and `ArgMax` are not invertible, they have a small throughput decay compared to time-based windows (Figure 13). This is because most invert operations do not affect the aggregate and, thus, do not require a recomputation. For example, it is unlikely that the tuple we shift to the next slice is the maximum of the slice. If the maximum remains unchanged, `max`, `MaxCount`, and `ArgMax` do not require a recomputation. In contrast, the `sum w/o invert` function shows the performance decay for a not invertible function which always requires a recomputation when removing tuples.

Impact of Holistic Aggregations. In Figure 13, we observe that holistic aggregations have a much lower throughput than algebraic and distributive aggregations. In Figure 14, we show that stream slicing still outperforms alternative approaches for these aggregations. The reason is that stream slicing prevents redundant computations for overlapping windows by sorting values within slices and by applying run length encoding. In contrast, Buckets and Tuple Buffer compute each window independently. The machine data set shows slightly higher throughputs because the aggregated column has only 37 distinct values compared to 84232 distinct values in the football dataset. Fewer distinct values increase the savings achieved by run length encoding. Aggregate trees (not shown) can hardly compute holistic aggregates. They maintain partial aggregates for all inner nodes of a large tree which is extremely expensive for holistic aggregations.

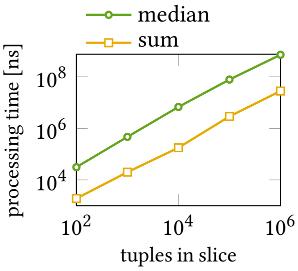

Figure 15: Processing Time for Recomputing Aggregates.

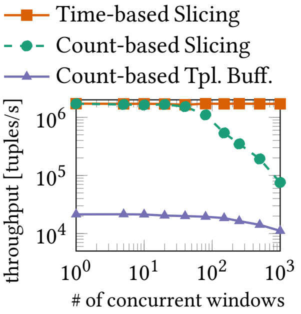

Figure 16: The Impact of Different Window Measures.

Summary. On time-based windows, stream slicing performs diverse distributive and algebraic aggregations with similarly high throughputs. Considering count-based windows and out-of-order tuples, invertible aggregations lead to higher throughputs than not invertible ones.

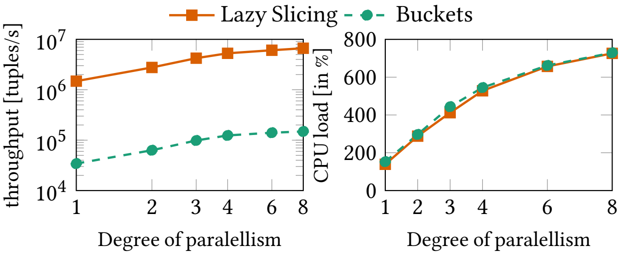
6.3.3 Impact of Window Types. The window type impacts the throughput if we process context-aware windows because these windows potentially require split operations. Note that context aware windows cover arbitrary user-defined windows which makes it impossible to provide a general statement on the throughput for all these windows. Thus, we evaluate the time required to recompute aggregates for slices of different sizes when a split operation is performed (Figure 15). Given a context aware window, one can estimate the throughput decay based on the number of split operations required and the time required for recomputing aggregates after splits. We show the sum aggregation as representative for an algebraic function and the median as example for a holistic function.

The processing time for the recomputation of an aggregate increases linearly with the number of tuples contained in the aggregate. If split operations are required to process a context aware window, a system should monitor the overhead caused by split operations and adjust the maximum size of slices accordingly. Smaller slices require more memory and cause repeated aggregate computation when calculating final aggregates for windows. In exchange, the aggregates of smaller slices are cheaper to recompute when we split slices.

6.3.4 Impact of Window Measures. We compare different window measures in Figure 16. We use the same setup as before (20% out-of-order tuples with delays between 0 and 2 seconds).

Time-Based Windows. For time-based windows, the throughput is independent from the number of concurrent windows as discussed in our throughput analysis in Section 6.2.2. The throughput for arbitrary advancing measures is the same as for time-based measures because they are processed identically [10].

Count-Based Windows. The throughput for count-based windows is almost constant for up to 40 concurrent windows and decays linearly for larger numbers. For up to 40 concurrent windows, most slices are larger than the delay of tuples. Thus, out-of-order tuples still belong to the current slice and require no slice updates. The more windows we add, the smaller our slices become. Thus, out-of-order tuples require an increasing number of updates for shifting tuples between slices which reduces the throughput. Tuple buffers are the fastest alternative to Slicing in our experiment. For 1000 concurrent windows, slicing is still an order of magnitude faster than tuple buffers.



(a) Throughput. **(b) Processor Load.**

Figure 17: Parallelizing the workload of a live-visualization dashboard (80 concurrent windows per operator instance).

Summary. The throughput of time-based windows stays constant whereas the throughput of count-based windows decreases with a growing number of concurrent windows.

6.4 Parallel Stream Slicing

In this experiment, we study stream slicing on the example of our dashboard application [45] which uses the M4 aggregation [26]. We vary the degree of parallelism to show the scalability with respect to the number of cores. We compare Lazy Slicing with Buckets which are used in Flink.

Results. In Figure 17, we increase the number of parallel operator instances of the windowing operation (degree of parallelism). The throughput scales linearly up to a degree of parallelism of four (Figure 17a). Up to this degree, each parallel operator instance runs on a dedicated core with other tasks (data source operator, writing outputs, operating system overhead, etc.) running on the remaining four cores. For higher degrees of parallelism the throughput and the CPU load increase logarithmically, approaching the full 800% CPU utilization (Figure 17b). Slicing achieves an order of magnitude higher throughput than buckets, because it prevents assigning tuples to multiple buckets (cf. Section 6.2.1). The memory consumption scaled linearly with the degree of parallelism for both techniques.

Summary. We conclude that stream slicing and buckets scale linearly with the number of cores for our application.

7 RELATED WORK

Optimizing Window Aggregations. Our general slicing techniques utilizes features of existing techniques such as on-the-fly slicing [28], incremental aggregation [42], window grouping [18, 19], and user-defined windows [10]. However, general stream slicing offers a unique combination of generality and performance. We base our general slicing implementation on a specialized technique which we presented earlier as a poster [46]. One can extend other slicing techniques based on this paper to reach similar generality and performance. Existing slicing techniques such as Pairs [28] and Panes [30] are limited to tumbling and sliding windows. Cutty can process user-defined window types, but does not support out-of-order processing [10]. Several publications optimize sliding window aggregations focusing on different aspects such as incremental aggregation [6, 15, 42] or worst-case constant time aggregation [43]. Hirzel et al. conclude that one needs to decide on a concrete algorithm based on the aggregation, window type, latency requirements, stream order, and sharing requirements because each specialized algorithm addresses a different set of requirements [22]. Instead of alternating between different algorithms, we provide a single solution which is generally applicable and allows for adding aggregation functions and window types without changing the core of our technique.

Stream Processing in Batches. In contrast to our techniques, which adopts a tuple-at-a-time processing approach, several works split streams in batches of data which they process in parallel [5, 27, 52]. SABER introduces *window fragments* to decouple *slide* and *range* of sliding windows from the batch size [27]. However, in contrast to our work, SABER does not consider aggregate sharing among queries. Balkesen et al. use panes to share aggregates among overlapping windows [5]. None of these works addresses the general applicability with respect to workload characteristics.

Complementary Techniques. Weaving optimizes execution plans to reduce the overall computation costs for concurrent window aggregate queries [18, 19, 38]. We use a similar approach to fuse window aggregation queries when window edges match. This optimization is orthogonal to the generalization of slicing which is the focus of this paper. Huebsch et al. study multiple query optimization when aggregating several data streams which arrive at different nodes [24]. General stream slicing complements this work with an increased per-node performance. Truviso proposes an alternative technique based on independent stream partitions to correct outputs when tuples arrive after the watermark [29]. While our work focuses on slicing streams and computing partial aggregations for slices, recent publications of Shein et al. further accelerate the final aggregation step which is required when windows end [39, 40]. Trill [11] is an analytics system that supports streaming, historical, and exploratory queries in the same system. Trill supports incremental aggregation and performs aggregations on snapshots, the state of the window at a certain point in time. Zeuch et al. [53] integrate stream slicing in a lock-free window aggregation operator to optimize throughput on modern hardware.

8 CONCLUSION

Stream slicing is a technique for streaming window aggregation which provides high throughputs and low latencies with a small memory footprint. In this paper, we contribute a generalization of stream slicing with respect to four key workload characteristics: Stream (dis)order, aggregation types, window types, and window measures. Our general slicing technique dynamically adapts to these characteristics, for example, by exploiting the invertibility of an aggregation or the absence of out-of-order tuples.

Our experimental evaluation reveals that general slicing is highly efficient without limiting generality. It scales to a large number of concurrent windows, and consistently outperforms state-of-the-art techniques in terms of throughput. Furthermore, it efficiently supports application scenarios with large fractions of out-of-order tuples, tuples with high delays, time-based and count-based window measures, context-aware windowing, and holistic aggregation functions. Finally, we observed that the throughput of general slicing scales linearly with the number of processing cores.

ABSTRACT

Dictionary-based entity extraction from documents is an important task for several real applications. To improve the effectiveness of extraction, many previous studies focused on the problem of approximate dictionary-based entity extraction, which aims at finding all substrings in documents that are similar to pre-defined entities in the reference entity table. However, these studies only consider syntactical similarity metrics, such as Jaccard and edit distance. In the real-world scenarios, there are many cases where syntactically different strings can express the same meaning. For example, *MIT* and *Massachusetts Institute of Technology* refer to the same object but they have a very low value of syntactic similarity. Existing approximate entity extraction work fails to identify such kind of semantic similarity and will definitely suffer from low recall.

In this paper, we come up with the new problem of approximate dictionary-based entity extraction with synonyms and propose an end-to-end framework Aeetes to solve it. We propose a new similarity measure Asymmetric Rule-based Jaccard (JACCAR) to combine the synonym rules with syntactic similarity metrics and capture the semantic similarity expressed in the synonyms. We propose a clustered index structure and several pruning techniques to reduce the filter cost so as to improve the overall performance. Experimental results on three real world datasets demonstrate the effectiveness of Aeetes. Besides, Aeetes also achieves high performance in efficiency and outperforms the state-of-the-art method by one to two orders of magnitude.

1 INTRODUCTION

Dictionary-based entity extraction [11] identifies all substrings from a document that match predefined entities in a reference entity table i.e. the dictionary. Compared with other kinds information extraction approaches, such as rule-based, machine learning and hybrid ones, dictionary-based entity extraction is good at utilizing extra domain knowledge encoded in the dictionary [24]. Therefore, it has been widely adopted in many real world applications that required Named entity recognition (NER), such as *academic search*, *document classification*, and *code auto-debugging*.

A typical application scenario is the *product analysis and reporting system* [10]. These systems maintain a list of well-defined products and require to find the mentions of product names in the online acquired documents. More precisely, these systems receive many consumer reviews, then they extract the substrings that mentioned reference product names from those reviews. Such mentions of referenced entities serve as a crucial signal for further analyzing the review documents, such sentiment analysis, opinion mining and recommendation. High-quality extraction of such mentions will significantly improve the effectiveness of these systems. Furthermore, the large volume of documents such systems receive turns improving the efficiency of extraction into a critical requirement.

Figure 1: Example of institution name extraction.

To provide high-quality entity extraction results and improve the recall, some prior work [12, 13, 35] studied the problem of Approximate dictionary-based Entity Extraction (AEE). As entities in the dictionary are represented as strings, they employ syntactic similarity functions (e.g. Jaccard and Edit Distance) to measure the similarities between entities and substrings from a document. The goal is to find not only the exactly matched substrings but also those *similar* to entities in the dictionary.

Though prior work has achieved significant degree of success in identifying the syntactic similar substrings from documents, they would still miss some substrings that are semantically similar to entities. In many cases, syntactically different strings can have very close semantic meaning. For example, consider a substring *"Mitochondrial Disease"* in a biomedical document and an entity *"Oxidative Phosphorylation Deficiency"* in the dictionary. Prior studies on AEE problems [13, 35] would fail in identifying this substring since they have very low similarity score under any syntactic similarity metric. However, *"Mitochondrial Disease"* and *"Oxidative Phosphorylation Deficiency"* actually refer to the same disease and they are expected to be included in the result. Therefore, it is necessary to propose a new framework to take both syntactic similarity and semantics carried by synonyms into consideration.

We can capture such synonyms by applying synonym rules on the basis of syntactic similarity. A `synonym rule` r is a pair of strings with the form ⟨ *lhs*⇔ *rhs*⟩ that express the same semantics. Here both `lhs` and `rhs` are token sequences. For example ⟨ *Big Apple*⇔ *New York*⟩ is a synonym rule as *"Big Apple"* is actually a

Series ISSN: 2367-2005

10.5441/002/edbt.2019.11

nickname for *"New York"*. Example 1.1 shows a real-life scenario demonstrating the effectiveness of applying synonym rules in entity extraction.

Example 1.1. Figure 1 provides an example document which contains PVLDB 2018 PC members. The dictionary includes a list of institution names, and the synonym rule table contains a list of synonym rules. The exact match approach only finds s_3 as it is the only one having an exact match in the dictionary. AEE based approaches like Faerie [13] can find s_3 and s_2 but misses s_1 and s_4. By applying rules, we can find all similar results s_1, s_2, s_3 and s_4.

As motivated above, applying synonym rules can significantly improve the effectiveness of approximate entity extraction. In this paper, we formally introduce the problem of Approximate Entity Extraction with Synonym (AEES) from dictionaries.

Though the application of synonym rules could improve effectiveness, it also brings significant challenges in computational performance. To address this issue, we study and propose new solutions for the AEES problem, along with techniques that optimize the performance. In fact, we propose an end-to-end framework called **A**pproximat**e** Dictionary-based **Ent**ity **E**xtraction with **S**ynonyms (Aeetes) that effectively and efficiently solves the AEES problem. We first propose a new similarity metric Asymmetric Rule-based Jaccard (JACCAR) to evaluate the similarity between substrings in documents and entities in the dictionary by considering both syntactic similarity and semantic relevance brought by synonyms. By properly designing the similarity measure, we can reduce the overhead of applying the synonym rules and capture the rich semantics at the same time. To support efficient extraction, we devise a clustered inverted index structure which enables skipping dissimilar entities when traversing the index. We also apply efficient sliding-window based pruning techniques to accelerate the filtering process by leveraging the overlaps between adjacent substrings in the document. We evaluate our proposed methods on three popular datasets with real application scenarios. Experimental results demonstrate the superiority of our method in both effectiveness and efficiency.

To summarize, we make the following contributions.

- We identify and formally define a new problem dictionary-based Approximate Entity Extraction from documents with Synonyms. And we propose an end-to-end framework Aeetes to efficiently address the problem.
- We devise a clustered index structure and several pruning techniques to improve the performance. Specifically, we proposed a dynamic prefix maintenance algorithm and a lazy candidate generation method to take advantage of the shared computation between substrings in a document so as to reduce the filter cost.
- We conduct an extensive empirical evaluation on three real-world datasets to evaluate the efficiency and effectiveness of the proposed algorithms. Experimental results demonstrate the effectiveness of our method. In addition, our method also achieved good efficiency: it outperforms the baseline methods by one to two orders of magnitude in extraction time.

The rest of this paper is organized as follows. We formalize the problem of AEES and introduce the overall framework in Section 2. We propose a clustered inverted index structure in Section 3. We devise the sliding window based filter techniques in Section 4. We make necessary discussions about some important issues in Section 5. The experimental results are reported in Section 6. We summarize the related work in Section 7. Finally, conclusions are made in Section 8.

2 PRELIMINARY

In this section, we first define some basic terminology to describe our work (Section 2.1). We then formulate the AEES problem and justify its definition (Section 2.2). Finally we provide an overview of our framework (Section 2.3).

2.1 Basic Terminology

Entity. An `entity` e is modeled as a token sequence, i.e, $e = e[1], ..., e[|e|]$ where $|e|$ is the number of tokens in e. For example, the entity e_2 =*"Purdue University USA"* in Figure 1 has three tokens and $e_2[3]$ = *"USA"*. We use $e[i, j]$ to denote the subsequence of tokens $e[i], ..., e[j]$ of e.

Applicable synonym rule. Given an entity e, a synonym rule r is an `applicable rule` for e if either *lhs* or *rhs* is a subsequence of e. In some cases, if two applicable rules have overlapping tokens and cannot be applied simultaneously, we call them `conflict rules`. For example, r_4 and r_5 are conflict rules as they have an overlapping token "UW". In order to generate derived entities, we need to obtain the optimal set of non-conflict rules, which includes all possible combinations. Unfortunately, finding the optimal set of non-conflict rules requires exponential time. To improve the performance, we propose a greedy algorithm to select the set of non-conflict rules whose cardinality is as large as possible (details in Section 5). We use $\mathcal{A}(e)$ to denote the sets of non-conflict rules of the entity e.

Derived entity. Given an entity e and one applicable rule r (⟨ *lhs*⇔ *rhs*⟩), without the loss of generality, we assume `lhs` is a subsequence of e. Applying r to e means replacing the `lhs` in the subsequence of e with *rhs* in r. The i^{th} new generated entity e^i is called `derived entity` of e. And e is called `origin entity` of e^i. And the set of all derived entities of e is denoted as $\mathcal{D}(e)$.

According to the previous study [3], we get a derived entity e^i of e by applying rules in a subset of $\mathcal{A}(e)$. In this process, each original token is rewritten by at most one rule [1]. Similar to previous studies [3, 29], different combination of rules in $\mathcal{A}(e)$ will result in different different derived entities. Following this routine, we can get $\mathcal{D}(e)$ by enumerating the combination of applicable rules. The cardinality of $|\mathcal{D}(e)|$ is $O(2^n)$ where $|\mathcal{A}(e)| = n$.

Consider the example data in Figure 1 again. For the entity e_3=*"UQ AU"* in the dictionary, the applicable rules $\mathcal{A}(e_3) = \{r_1, r_3\}$. Thus, $\mathcal{D}(e_4)$ can be calculated as following: {*"UQ AU"*, *"University of Queensland AU"*, *"UQ Australia"*, *"University of Queensland Australia"*}.

For a dictionary of entities $\mathcal{E}_0$, we can generate the `derived dictionary` $\mathcal{E} = \bigcup_{e \in \mathcal{E}_0} \mathcal{D}(e)$.

2.2 Problem Formulation

For the problem of approximate string join with synonyms (ASJS), previous studies have already defined some synonym-based similarity metrics, such as *JaccT* [3], *SExpand* [19] and *pkduck* [29]. In the problem setting of ASJS, we know the threshold in off-line step and need to deal with synonym rules and two collections of strings in the on-line step. So the above similarity metrics apply

[1] As shown in [3], if a new generated token is allowed to apply rules again, then it becomes a non-deterministic problem.

the synonym rules on both strings during the join processing. Suppose the lengths of two strings involved in join is S_1 and S_2, then the search space for joining the two strings is $O(2^{S_1} \cdot 2^{S_2})$

However, for our AEES problem, we obtain the entity dictionary and synonym rules in the off-line step but need to deal with the documents and threshold in the on-line step. Moreover, the length of a document will be much larger than that of entities. Unlike ASJS which computes the similarity between two strings, AEES aims at identifying `substrings` from a document that are similar to entities. Therefore, applying rules onto documents in the on-line step will be too expensive for the AEES problem. Suppose the size of a document is D and the length of an entity is e, if we directly use the similarity metrics of ASJS problem, the search space for extracting e would be $O(2^D \cdot 2^e)$. While r and s will always be similar in ASJS problem, in AEES problem the value of D is usually 10-20 times larger than e. Therefore such a complexity is not acceptable.

Based on the above discussion, we devise our asymmetric similarity metric JACCAR (for Asymmetric Rule-based Jaccard). Unlike previous studies on the ASJS problem, we only apply the synonym rules on the entities to generate derived entities in the off-line step. In the on-line extraction step, instead of applying rules on substrings in the document, we just compute the similarity between the substrings and all derived entities which have been generated in the off-line step. Here we use Jaccard to evaluate the syntactic similarity. Our techniques can also be easily extended to other similarity metrics, such as Overlap, Cosine and Dice. To verify the JACCAR value between an entity e and a substring s from the document, we first find $\mathcal{A}(e)$ and generate all derived entities of e. Then for each $e^i \in \mathcal{D}(e)$, we calculate the value of JAC (e^i, s). Finally we select the maximum JAC (e^i, s) as the value of JACCAR (e,s). The detailed definition is formalized in Definition 2.1.

Definition 2.1 (Asymmetric Rule-based Jaccard). Given an entity e in the dictionary and a substring s in the document, let $\mathcal{D}(e)$ be the full set of derived entities of e by applying rules in $\mathcal{A}(e)$. Then JACCAR(e, s)) is computed as follows:

$$\text{JACCAR}(e, s) = \max_{e^i \in \mathcal{D}(e)} \text{JAC}(e^i, s) \tag{1}$$

We want to highlight that the main difference between previous synonym-based similarity metrics for ASJS and JACCAR is that *previous approaches apply synonyms on both records that are involved into the join process; while* JaccAR *only applies synonyms on the entities in the dictionary*. Recall the above time complexity, by using JACCAR instead of similarity metrics for ASJS problem, we can reduce the time complexity from $O(2^D \cdot 2^e)$ to $O(D \cdot 2^e)$. The intuition behind JACCAR is that some rules have the same lhs/rhs, which might lead to potentially dissimilar derived entities. In order to identify a similar substring, we should focus on the derived entity that is generated by the set of synonym rules that is related to the context of substrings. By selecting the derived entity with the largest syntactic similarity, we can reach the goal of using the proper set of synonym rules to extract similar substrings from a document. JACCAR can achieve such a goal by avoiding the synonym rules which would decrease the similarity and applying those which increases the similarity.

Using the definition of Asymmetric Rule-based Jaccard, we can now characterize the AEES problem by Definition 2.2 below. Following previous studies of ASJS [3, 19], it is safe to assume that the set of synonym rules are given ahead of time. As many studies can effectively discover synonyms [2], our work can be seamlessly integrated with them. Although a recent study [29] supports discovering rules from dataset, it can only deal with abbreviations while our work here needs to support the general case of synonyms.

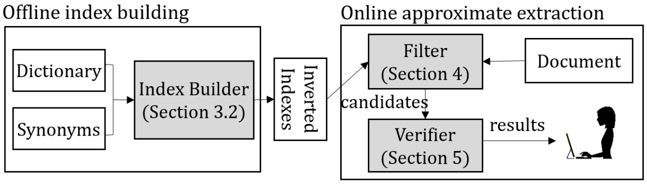

Figure 2: Architecture of Aeetes.

Definition 2.2 (AEES). Given a dictionary of entities $\mathcal{E}_0$, a set of synonym rules $\mathcal{R}$, a document d, and a threshold of Asymmetric Rule-based Jaccard τ, the goal of AEES is to return all the (e, s) pairs where s is a substring of d and $e \in \mathcal{E}_0$ such that $\text{JACCAR}(e, s) \geq \tau$.

Consider the dataset in Figure 1 again. Assume the threshold value is 0.9, then AEES returns the following pairs as results: (e_2, s_2), (e_1, s_3), (e_3, s_4). The JACCAR scores of the above three pairs are all 1.0.

2.3 Overview of Framework

As shown in Figure 2, Aeetes is an end-to-end framework which consists of two stages: off-line preprocessing and on-line extraction. The whole process is displayed in Algorithm 1. In the off-line preprocessing stage, we first find applicable synonym rules for each entity in the dictionary. Then we apply them to entities and generate the derived dictionary (line: 3). Next we create a clustered inverted index for the derived entities, which will be explained later in Section 3 (line: 4).

In the on-line extraction stage, we have a similarity threshold τ and a document d as input, and the goal is to extract all similar substrings from d. To this end, we propose a filter-and-verification strategy. In the filter step, if a derived entity e^i is similar to a substring $s \in d$, we will regard its corresponding origin entity e as the candidate of s (line: 5). In this way, we can adopt the filter techniques of Jaccard to get candidates for JACCAR. We propose effective pruning techniques in Section 4 to collect such candidates. In the verification phase, we verify the real value of JACCAR for all candidates (lines: 6-9).

3 INDEX CONSTRUCTION

In this section, we first review the length and prefix filter techniques, which serves as the cornerstone of our approaches (Section 3.1). Then we devise a clustered inverted index to facilitate the filter techniques (Section 3.2).

3.1 Filtering Techniques Revisit

In order to improve the performance of overall framework, we need to employ effective filtering techniques. As the length of a document is much larger than that of an entity, we should be able to exactly locate mentions of entities in the documents and avoid enumerating dissimilar candidates. To describe the candidate substrings obtained from the document, we use the following terminologies in this paper. Given a document d, we denote a

[2] These are introduced in Section 7, whereas generalizations of this approach are further discussed in Section 5.

Algorithm 1: Aeetes ($\mathcal{E}_0$, $\mathcal{R}$, d, τ)

```
Input: $\mathcal{E}_0$: The dictionary of entities; $\mathcal{R}$: The set of synonym
       rules; $d$: The given Docuemnt; $\tau$: The threshold of
       Asymmetric Rule-based Jaccard
Output: $\mathcal{H} = \{< e, s > | e \in \mathcal{E} \wedge s \in d \wedge \text{JACCAR}(e, s) \geq \tau\}$
begin
    Initialize $\mathcal{H}$ as $\emptyset$;
    Generate a derived dictionary $\mathcal{E}$ using $\mathcal{E}_0$ and $\mathcal{R}$;
    Construct the inverted index for all derived entities in $\mathcal{E}$;
    Traverse substrings $s \in d$ and the inverted index, generate
    a candidate set $C$ of $< s, e >$ pairs;
    for each pair $< s, e > \in C$ do
        Verify the value of JACCAR$(s, e)$;
        if JACCAR$(s, e) \geq \tau$ then
            Add $< s, e >$ into $\mathcal{H}$;
    return $\mathcal{H}$;
end
```

substring with start position p and length l as $\mathcal{W}_p^l$. A token $t \in d$ is a valid token if there exists a derived entity $e_i^j \in \mathcal{E}$ containing t. Otherwise it is an invalid token. We call a group of substrings with the same start position p in the document as a window, denoted as $\mathcal{W}_p$. Suppose the maximum and minimum length of substrings in $\mathcal{W}_p$ is l_{max} and l_{min} respectively, this window can further be denoted as $\mathcal{W}_p(l_{min}, l_{max})$.

One primary goal of the filter step is to prune dissimilar candidates. To this end, we employ the state-of-the-art filtering techniques: length filter [25] and prefix filter [9].

Length filter. The basic idea is that if two strings have a large difference between their lengths, they cannot be similar. Specifically, given two strings e, s and a threshold τ, if $|s| < \lfloor |e| * \tau \rfloor$ or $|s| > \lceil \frac{|e|}{\tau} \rceil$, then we have JAC$(s, e) < \tau$.

Suppose in the derived dictionary $\mathcal{E}$, the minimum and maximum lengths of derived entities are denoted as $|e|_\perp = \min\{|e| \, |e \in \mathcal{E}\}$ and $|e|_\top = \max\{|e| \, |e \in \mathcal{E}\}$, respectively. Then given a threshold τ, we can safely claim that only the substring $s \in d$ whose length $|s|$ is within the range $[\mathcal{E}_\perp \, \mathcal{E}_\top]$ could be similar to the entities in the dictionary where $\mathcal{E}_\perp = \lfloor |e|_\perp * \tau \rfloor$, $\mathcal{E}_\top = \lceil \frac{|e|_\top}{\tau} \rceil$.

Prefix filter. It first fixes a global order $\mathcal{O}$ for all tokens from the dataset (details in next subsection). Then for a string s, we sort all its tokens according to $\mathcal{O}$ and use $\mathcal{P}_\tau^s$ to denote the τ-prefix of string s. Specifically, for Jaccard similarity, we can filter out dissimilar strings using Lemma 3.1.

LEMMA 3.1 (PREFIX FILTER [9]). *Given two strings e, s and a threshold τ, the length of $\mathcal{P}_\tau^s$ ($\mathcal{P}_\tau^e$) is $\lfloor (1 - \tau)|s| + 1 \rfloor$ ($\lfloor (1 - \tau)|e| + 1 \rfloor$). If $\mathcal{P}_\tau^s \cap \mathcal{P}_\tau^e = \emptyset$, then we have* JAC$(s, e) < \tau$.

3.2 Index structure

With the help of length filter and prefix filter, we can check quickly whether a substring $s \in d$ is similar to an entity $e \in \mathcal{E}_0$. However, enumerating s with all the entities one by one is time consuming due to the huge number of derived entities.

To accelerate this process, we build a *clustered inverted index* for entities in the derived dictionary. The inverted index of t, denoted as $\mathcal{L}[t]$, is a list of (e^i, pos) pairs where e^i is the identifier of a derived entity containing the token t and pos is the position of t in the ordered derived entity. For all tokens in the derived entities, we assign a global order $\mathcal{O}$ among them. Then for one derived entity, we sort its tokens by the global order and pos is the

position of t in e^i under this order. Here as is same with previous studies [5, 36], we use the ascending order of token frequency as the global order $\mathcal{O}$. It is natural to deal with invalid tokens: in the on-line extraction stage, if a token $t \in d$ is an invalid token, we will regard its frequency as 0. With the help of pos, we can prune dissimilar entities with the prefix filter.

According to a recent experimental survey [21], the main overhead in set-based similarity queries comes from the filter cost. To reduce such overhead caused by traversing inverted index, we can skip some dissimilar entries by leveraging length filter: in each $\mathcal{L}[t]$, we group all the (e^i, pos) pairs by the length $l = |e^i|$. And such a group of derived entities is denoted as $\mathcal{L}_l[t]$. Then when scanning $\mathcal{L}[t]$ for $t \in s$, if l and $|s|$ does not satisfy the condition of length filter, we can skip $\mathcal{L}_l[t]$ in batch to reduce the number of accessed entries in the inverted index.

In addition, by leveraging the relationship between origin and derived entities, we can further cluster $e^i \in \mathcal{D}(e)$ within each group $\mathcal{L}_l[t]$ according to their original entity. Here we denote the group of entries with origin entity e and length l as $\mathcal{L}_l^e$. When looking for candidate entities for a substring s, if a derived entity e^i is identified as a candidate, *we will regard its origin entity e rather than the derived entity itself* as the candidate of s. If an origin entity e has already been regarded as the candidate of s, we can skip $\mathcal{L}_l^e[t]$ in batch when traversing $\mathcal{L}[t]$ where $t \in s$. Figure 3 visualizes the index structure.

Example 3.2. To have a better understanding of the index structure, we show the index (in Figure 4) built for the example data in Figure 1. As we can see, the token t="*University*" appears in five derived entities e_2^1, e_3^3, e_3^4, e_4^2, and e_4^3. And the positions of "*University*" in the corresponding ordered derived entities are 2, 3, 3, 2, and 2. Therefore, we store five (id, pos) pairs, i.e., $(e_2^1, 2)$, $(e_3^3, 3)$, $(e_3^4, 3)$, $(e_4^2, 2)$ and $(e_4^3, 2)$, in the inverted list $\mathcal{L}[University]$. The five pairs are organized into three groups (see the blue boxes) based on their original entities. For instance, $(e_3^3, 3)$ and $(e_3^4, 3)$ are

```

2      Generate a derived dictionary $\mathcal{E}$ using $\mathcal{E}_0$ and $\mathcal{R}$;
3      Initilize $\mathcal{CI} = \emptyset$ and obtain the global order $O$;
4      foreach derived entitiy $e' \in \mathcal{E}$ do
5          $l \leftarrow |e'|$, $e \leftarrow$ origin entity of $e'$;
6          foreach token $t \in e'$ do
7              Add the pair $(e', pos)$ into the corresponding
               group in inverted list $\mathcal{L}_l^e[t]$;
8      foreach $\mathcal{L}[t]$ do
9          $\mathcal{CI} = \mathcal{CI} \cup \mathcal{L}[t]$
10     return $\mathcal{CI}$;
11 end
```

grouped together as both e_3^3 and e_3^4 derived entities are from the same original entity e_3. In addition, they are further clustered into a group based on their lengths (see the red boxes). In this example, these five pairs are grouped into a length-4 group as the length of the derived entities are 4.

Algorithm 2 gives the details of constructing an inverted index. It first applies synonyms to the entities in the dictionary to get a derived dictionary (line 2). Then for each token t in the derived entities, it stores a list of (e', pos) pairs where e' is the identifier of a derived entity containing t and pos is the position of t in this derived entity according to the global order O (line: 4-7). The (e', pos) pairs in each list are organized into groups based on the length l and their corresponding origin entity e (line 5). Finally, we aggregate all the inverted lists and get the clustered index (line: 9).

4 SLIDING WINDOW BASED FILTERING

Based on the discussion in Section 3, we can come up with a straightforward solution for the AEES problem: we slide the window $\mathcal{W}_p(\mathcal{E}_\perp, \mathcal{E}_\top) \in d$ from the beginning position of document d. For each window, we enumerate the substrings and obtain the prefix of each substring. Next, we recognize the valid tokens from the prefix for each substring and scan the corresponding inverted lists to obtain the candidates. Finally, we verify the candidates and return all truly similar pairs.

Although we can prune many dissimilar substrings by directly applying length filter and prefix filter with the help of inverted index, the straightforward method needs to compute the prefix for a large number of substrings. Thus it would lead to low performance. In this section, we propose a sliding window based filtering mechanism to efficiently collect the candidates from a given document. To improve the overall efficiency, we devise effective techniques based on the idea of sharing computations between substrings and windows. We first devise a dynamic (incremental) prefix computation technique to take advantage of the overlaps between adjacent substrings and windows in Section 4.1. Next we further propose a lazy strategy to avoid redundant visits on the inverted index in Section 4.2.

4.1 Dynamic Prefix Computation by Shared Computation

We have the following observations w.r.t the windows and substrings. On the one hand, for two substrings in the same window with different length i.e. $\mathcal{W}_p^{l_i}$ and $\mathcal{W}_p^{l_j}(\mathcal{E}_\perp \leq l_i < l_j \leq \mathcal{E}_\top)$, they share l_i common tokens. On the other hand, two adjacent windows $\mathcal{W}_p(\mathcal{E}_\perp, \mathcal{E}_\top)$ and $\mathcal{W}_{p+1}(\mathcal{E}_\perp, \mathcal{E}_\top)$ share $\mathcal{E}_\top - 1$ common tokens. This is very likely that there is a large portion of common tokens between the prefixes of $\mathcal{W}_p^{l_i}$ and $\mathcal{W}_p^{l_j}$ and those of $\mathcal{W}_p^{l_i}$ and $\mathcal{W}_{p+1}^{l_i}$.

Motivated by these observations, we can improve the performance of the straightforward solution by dynamically computing the prefix for substrings in the document. Here we use $\mathcal{P}_\tau^{p,l}$ to denote the set of tokens of the τ-prefix(i.e., prefix of length $\lfloor(1 - \tau) * l + 1\rfloor$) of substring $\mathcal{W}_p^l$. Then we can obtain the prefix of one substring by utilizing that of a previous one. Specifically, for a given window $\mathcal{W}_p$, we first directly obtain $\mathcal{P}_\tau^{p,0}$ and then incrementally compute $\mathcal{P}_\tau^{p,l}$ on the basis of $\mathcal{P}_\tau^{p,l-1}$. Then for each substring $\mathcal{W}_p^l \in \mathcal{W}_p$, we scan the inverted lists of the valid tokens and collect the candidate entities. Similarly, for a substring $\mathcal{W}_{p+1}^l \in \mathcal{W}_{p+1}$, we can obtain its prefix $\mathcal{P}_\tau^{p+1,l}$ from $\mathcal{P}_\tau^{p,l}$. Then we can collect the candidate entities for each substring in $\mathcal{W}_{p+1}$ with the same way above.

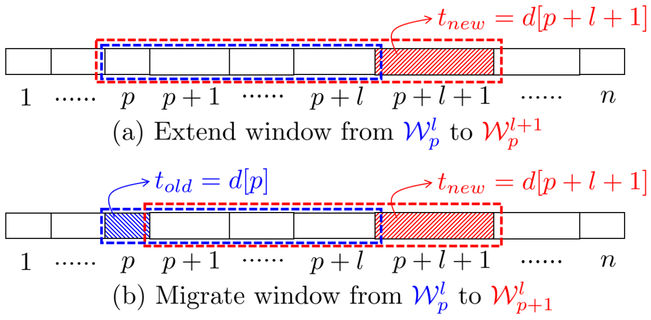
To reach this goal, we propose two operations Window Extend and Window Migrate to dynamically compute the prefix of substrings and collect candidate pairs for the above two scenarios.

Window Extend This operation allows us to obtain $\mathcal{P}_\tau^{p,l+1}$ from $\mathcal{P}_\tau^{p,l}$. Figure 5(a) gives an example of extending the window $\mathcal{W}_p^l$ to $\mathcal{W}_p^{l+1}$. As shown, when performing Window Extend, the length of the substring increases by 1. In this case, the length of the τ-prefix of $\mathcal{W}_p^{l+1}$ (i.e. $\lfloor(1-\tau)*(l+1)+1\rfloor$) can either increase by 1 or stay the same compared with the length of the τ-prefix of $\mathcal{W}_p^l$ (i.e. $\lfloor(1 - \tau) * l + 1\rfloor$). Then we can perform maintenance on the prefix accordingly:

- If the length of τ-prefix stays the same, we need to check whether the newly added token $d[p + l + 1]$ will replace a token in $\mathcal{P}_\tau^{p,l}$. If so, we need to replace a lowest ranked token $t \in \mathcal{W}_p^l$ with $d[p+l+1]$ in the new prefix. Otherwise, there is no change in the prefix i.e. $\mathcal{P}_\tau^{p,l+1} = \mathcal{P}_\tau^{p,l}$.
- If the length of τ-prefix increases by 1, then we need to discuss whether the newly added token $d[p + l + 1]$ belongs to the new prefix $\mathcal{P}_\tau^{p,l+1}$. If so, we can just have $\mathcal{P}_\tau^{p,l+1} = \mathcal{P}_\tau^{p,l} \cup d[p + l + 1]$. Otherwise, we should find a token $t \in \mathcal{W}_p^l$ and $t \notin \mathcal{P}_\tau^{p,l}$ with the highest rank. Then we have $\mathcal{P}_\tau^{p,l+1} = \mathcal{P}_\tau^{p,l} \cup t$.

Example 4.1. Assume $\tau = 0.8$, when extending window from $\mathcal{W}_3^3$ to $\mathcal{W}_3^4$ (see Figure 6(a)), $|\mathcal{P}_\tau^{3,3}| = \lfloor(1 - 0.8) * 3 + 1\rfloor = 1$ and $|\mathcal{P}_\tau^{3,4}| = \lfloor(1 - 0.8) * 4 + 1\rfloor = 1$. So the length of τ-prefix stays the same. $\mathcal{P}_\tau^{3,3} = \{t_4\}$ as t_4 has the highest rank in window $\mathcal{W}_3^3$. The rank of new token t_6 in window $\mathcal{W}_3^4$ is 18, so t_6 will not replace a token in $\mathcal{P}_\tau^{3,3}$, so $\mathcal{P}_\tau^{3,4} = \mathcal{P}_\tau^{3,3} = \{t_4\}$. If the rank of t_6 is 2 instead of 18, then t_6 will replace a token in $\mathcal{P}_\tau^{3,3}$. In this case, $\mathcal{P}_\tau^{3,4} = \mathcal{P}_\tau^{3,3} - \{t_4\} \cup \{t_6\} = \{t_6\}$.

Now let's see the example in Figure 6(b) where we extend window from $\mathcal{W}_3^4$ to $\mathcal{W}_3^5$. The length of $\mathcal{P}_\tau^{3,4}$ is $\lfloor(1 - 0.8) * 4 + 1\rfloor = 1$ and $\mathcal{P}_\tau^{3,4} = \{t_4\}$. But the length of $\mathcal{P}_\tau^{3,5}$ now is $\lfloor(1 - 0.8) * 5 + 1\rfloor = 2$. The newly added token t_7 with rank 2 is in $\mathcal{P}_\tau^{3,5}$, so $\mathcal{P}_\tau^{3,5} = \mathcal{P}_\tau^{3,4} \cup \{t_7\} = \{t_4, t_7\}$. If the rank of t_7 is 10 instead of 2, then t_7 should not be a token in $\mathcal{P}_\tau^{3,5}$. In this case,

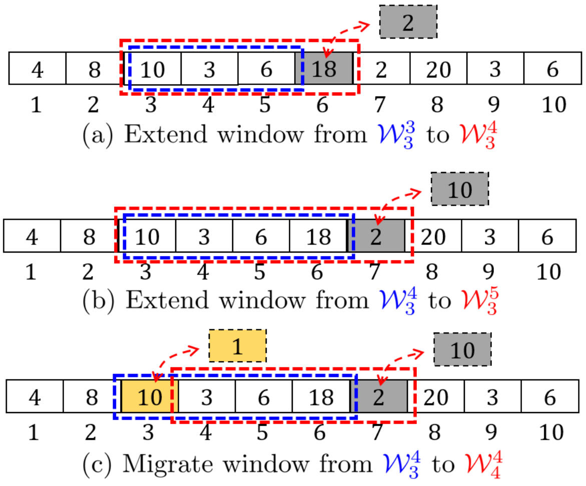


$t_{new} = d[p+l+1]$
1 …… p $p+1$ …… $p+l$ $p+l+1$ …… n
$t_{old} = d[p]$
$t_{new} = d[p+l+1]$
1 …… p $p+1$ …… $p+l$ $p+l+1$ …… n

(a) Extend window from $\mathcal{W}_p^l$ to $\mathcal{W}_p^{l+1}$

(b) Migrate window from $\mathcal{W}_p^l$ to $\mathcal{W}_{p+1}^l$

Figure 5: Example of window extend and window migrate.



(a) Extend window from $\mathcal{W}_3^3$ to $\mathcal{W}_3^4$

(b) Extend window from $\mathcal{W}_3^4$ to $\mathcal{W}_3^5$

(c) Migrate window from $\mathcal{W}_3^4$ to $\mathcal{W}_4^4$

Figure 6: Example of the Window Extend operator and the Window Migrate operator. Values in the boxes are the ranks of tokens according to a global order. Value k means the ranking of the token is top-k.

$\mathcal{P}_\tau^{3,5} = \mathcal{P}_\tau^{3,4} \cup \{t_5\} = \{t_4, t_5\}$ as t_5 has the highest rank, $t_5 \in \mathcal{W}_3^4$ and $t_5 \notin \mathcal{P}_\tau^{3,4}$.

Window Migrate This operation allows us to obtain the prefix of $\mathcal{W}_{p+1}^l$ from that of $\mathcal{W}_p^l$. Figure 5(b) shows an example of migrating the window $\mathcal{W}_p^l$ to $\mathcal{W}_{p+1}^l$. We can see that when performing Window Migrate, the length of substring will stay the same. In this case, for a substring $\mathcal{W}_{p+1}^l$, the token $t_{old} = d[p]$ will be removed and the token $t_{new} = d[p+1+l]$ will be inserted. Then we discuss the maintenance of prefix according to t_{old}: .

- If $t_{old} \notin \mathcal{P}_\tau^{p,l}$, it makes no influence on the prefix, we only need to check whether t_{new} will replace a token in $\mathcal{P}_\tau^{p,l}$ to form $\mathcal{P}_\tau^{p+1,l}$. If so, we need to replace the lowest ranked token $t \in \mathcal{W}_p^l$ with t_{new} in $\mathcal{P}_\tau^{p+1,l}$. Otherwise, we have $\mathcal{P}_\tau^{p,l+1} = \mathcal{P}_\tau^{p,l}$.
- If $t_{old} \in \mathcal{P}_\tau^{p,l}$, we still need to check whether t_{new} will appear in $\mathcal{P}_\tau^{p+1,l}$ in a similar way. If so, we need to replace t_{old} with t_{new} to generate $\mathcal{P}_\tau^{p+1,l}$; Otherwise, we need to replace t_{old} with a token t s.t. $t \in \mathcal{W}_p^l$ and $t \notin \mathcal{P}_\tau^{p,l}$ with the highest rank.

Example 4.2. Consider the case when migrating window from $\mathcal{W}_3^4$ to $\mathcal{W}_4^4$ (see Figure 6(c)), both $\mathcal{W}_3^4$ and $\mathcal{W}_4^4$ have the length $\lfloor(1-0.8)*3+1\rfloor = 1$ (assume $\tau = 0.8$). $\mathcal{P}_\tau^{3,4} = \{t_4\}$ as t_4 has the highest rank in window $\mathcal{W}_3^4$. After this migration, we have $t_{old} = t_3$ (with rank 10) and $t_{new} = t_7$ (with rank 2). Then we know $t_{old} \notin \mathcal{P}_\tau^{3,4}$ and t_{new} will replace a token in $\mathcal{P}_\tau^{3,4}$, thus we have $\mathcal{P}_\tau^{4,4} = \mathcal{P}_\tau^{3,4} - \{t_4\} \cup \{t_7\} = \{t_7\}$. If the rank of t_7 is 10 rather than 2 (see the blocks with gray color), then t_{new} will not replace a token in $\mathcal{P}_\tau^{3,4}$ and $\mathcal{P}_\tau^{4,4} = \mathcal{P}_\tau^{3,4} = \{t_4\}$.

Further, if the rank of t_3 is 1 instead of 10 (see the blocks with yellow color), then $\mathcal{P}_\tau^{3,4} = \{t_3\}$ as now t_3 has the highest rank in the window $\mathcal{W}_3^4$. Then we know $t_{old} \in \mathcal{P}_\tau^{3,4}$ and t_{new} (with rank 2) will occur in $\mathcal{P}_\tau^{4,4}$, so $\mathcal{P}_\tau^{4,4} = \mathcal{P}_\tau^{3,4} - \{t_{old}\} \cup \{t_{new}\} = \{t_7\}$. If the rank of t_7 is 10 rather than 2 (see the blocks with gray color), then we need to replace t_{old} with t_4 as t_4 has the highest rank such that $t_4 \in \mathcal{W}_3^4$ and $t_4 \notin \mathcal{P}_\tau^{3,4}$. Therefore, $\mathcal{P}_\tau^{4,4} = \{t_4\}$.

We show the steps of candidate generation with dynamic prefix computation in Algorithm 3. To implement the operations defined above, we need to use some helper functions. First, we define the function *ScanInvetedIndex* which takes the inverted index and $\mathcal{P}_\tau^{p,l}$ as input and return all the candidate entities of $\mathcal{W}_p^l$ by visiting the inverted indexes that are corresponding to valid tokens in $\mathcal{P}_\tau^{p,l}$. For a valid token $t \in \mathcal{P}_\tau^{p,l}$, we can obtain the candidates from the inverted index $\mathcal{L}[t]$. Note that since we have grouped all items in the inverted index by length, for a group $\mathcal{L}_{l_e}[t] \in \mathcal{L}[t]$, if l_e and l does not satisfy the length filter, we can skip $\mathcal{L}_{l_e}[t]$ in batch. Similarly, if the position of t is beyond the τ-prefix of a derived entity e^i, we can also discard e^i.

Then we devise the function *ExtCandGeneration* to support the Window Extend operation. It first derives the prefix of the current substring from the prefix of previous substring according to the above description; then it obtains the candidates for the current substring. Similarly, we also devise the *MigCandGeneration* function to support Window Migrate operation. Due to the space limitation, we omit their pseudo codes here.

Algorithm 3: Candidate Generation($\mathcal{CI}$, d, τ)

```
Input: $\mathcal{CI}$: The Inverted Index; $d$: The given Document; $\tau$:
       The threshold of Asymmetric Rule-based Jaccard
Output: $C$: The set of candidate pairs
1  begin
2      Initialize $C \leftarrow \emptyset, p \leftarrow 1$;
3      Obtain the prefix $\mathcal{P}_\tau^{p,\mathcal{E}_\perp}$;
4      $C = C \cup$ ScanInvetedIndex($\mathcal{CI}, \mathcal{P}_\tau^{p,\mathcal{E}_\perp}$);
5      for $len \in [\mathcal{E}_\perp + 1, \mathcal{E}_\top]$ do
6          $C_p^{len}, \mathcal{P}_\tau^{p,len} \leftarrow$ ExtCandGeneration($\mathcal{P}_\tau^{p,len-1}$);
7          $C = C \cup C_{len}$;
8      while $p < |d| - \mathcal{E}_\perp$ do
9          if $C_{p-1} \neq \emptyset$ then
10             for $len \in [\mathcal{E}_\perp, \mathcal{E}_\top]$ do
11                 $C = C \cup$ MigCandGeneration($\mathcal{P}_\tau^{p-1,len}$);
12         else
13             Obtain the candidates of $C_p$ in the same way of
               line 6 to line 7;
14         $p \leftarrow p + 1$;
15     Perform Window Extend on the last window with length
       $|d| - \mathcal{E}_\perp + 1$ to collect candidates;
16     return $C$;
17 end
```

The whole process of the algorithm is as follows. We first initialize the candidate set C and start from the first position of the document (line: 2). Here we denote the candidates from window $\mathcal{W}_p$ as C_p. For the first window, we perform Window Extend and collect all the candidates of substrings $\mathcal{W}_0^l$ (line: 4-line: 7). Next we enumerate the start position of the window and look at the previous window. If the previous window has candidate substrings, we will perform Window Migrate on the previous window to obtain the prefix for each substring in the current window and then collect the candidates for each substring (line: 9). Otherwise, we will obtain the prefix of each substring with Window Extend (line: 12). Such processes are repeated until we reach the end of the document. Finally, we return all the candidates and send them to the verification step (line: 16).

Example 4.3. Consider the example data in Figure 1 again. We have $\mathcal{E}_\perp = 1$ and $\mathcal{E}_\top = 5$. Assume document d has 1000 tokens. The total number of the function calls of ExtCandGeneration and MigCandGeneration is $1000 \times (\mathcal{E}_\top - \mathcal{E}_\perp) = 4000$. Notice that, both ExtCandGeneration and MigCandGeneration compute the prefix incrementally. However, the straightforward method needs to compute the prefix for $500,500$ substrings, as it requires to enumerate all possible substrings and compute the prefix for each of them independently.

4.2 Lazy Candidate Generation

With the dynamic prefix computation method, we avoid obtaining the prefix of each substring from scratch. However, there is still room for improvement. We can see that in Algorithm 3, we need to traverse the inverted indexes and generate candidates for all the valid tokens after obtaining the prefix. As substrings within the same window could have a large overlap in their prefix, they could also share many valid tokens. Moreover, a valid token t is also likely to appear anywhere within the same document. Even if t belongs to disjoint substrings, the candidate entities are still from the same inverted index $\mathcal{L}(t)$.

To further utilize such overlaps, we come up with a lazy strategy for candidate generation. The basic idea is that after we compute the prefix of a substring, we will not traverse the inverted indexes to obtain candidates immediately. Instead, we just collect the valid tokens for each substring and construct a global set of valid tokens $\mathcal{T}$. Finally, we will postpone the visits to inverted indexes after we finish recognizing all the valid tokens and corresponding substrings. In this way, *for each valid token $t \in \mathcal{T}$, we only need to traverse its associated inverted index $\mathcal{L}_t$ once during the whole process of extraction for one document.*

The difficulty of implementing the lazy strategy is two-fold. The first problem, i.e. the one of large space overhead required is discussed next, whereas the second one, i.e. the one related to different substring lengths is discussed later. Since we do not collect candidates immediately for each substring, we need to maintain the valid tokens for each substring. As the number of substrings is rather large, there will be heavy space overhead. To solve this problem, we take advantage of the relationship between substrings within the same window. Here we denote the valid token set of a substring $\mathcal{W}_p^l$ as $\Phi_p(l)$. For one window $\mathcal{W}_p$, we only keep the full contents of $\Phi_p(\mathcal{E}_\perp)$. To obtain $\Phi_p(l), l > \mathcal{E}_\perp$, we utilize a light-weighted structure `delta valid token`, which is represented as a tuple $< t, \circ >$. Here t is the valid token that is different from the previous substring; $\circ$ is a symbol to denote the operation on t. If $\circ$ is $+$ $(-)$, it means we need to insert t into(remove t from) the previous valid token set. We denote the set of delta valid tokens of substring $\mathcal{W}_p^l$ as $\Delta\phi(l)$. And then we have:

$$\Phi_p(l+1) = \Phi_p(l) \biguplus \Delta\phi(l) \tag{2}$$

where $\uplus$ means applying all operations of the corresponding token in $\Delta\Phi(l)$ on the given valid token set. If $\Delta\phi(l) = \emptyset$, it means that $\Phi_p(l+1) = \Phi_p(l)$. Then we can obtain all valid tokens and the corresponding candidate substrings of window $\mathcal{W}_p$ as:

$$\Psi(p) = \bigcup_{l \in [\mathcal{E}_\perp, \mathcal{E}_\top]} < \mathcal{W}_p^l, \Phi_p(\mathcal{E}_\perp) \biguplus \Sigma_{i=\mathcal{E}_\perp}^{l} \Delta\phi_p(i) > \tag{3}$$

Example 4.4. Consider the example document in Figure 6 again. Assume we have $\mathcal{E}_\perp = 1$, $\mathcal{E}_\top = 4$ and $\tau = 0.6$. $\Phi_3(1) = \{t_3\}$ as t_3 is the only valid token in $\mathcal{P}_\tau^{3,1}$. Then $\Phi_3(2) = \Phi_3(1) \uplus \{< t_3, - >, < t_4, + >\}$ as t_3 is not a valid token for $\mathcal{W}_3^2$ but t_4 is. Similarly, we have $\Phi_3(3) = \Phi_3(2) \uplus \{< t_5, + >\}$ and $\Phi_3(4) = \Phi_3(3)$. Therefore, according to Equation 3, the valid tokens and the corresponding candidate substrings of window $\mathcal{W}_3^4$ can be expressed as:

$$\Psi(3) = < \mathcal{W}_3^1, \{t_3\} > \bigcup < \mathcal{W}_3^2, \{t_4\} > \bigcup \\ < \mathcal{W}_3^3, \{t_4, t_5\} > \bigcup < \mathcal{W}_3^4, \{t_4, t_5\} >$$

The second issue follows from the fact that the candidate substrings have different lengths. For one valid token $t \in \mathcal{T}$, it might belong to multiple $\Phi_p(l)$ with different values of l. Then we should be able to identify $\mathcal{W}_p^l$ with different l by scanning $\mathcal{L}[t]$ only once. To reach this goal, we propose an effective data structure to connect the candidate substrings and list of entities. Specifically, after moving to the end of the document using Window Extend and Window Migrate, we collect the first valid token set $\Phi_p(\mathcal{E}_\perp)$ and delta valid token sets $\Delta\phi(l)$ for all windows $\mathcal{W}_p$. Next we obtain $\Psi(p)$ using Equation 3 and construct an inverted index $\mathcal{I}$ for candidate substrings. Here a substring $\mathcal{W}_p^l \in \mathcal{I}[t]$ means that $\mathcal{W}_p^l$ is a candidate for entities in $\mathcal{L}[t]$. Then to meet the condition of length and prefix filter, we also group $\mathcal{W}_p^l \in \mathcal{I}[t]$ by length l, denoted as $\mathcal{I}_l[t]$. For substrings $s \in \mathcal{I}_l[t]$, only the entities in groups $\mathcal{L}_{|e|}[t]$ s.t. $|e| \in [\lfloor l * \tau \rfloor, \lceil \frac{l}{\tau} \rceil]$ can be candidate of s. In this way, we can obtain the entity for all $\mathcal{W}_p^l$ with $t \in \Phi_p(l)$ by scanning $\mathcal{L}[t]$ only once. Then for a candidate substring $\mathcal{W}_p^l$, the set of entities can be obtained by $\bigcup_{t \in \mathcal{W}_p^l} \mathcal{L}_{|e|}[t]$.

Algorithm 4 demonstrates the steps of lazy candidate generation. We first collect $\Phi_p(0)$ and $\Delta\phi_p(l)$ for each window using the same method in Algorithm 3. We then initialize the global token dictionary and inverted index for substrings (line: 3). But unlike Algorithm 3, here we only track the valid tokens for each substring instead of generating the candidates. Next, we generate the valid token set for each substring using Equation 2 (line: 4). And we can collect all the valid tokens and their corresponding substrings from them (line: 5- 7). With such information, we can build a mapping between the groups with different lengths $|e|$ in the inverted index and the candidate substrings with different lengths l s.t. $\lfloor |e| * \tau \rfloor \leq l \leq \lceil \frac{|e|}{\tau} \rceil$(line: 9). Then we scan the inverted list only once and collect the candidates. Finally, the entities for a candidate substring can be obtained from the union of the inverted indexes of all its valid tokens (line: 11). We summarize the correctness of Lazy Candidate Generation in Theorem 4.5.

THEOREM 4.5 (CORRECTNESS). *The Lazy Candidate Generation method will not involve any false negative.*

Algorithm 4: Lazy Candidate Generation($\mathcal{CI}$, d, τ)

```
Input: $\mathcal{CI}$: The Inverted Index; $d$: The Document; $\tau$: The
       threshold of JAC
Output: $C$: The candidates
begin
    Use similar methods in Algorithm 3 to generate $\Phi_p(0)$
    and $\Delta\phi_p(l)$ for each window $\mathcal{W}_p$.
    Initialize $\mathcal{T}$ and $\mathcal{I}$;
    Generate all valid token set $\phi_l(p)$ using Equation 2;
    foreach $\phi_p(l)$ do
        collect the valid tokens, update $\mathcal{T}$;
        Construct the inverted index for substrings $\mathcal{I}$;
    foreach $t \in \mathcal{T}$ do
        Map entities in $\mathcal{L}_{|e|}[t]$ with candidate substrings in
        $\mathcal{I}_l[t]$ s.t. length filter;
        Scan $\mathcal{L}[t]$, obtain candidates for each $l$;
        $C = C \cup < \mathcal{W}_p^l, \bigcup_{t \in \mathcal{W}_p^l} \mathcal{L}_{|e|}[t] >$;
    return $C$;
end
```

5 DISCUSSION

In this section, we discuss about the scope as well as the generalization of our work.

Gathering Synonym Rules We first discuss about the way to obtain synonym rules. In our work, we make an assumption that the set of synonyms are known ahead of time. But it will not influence the generalization of our Aeetes framework. For a collection of documents, there are multiple sources of the synonyms rules. We list some of them below:

- Firstly, the synonym rules can come from common sense as well as knowledge bases. For example, we can use the synonyms provide by WordNet [3] as the input of Aeetes. The common sense knowledge can also provide rich source of synonyms, such as the abbreviation of institutes, address and locations used in our DBWorld and USJob datasets.
- Secondly, some domain specific applications provided the set of synonyms. For example, in the PubMed dataset, the synonyms are created by domain experts, which are very important information in understanding the medical publications. Therefore, performing AEES on such kinds of applications is with great values of practical application.
- Lastly, we can also discover the synonyms from documents with existing systems. For example, the output of [7] and [22] can be utilized directly as the input of our framework.

There are also some previous studies about data transformation and learning by example, which are summarized in Section 7. These studies are orthogonal to our work as they focused on detecting high-quality set of rules while our problem is about how to perform approximate entity extraction with predefined synonym rules. The synonyms discovered by them can also be used as the input of our framework.

Generation of Non-conflict Rule Set Given an entity e, let $\mathcal{A}_c(e)$ be the set of complete applicable rules of e and lhs_i be the left-hand of the rule r_i ($\langle$ $lhs_i \Leftrightarrow rhs_i \rangle$). Without loss of generality, we assume the lhs of an applicable rule is a subsequence of the entity. Two rules r_i and r_j are conflict rules if $lhs_i \cap lhs_j \neq \emptyset$. Our goal is to choose a non-conflict set $\mathcal{A}(e) \subseteq \mathcal{A}_c(e)$ such that (i) all rules in $\mathcal{A}(e)$ are non-conflict and (ii) the cardinality of $\mathcal{A}(e)$ is as large as possible.

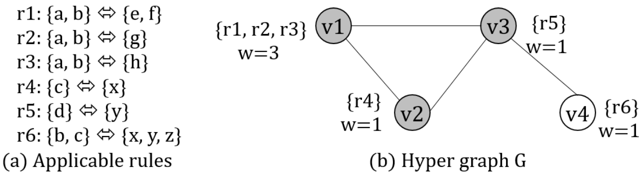


Figure 7: Hypergraph for the applicable rules of the entity $\{a, b, c, d\}$.

The non-conflict rule set can be obtained in the following way:

(1) First build a hypergraph $G = (V, E, W)$ for $\mathcal{A}_c(e)$. Each vertex $v \in V$ corresponds to a set of applicable rules whose left-hands are the same. The number of rules in the vertex v is the weight w of v. There is an edge $e \in E$ between two vertices whose rules are non-conflict.
(2) With such a hypergraph, we can obtain the set of non-conflict rules by finding the maximum weighted clique in the hypergraph G.

Example 5.1. Consider the set of complete applicable rules $\mathcal{A}_c(e)$ for the entity $e = \{a, b, c, d\}$ in Figure 7(a). The corresponding hypergraph G is shown in Figure 7(b). For instance, v_1 contains $\{r_1, r_2, r_3\}$ as they have identical left-hands, i.e., $\{a, b\}$. There is an edge between v_1 and v_2 since $\{a, b\} \cap \{c\} = \emptyset$. In this hypergraph, $\{v_1, v_2, v_3\}$ is the maximal weighted clique. Therefore, the final non-conflict applicable rules $\mathcal{A}(e) = \{r_1, r2, r_3, r_4, r_5\}$.

Unfortunately, finding the maximal weighted clique is a well-known NP-Complete problem. In order to efficiently find $\mathcal{A}(e)$ with large enough cardinality, we adopt a greedy algorithm with the following steps. Firstly, we choose the vertex v^* with maximal weight as a start point. Next we pick the next vertex v with the maximal weight among the unseen vertices such that adding v to the current clique is still a clique. Then we repeat step 2 until no more vertex can be added into the result set.

Example 5.2. Consider the set of complete applicable rules $\mathcal{A}_c(e)$ for entity $e = \{a, b, c, d\}$ in Figure 7 again. The greedy algorithm first chooses v_1 as it has the maximal weight. Then the algorithm picks v_2 since , it is still a clique after adding v_2. Similarly, v_3 is also added. Finally, the clique is $\{v_1, v_2, v_3\}$ and the corresponding non-conflict applicable rules are $\mathcal{A}(e) = \{r_1, r2, r_3, r_4, r_5\}$. Here the greedy algorithm achieves the optimal result.

6 EXPERIMENTS

6.1 Environment and Settings

In this section, we evaluated the effectiveness and efficiency of all proposed algorithms on three real-life datasets:

- PubMed. It is a medical publication dataset. We selected 100, 000 paper abstracts as documents and keywords from 10, 000, 000 titles as entities to construct the dictionary. In addition, we collect 50, 476 synonym Mesh [4] (Medical Subject Headings)[5] term pairs, which are provided by the domain experts.

[3] https://wordnet.princeton.edu/

[4] https://www.ncbi.nlm.nih.gov/mesh

[5] Mesh is the NLM controlled vocabulary thesaurus used for indexing articles for PubMed.

- DBWorld. We collected 1,000 message contents as documents and keywords in 1,414 titles as entities in the dictionary. We also gather 1076 synonym rules including conference names, university names and country names which are common sense knowledge.
- USJob. We chosen 22,000 job descriptions as documents, and 1,000,000 keywords in the job titles as entities in the dictionary. In addition, we collected 24,305 synonyms including the abbreviations of company names, state names and the different names of job positions.

Table 1 gives the statistics of datasets, including the average number of tokens in documents (avg $|d|$), average number of tokens in entities (avg $|e|$), and average number of applicable rules on one entity (avg $|\mathcal{A}(e)|$).

Table 1: Dataset statistics.

	# docs	# entities	# synonyms	avg $\|d\|$	avg $\|e\|$	avg $\|\mathcal{A}(e)\|$
PubMed	8,091	370,836	24,732	187.81	3.04	2.42
DBWorld	1,414	113,288	1,076	795.89	2.04	3.24
USJob	22,000	1,000,000	24,305	322.51	6.92	22.7

All experiments were conducted on a server with an Intel(R) Xeon(R) CPU processor (2.7 GHz), 16 GB RAM, running Ubuntu 14.04.1. All the algorithms were implemented in C++ and compiled with GCC 4.8.4.

6.2 Evaluation of Effectiveness

First, we evaluate the effectiveness of our metric JACCAR by comparing with the state-of-the-art syntactic similarity metrics.

Ground truth For our task, there is no ground truth on these datasets. Borrowing the idea from previous studies on ASJS problem [19, 29], we manually create the ground truths as following: We marked 100 substrings in the documents of each dataset such that each of the marked substrings has one matched entity in the origin entity dictionary. Each pair of marked substring and the corresponding entity is a ground truth. For example, (*Primary Hypertrophic Osteoarthropathy*, *Idiopathic Hypertrophic Osteoarthropathy*), (*Univ. of California Berkeley USA*, *UC Berkeley USA*), and (*SDE in FB*, *software development engineer in Facebook*) are ground truths in PubMed, DBWorld and USJob dataset respectively.

Baseline methods To demonstrate the effectiveness of applying synonym rules, we compare JACCAR with two state-of-the-art syntactic similarity metrics: (i) Jaccard, which is the original Jaccard similarity; and (ii) Fuzzy Jaccard (FJ), which is proposed in [32]. As they are just based on syntactic similarity, they cannot make use of the synonym rules.

We evaluate the effectiveness of all the similarity measures by testing the *Precision* (short for "P"), *Recall* (short for "R"), and *F-measure* (short for "F"), where F-measure = $\frac{2 \times P \times R}{P+R}$ on the three datasets.

Results Table 2 reports the precision, recall and the F-measure of all similarity measures on three datasets. We have the following observations. Firstly, JACCAR obtains higher F-measure scores than Jaccard and FJ. The reason is that JACCAR can use synonym rules to detect the substrings that are semantically similar to the entities, which indicates the advantage of integrating syntactic metrics with synonyms in the entity extraction problem. Secondly, FJ has higher Precision scores than Jaccard as FJ can identify tokens with minor typos. However, Jaccard has higher Recall scores than FJ because FJ may increase the similarity score for substrings that are not valid ground truth.

We present a sample of ground truth for each dataset in Figure 8 to perform a case study on the quality of three similarity metrics. We can see that in PubMed, both Jaccard and FJ are equal to 0. This is because the ground truth substring has no common (or similar) tokens with the entity. JACCAR =1.0 as JACCAR can apply the second synonym to the entity. In DBWorld, FJ has higher similarity score than Jaccard. The reason is that Jaccard can only find three common tokens "The University of " between the substring and the entity. But FJ can get extra benefit by identifying "Aukland" in the document is similar to "Auckland" in the entity (as their edit-distance is only 1). JACCAR achieves the highest score as JACCAR can apply the first synonym on the entity to obtain two more common tokens, i.e., "New Zealand". Similarly, in USJob, FJ has a higher score than Jaccard and JACCAR achieves the highest score.

6.3 Evaluation of Efficiency

Next we look at the efficiency of proposed techniques. We use the average extraction time per document as the main metric for evaluation.

End-to-end performance First we report the end-to-end performance. As there is no previous study on the AEES problem, we extend Faerie [13], which reports the best performance in AEE task, and propose FaerieR to serve as the baseline method. In order to let FaerieR handle the AEES problem, for each dataset we perform a preprocessing by using all applicable synonym rules to all entities in the dictionary so as to construct a derived dictionary. Then we use such a derived dictionary as the input of Faerie. After that, we conduct post-processing to recognize the pairs of origin entity and substrings in the document. For FaerieR, we omit the preprocessing and post-processing time and only report the extraction time by the original Faerie framework. For the implementation of Faerie, we use the code obtained from the original authors.

We compare the overall performance of Aeetes and FaerieR with different threshold values ranging from 0.7 to 0.9 on all three datasets. As shown in Figure 9, Aeetes outperforms FaerieR by one to two orders of magnitudes. The main reason is that we proposed a series of pruning strategies to avoid duplication computation came from applying synonyms and the overlaps in documents.

In the experiment, we observe that the bottleneck of memory usage is index size. And we report it for Aeetes and FaerieR as following. In PubMed, the index sizes of Aeetes and FaerieR are 10.6 MB and 6.9 MB, respectively. In DBWorld, the index sizes of Aeetes and FaerieR are 4.2 MB and 1.9 MB, respectively. While in USJob, the results are 113.2 MB and 54.3 MB, respectively. We can see that compared with FaerieR, the clustered inverted index of Aeetes has around twice larger size than FaerieR. The main reason is that we need to record the group relation for clustered index and use hashing tables to accelerate the query processing. But Aeetes can achieve much better performance by proper designing the search algorithm and utilizing the memory space smartly.

Optimizations Techniques We evaluate the filtering techniques proposed in Section 4. We implement four methods: Simple is the straightforward method to directly apply length and prefix filter by enumerating substrings; Skip is the method that adopts the

Table 2: Quality of similarity measures (P: short for Precision, R: short for Recall, F: short for F-measure).

Figure 9: End-to-end performance

clustered inverted index to skip dissimilar groups; Dynamic is the method that dynamically computes the prefix for substrings in a document; Lazy is the method that generates candidates in a lazy manner.

The results of the average extraction time are shown in Figure 10. We can see that Lazy achieves the best results. This is because it only needs to scan the inverted index of each token once. Although it requires some extra processing to allocate the candidate substrings with entities, the overhead can be very slight with proper implementation. The performance of Dynamic ranks second as it can dynamically maintain the prefix and does not need to compute from scratch. The reason it has worse performance than Lazy is that if a valid token exists in different windows, it needs to scan the same inverted index multiple times, which leads to heavy filter cost. Skip performs better than Simple as it utilizes the clustered inverted index to avoid visiting groups of entities that do not satisfy the requirement of length filter.

To further demonstrate the effect of filter techniques, we report in Figure 11 the average number of accessed entries in the inverted indexes, which provides a good metric to evaluate the filter cost. We can see that the results are consistent with those in Figure 10. For example, on the PubMed dataset when $\tau = 0.8$, Simple needs to access $326,631$ inverted index entries per document; Skip reduces the number to $126,895$; while the numbers of Dynamic and Lazy are $16,002$ and $6,120$, respectively.

Scalability Finally, we evaluate the scalability of Aeetes. In Figure 12, we vary the number of entities in each dataset and test the average search time for different threshold values. We can see that as the number of entities increased, Aeetes scales very well and achieves near linear scalability. For example, on the USJob dataset for $\tau = 0.75$, when the number of entities ranges from $200,000$ to $1,000,000$, the average running time is 43.26, 48.82, 62.71, 80.43 and 125.52 ms respectively.

7 RELATED WORK

Approximate dictionary-based Entity Extraction Previous studies focusing on this problem only consider syntactic similarity. Chakrabarti et al. [8] proposed a hash-based method for membership checking. Wang et al. [35] proposed a neighborhood generation-based method for AEE with edit distance constraint, while Deng et al. [12] proposed a trie-based framework to improve the performance. Deng et al. [13] proposed Faerie, an all-purposed framework to support multiple kinds of similarity metrics in AEE problem. Wang et al. [34] addressed the local similarity search problem, which is a variant of AEE problem but with more limitations. All above methods only support syntactic similarity and cannot take synonyms into consideration.

String Transformation and Synonym Discovery In some scenarios, the synonym rules may not exist, and it is impractical for a human to manually create a large set of rules. To solve this problem, some previous studies learn the rules using both supervised and unsupervised techniques. Arasu et al. [4] learned general syntactic rules from a small set of given matched records. Singh et al. improved the performance by leveraging language models [27] and semi-supervised learning [26]. Abedjan at al. [1] proposed the DataXFormer system to discover general transformations from web corpus. Singh et al. [28] addressed the same problem using program synthesis rules. Chakrabarti et al. [7] proposed novel similarity functions for synonym discovery from web scale data while He et al. [16] focused on finding synonyms in web tables. Qu et al. [22] discovered synonyms from text corpus with the help of knowledge base.

Entity Matching Entity matching has been a popular topic for decades. An extensive survey is conducted in [14]. Bilenko et al. [6] treated entity matching as a classification problem and proposed machine learning based solutions. Argrawal et al. [2] improved the quality of entity matching by considering errors in words and proposed efficient indexing techniques to improve performance. Wang et al. [33] proposed a learning-based framework to automatically learn the rules for entity matching. Firmani et al. [15] adopted a graph based model to develop an on-line framework for entity matching. Verroios et al. [30] integrated human ratings into entity matching and designed a crowdsourcing framework. Lin et al. [18] proposed a novel ranking mechanism to investigate the combinations of multiple attributes. Such studies mainly worked on collections of entities, while our problem requires to recognize approximate matching entities from documents. It could be an interesting direction of the future work to extend our framework to support other semantic similarity functions proposed here.

String Similarity Query Processing Approximate dictionary-based Entity Extraction (AEE) is a typical application in the field of string similarity query processing. There are also many studies on string similarity queries. Most of them only support syntactic similarity metrics. Among them some are designed for token-based similarity metrics, i.e. Jaccard, Cosine and Overlap, such as [9, 23, 36, 39, 40]; Others are designed for character-based similarity metrics i.e. edit distance, [17, 31, 37, 38]. Wang et al. [32]

combined above two categories of similarity metrics and proposed an efficient framework to support string similarity join. Some previous works tried to support synonym rules in the problem of string similarity join. They proposed some similarity functions to integrate the semantic of synonym rules into Jaccard similarities, such as *JaccT* [3], *SExpand* [19, 20] and *pkduck* [29]. However, they cannot be applied in the AEES problem as we have discussed in Section 2.

8 CONCLUSION AND FUTURE WORK

In this paper, we formally introduced the important problem of Approximate dictionary-based Entity Extraction with Synonyms and proposed an end-to-end framework Aeetes as the solution. We proposed a new similarity metrics to combine syntactic similarity metrics with synonyms and avoid the large overhead of on-line processing documents. We then designed and implemented a filter-and-verification strategy to improve the efficiency. Specifically, for the filtering step, we proposed a dynamic prefix computing mechanism and a lazy candidate generation method to reduce the filter cost. Experimental results on real world dataset demonstrated both the efficiency and effectiveness of our proposed framework.

For future work, we will (i) devise techniques to improve the verification step; (ii) extend our framework to support character-based similarity functions such as Edit Distance for tolerating typos in documents; (ii) support weighted synonym rules by assigning different weights to different rules; and (iii) integrate our techniques into open-source database systems.

ABSTRACT

Social event planning has received a great deal of attention in recent years where various entities, such as event planners and marketing companies, organizations, venues, or users in Event-based Social Networks, organize numerous social events (e.g., festivals, conferences, promotion parties). Recent studies show that "attendance" is the most common metric used to capture the success of social events, since the number of attendees has great impact on the event's expected gains (e.g., revenue, artist/brand publicity). In this work, we study the *Social Event Scheduling* (SES) problem which aims at identifying and assigning social events to appropriate time slots, so that the number of events attendees is maximized. We show that, even in highly restricted instances, the SES problem is NP-hard to be approximated over a factor. To solve the SES problem, we design three efficient and scalable algorithms. These algorithms exploit several novel schemes that we design. We conduct extensive experiments using several real and synthetic datasets, and demonstrate that the proposed algorithms perform on average half the computations compared to the existing solution and, in several cases, are 3-5 times faster.

1 INTRODUCTION

The event planning industry has grown enormously in the past decade, with large *event planning* and *marketing* companies (e.g., MKG, GPJ), organizing and managing a variety of social events (e.g., multi-themed festivals, promotion parties, conferences). In addition to companies, social events are also organized by *venues* (e.g., theaters, night clubs), *organizations* (e.g., ACM, TED), as well as *users* in *Event-based Social Networks* (e.g., Meetup, Eventbrite, Plancast).

The *Event Marketing Benchmark Report 2017*,[1] where marketing decision-makers from large organizations participate, indicates that "*attendance*" *is the most common metric used to measure the success of social events*, since the number of attendees has a great influence on the event's expected gains (e.g., revenue, artist publicity). Therefore, achieving maximum attendance is the *organizers first challenge*, as also indicated in the *Event Marketing Trends 2018* study.[2]

Examples of events organization include large festivals and conferences where a large number of (multi-themed) events are organized over several stages and sessions attracting several thousands of people. For example, *Summerfest Festival* has performances from over 800 bands, attracting more than 800K people each year. Beyond music concerts, numerous multi-themed events take place, ranging from art-makings and theatrical performances to fitness activities and parties. In such scenarios, successful event planning is extremely challenging, since various factors need to be taken into account, such as the *large number of events* and available *time slots*, the *diversity of events' themes* and *user interests*, the presence of *overlapped events*, the *available resources* (e.g., available stages), etc.

Assume the following scenario. On Monday two events are scheduled to take place during a festival: (1) a *rock concept* from 19:00 to 22:00; and (2) a *fashion show* between 19:00 and 21:00. Additionally, from 18:00 to 20:00 a music concert of a *rock singer* is taking place in a nearby (competing) venue. Consider that Alice enjoys listening to *rock music*, and is a *fashion lover*. Although Alice is interested in all three events, she is only able to attend one of them.

In this work, we study the *Social Event Scheduling* (SES) problem [4]. *Given a set of candidate events, a set of time intervals and a set of users, SES assigns events to time intervals, in order to maximize the overall number of participants.* The assignments are determined by considering several events' and users' factors, such as user preferences and habits, events' spatiotemporal conflicts, etc.

Recently, several studies have been published examining the problem of assigning *users* (i.e., participants) to a set of *pre-scheduled events* in Event-based Social Networks [6, 12, 26–29, 31]. The objective in these works is to find the *user-event assignments that maximizes the satisfaction of the users*. Here, in contrast to existing works, we study a substantially different problem. Briefly, instead of assigning users to events, we assign *events* to *time intervals*. The objective here is to find the *event-time assignments that maximize the number of event's attendees*. More or less, the SES problem studies the "satisfaction" (e.g., revenue, publicity) of the entities involved in event organization (e.g., organizer, artist, sponsors, services' providers). In other words, SES is an "*organizer-oriented*" problem, while the existing works are "*participant-oriented*". Overall, the objective, the solution and the setting of the SES problem are substantially different from the related works.

The SES problem was recently introduced in [4] where a greedy algorithm was proposed. In the proposed solution, in each assignment selection, the algorithm recomputes (i.e., updates) the scores for a large number of assignments. Additionally, in each selection the algorithm has to examine (e.g., check for validity) all the assignments. The aforementioned result to poor performance of this solution. In this work, we design three efficient and scalable algorithms which are implemented on top of the following novel schemes. First, we propose an *incremental updating* scheme in which a reduced number of score computations are performed in an incremental manner. Further, we design an *assignment organization* scheme which significantly reduces the number of assignments that are examined. Finally, an *assignment selection policy* is proposed, minimizing the impact of performing a part of the required score computations, on the quality of the results. In our extensive experiments, we illustrate that the proposed algorithms perform about half the computations and, in several cases, are 3-5× faster compared to the method proposed in [4].

Further, examining the theoretical aspects of the SES problem, we study its approximation, showing that even in highly restricted instances, it is NP-hard to be approximated over a factor larger than $(1 - \epsilon)$.

Contributions. The main contributions of this work are summarized as follows: (1) We show that the SES problem is NP-hard to be approximated over a factor larger than $(1 - \epsilon)$. (2) We design three efficient and scalable approximation algorithms. These algorithms outperform the existing algorithm by exploiting a series of schemes that we develop. (3) We conduct an detailed experimental analysis using several real and synthetic datasets.

2 SOCIAL EVENT SCHEDULING PROBLEM

In this section we first define the *Social Event Scheduling* (SES) problem; and then we study its approximation. In what follows, we present a simple example that introduces the main entities involved in SES problem.

Example 1. [*Running Example*] Figure 1 outlines our running example involving four *candidate events* (e_1–e_4), two *time intervals* (t_1, t_2), two *competing events* (c_1, c_2), and *two users* (u_1, u_2).

The *location* of each *candidate event* is presented in Figure 1a We notice that both e_1 and e_2 are going to be hosted at Stage 1. Hence, these events cannot be scheduled to take place during the same time period. Figure 1c presents the *competing events* along with the time periods during which these are scheduled to take place. For example, c_1 is schedule to take place on Friday between 6:00 and 9:00pm (at a nearby competing venue). Further, in Figure 1b we observe that there is the candidate *time interval* t_1 defined on the same day between 8:00 and 11:00pm. Thus, due to overlapping time periods, a user cannot attend both c_1 and a candidate event that will be possibly scheduled to take place during t_1.

Finally, Figure 1d shows, for each user, the *interest values* (i.e., affinity) for the events, as well as the *social activity probability* (e.g., based on user habits) during the time periods defined by the two intervals. For example, u_1 has high social activity probability (equals to 0.8) at t_1, since Friday night u_1 does not work and usually goes out and participates in social activities.

2.1 Problem Definition

In our problem, we assume an ***organizer*** (e.g., company, venue) managing the events' organization. Each organizer possesses a number of ***available resources*** $\theta \in \mathbb{R}^+$. These are abstractions used to refer to staff, materials, budget or any other means related to event organization.

Further, let $\mathcal{T}$ be a set of ***candidate time intervals***, representing time periods that are available for organizing events.

Assume a set $\mathcal{E}$ of available events to be scheduled, referred as ***candidate events***. Each $e \in \mathcal{E}$ is associated with a ***location*** ℓ_e representing the place (e.g., a stage) that is going to host the event. Further, each event e requires a specific amount of resources $\xi_e \in \mathbb{R}_0^+$ for its organization, referred as ***required resources***.

An ***assignment*** α_e^t denotes that the candidate event $e \in \mathcal{E}$ is scheduled to take place at $t \in \mathcal{T}$. An event ***schedule*** $\mathcal{S}$ is a set of assignments, where there exist no two assignments referring to the same event. Given a schedule $\mathcal{S}$, we denote as $\mathcal{E}(\mathcal{S})$ the set of all candidate events that are scheduled by $\mathcal{S}$, i.e., $\mathcal{E}(\mathcal{S}) = \{e \mid a_e^t \in \mathcal{S}\}$; and $\mathcal{E}_t(\mathcal{S})$ the candidate events that are scheduled by $\mathcal{S}$ to take place at t (i.e., assigned to t). Further, for a candidate event $e \in \mathcal{E}(\mathcal{S})$, we denote as $t_e(\mathcal{S})$ the time interval on which $\mathcal{S}$ assigns e.

A *schedule* $\mathcal{S}$ is said to be ***feasible*** if the following constraints are satisfied: (1) $\forall t \in \mathcal{T}$ holds that $\nexists e_i, e_j \in \mathcal{E}_t(\mathcal{S})$ with $\ell_{e_i} = \ell_{e_j}$ (***location constraint***); and (2) $\forall t \in \mathcal{T}$ holds that $\sum_{\forall e \in \mathcal{E}_t(\mathcal{S})} \xi_e \leq \theta$ (***resources constraint***). In analogy, an *assignment* α_e^t is said to be ***feasible*** if the aforementioned constraints hold for t. Further, we call ***valid assignment***, an assignment α_e^t when the assignment is *feasible* and $e \notin \mathcal{E}(\mathcal{S})$.

Let C be a set of ***competing events***, with $C \cap \mathcal{E} = \varnothing$. As competing events we define events that have already been scheduled by third parties, and will possibly attract potential attendees of the candidate events. Based on its scheduled time, each competing event $c \in C$ is associated with a time interval $t_c \in \mathcal{T}$. Further, as C_t we denote the competing events that are associated with the time interval t.

Consider a set of users $\mathcal{U}$, for each ***user*** $u \in \mathcal{U}$ and event $h \in \mathcal{E} \cup C$, there is a function $\mu\colon \mathcal{U} \times (\mathcal{E} \cup C) \to [0, 1]$, denoted as $\mu_{u,h}$, that models the ***interest*** of user u over h. The interest value (i.e., affinity) can be estimated by considering a large number of factors (e.g., preferences, social connections).

Moreover, we define the ***social activity probability*** σ_u^t, representing the probability of user u participating in a social activity at t. This probability can be estimated by examining the user's past behavior (e.g., number of check-ins).

Assume a user u and a candidate event $e \in \mathcal{E}$ that is scheduled by $\mathcal{S}$ to take place at time interval t; $\rho_{u,e}^t$ denotes the ***probability of u attending e at t***. Considering the *Luce's choice theory* [17], the probability $\rho_{u,e}^t$ is influenced by the social activity probability σ of u at t, and the interest μ of u over e, C_t and $\mathcal{E}_t(\mathcal{S})$. We define the *probability of u attending e at t* as:

$$\rho_{u,e}^t = \sigma_u^t \, \frac{\mu_{u,e}}{\sum\limits_{\forall c \in C_t} \mu_{u,c} + \sum\limits_{\forall p \in \mathcal{E}_t(\mathcal{S})} \mu_{u,p}} \tag{1}$$

Furthermore, considering all users $\mathcal{U}$, we define the ***expected attendance*** for an event e scheduled to take place at t as:

$$\omega_e^t = \sum_{\forall u \in \mathcal{U}} \rho_{u,e}^t \tag{2}$$

The ***total utility*** for a schedule $\mathcal{S}$, denoted as $\Omega(\mathcal{S})$, is computed by considering the expected attendance over all scheduled events:

$$\Omega(\mathcal{S}) = \sum_{\forall e \in \mathcal{E}(\mathcal{S})} \omega_e^{t_e(\mathcal{S})} \tag{3}$$

The *Social Event Scheduling* (SES) problem is defined as follows: [3]

Social Event Scheduling Problem (SES). Given an positive *integer* k, a set of candidate *time intervals* $\mathcal{T}$; a set of *competing events* C; a set of *candidate events* $\mathcal{E}$; and a set of *users* $\mathcal{U}$; our goal is to find a *feasible schedule* $\mathcal{S}_k$ that determines how to assign k candidate events such that the *total utility* Ω is maximized; i.e., $\mathcal{S}_k = \arg\max \Omega(\mathcal{S})$ and $|\mathcal{S}| = k$.

Note that, by performing trivial modifications to the algorithms proposed here, additional factors and constraints to those defined in SES, can be easily handled. For example, include event's organization cost/fee (to define a "profit-oriented" version of the SES problem), associate events with duration, or define weights over the users (e.g., based on their influence).

2.2 Approximation Hardness

Here, we show that even in highly restricted instances the SES problem is NP-hard to be approximated over a factor. Therefore, SES does not admit a *Polynomial Time Approximation Scheme* (PTAS).

Theorem 1. There exists an $\epsilon > 0$ such that it is NP-hard to approximate the SES problem within a factor larger than $(1 - \epsilon)$. Thus, SES does not admit a PTAS. [4]

PROOF SKETCH. In our proof we reduce the 3-Bounded 3-Dimensional Matching problem (3DM-3) [10] to a restricted instance of SES. The following is an instance of the 3DM-3 problem. Given a set $T \subseteq X \times Y \times Z$, with $|X| = |Y| = |Z| = n$, $|T| = m$ and with each element of $X \cup Y \cup Z$ appearing at most 3 times as a coordinate of an element of T. A matching in T is a subset $M \subseteq T$, such that no elements in M agree in any coordinate. In our proof, we exploit the following result: [10] showed that in 3DM-3 there exists an $\epsilon_0 > 0$ such that it is NP-hard to decide whether an instance has a matching of size n or if every matching has size at most $(1 - \epsilon_0)n$.

Consider the following *associations between* 3DM-3 and SES: edges g in T to time intervals; and elements in X, Y, Z to candidate events, with required resources $\xi = 1$. Let the aforementioned candidate events form a set E_1 (i.e., $|E_1| = 3n$).

Further, in the proof, we consider the following *restricted instance of* SES: (1) The *available resources* are three. (2) There are no *location constraints*. (3) There is only one *competing event* in each time interval. (4) The *social activity probability* is the same for each user and time interval. (5) The *users* are as many as the candidate events. (6) There is a set E_2 that contains $m - n$ additional (w.r.t. E_1) candidate events, with $\xi = 3$. Thus, the candidate events $\mathcal{E}$ in the restricted instance is $\mathcal{E} = E_1 \cup E_2$, with $E_1 \cap E_2 = \varnothing$. (7) Regarding the *interest function* we assume two disjoint sets of users $|U_1| = 3n$ and $|U_2| = m - n$, a well as the following: ($7a$) Each user $u_1 \in U_1$ likes only one event $e_1 \in E_1$ (as a result, each e_1 is liked only by one user u_1), with $\mu_{u_1,e_1} = 0.25$. ($7b$) Regarding the *competing events* and the users U_1 we have the following. Fix a positive constant $\delta < \frac{1}{12}$. Let $u_p \in U_1$ the user that likes the event e_p, where e_p corresponds to the element y_p in 3DM-3. Then, if y_p is included in the edge g_t (i.e., $y_p \in g_t$), the interest of u_p in the competing event c that appears in the interval t (which in 3DM-3 corresponds to edge g_t) is $\mu_{u_p,c} = 0.25(0.75 - \delta)/(0.25 + \delta)$ and 0.75, otherwise. ($7c$) Each user $u_2 \in U_2$ likes only one event $e_2 \in E_2$ (as a result, each e_2 is liked only by one user u_2), with $\mu_{u_2,e_2} = 0.75$. ($7d$) For each competing event c and user $u_2 \in U_2$, we have $\mu_{u_2,c} = 0$.

We can verify that, for each matching in 3DM-3, we can obtain a schedule in SES with total utility $3(0.25 + \delta)$, by assigning 3 events of E_1 in a same interval. Then, if 3DM-3 has a matching of size n, we can verify that the total utility in SES is $3n(0.25 + \delta) + m - n$. Otherwise, if every matching has size at most $(1 - \epsilon_0)n$, the total utility in SES is $1 - \frac{\epsilon_0 - 12\delta\epsilon_0}{12\delta + 3} < 1 - \frac{1}{3}\epsilon_0$. ■

3 ALGORITHMS

SES is known to be strongly NP-hard, even in highly restricted instances [4]. Due to its hardness, it is computationally prohibitive to find an optimal solution even in small problem sizes. Particularly, in the worst case, we have to enumerate an exponential number of possible assignments, where each assignment requires always $|\mathcal{U}|$ computations. For example, the greedy algorithm proposed in [4], in several cases in our experiments, took more than 5 hours to solve the problem in the default parameters setting, while more than 31 hours in larger settings. To this end, to cope with the hardness of the SES problem we design three efficient and scalable approximation algorithms which perform about half the computations and, in several cases, are 3-5 times faster compared to the method proposed in [4].

3.1 Existing Solution

Here, we outline the previously proposed algorithm. First, we define the assignment score. Given a schedule $\mathcal{S}$ and an assignment α_r^t, as ***assignment score*** (also referred as ***score***) of an assignment α_r^t, denoted as $\alpha_r^t.S$, we define the *gain* in the expected attendance by including α_r^t in $\mathcal{S}$. The assignment score (based on Eq. 2) is defined as:

$$\alpha_r^t.S \;=\; \sum_{\substack{\forall e_j \in \\ \mathcal{E}_t(\mathcal{S}) \cup \{r\}}} \omega'^{\,t}_{e_j} \;-\; \sum_{\substack{\forall e_i \in \\ \mathcal{E}_t(\mathcal{S})}} \omega^t_{e_i} \tag{4}$$

Given a set of assignments, the term ***top assignment*** refers to the assignment with the largest score.

In [4], a simple greedy algorithm is outlined, referred here as ALG. This method starts by initially generating assignments between all pairs of events and intervals. Then, in each iteration, the assignment with the largest score (i.e., top assignment) is selected. After selecting an assignment, a subset of the assignment's scores need to be updated. Recall that, the assignment's score is defined w.r.t. the events assigned in the assignment's interval (Eq. 4). Hence, when an assignment α_e^t is selected, then the scores of the assignments referring to interval t need to be recomputed (updated). The time complexity of ALG is $O(|\mathcal{U}||C| + |\mathcal{E}||\mathcal{T}||\mathcal{U}| + k|\mathcal{E}||\mathcal{T}| + k|\mathcal{E}||\mathcal{U}| - k^2|\mathcal{T}| - k^2|\mathcal{U}|)$; and the space complexity is $O(|\mathcal{E}||\mathcal{T}|)$.

Example 2. [*ALG Algorithm*] Based on our running example, Figure 2 outlines the execution of the ALG algorithm. In this, as well as in the rest of the examples, we assume that $k = 3$. That is, three out of four events have to be scheduled. Each row represents the selection of a single assignment. Rows include the assignment scores (Eq. 4), as well as the selected assignment (presented in bold red

[3] Several of the problem's involved factors (e.g., user interest, activity and attendance probability) can be computed using event-based mining methods, e.g., [5, 7, 13, 19, 21, 36, 37, 40, 41]. However, this is beyond the scope of this work.

[4] Due to lack of space, we only include proof sketches, while in simple cases, the proof sketch is also omitted.

	$\alpha_{e_1}^{t_1}$	$\alpha_{e_2}^{t_1}$	$\alpha_{e_3}^{t_1}$	$\alpha_{e_4}^{t_1}$	$\alpha_{e_1}^{t_2}$	$\alpha_{e_2}^{t_2}$	$\alpha_{e_3}^{t_2}$	$\alpha_{e_4}^{t_2}$		**Select**	**Update**
①	0.59	0.52	0.10	~~0.64~~	0.53	0.57	0.09	**0.66**	→	$\alpha_{e_4}^{t_2}$	$\alpha_{e_1}^{t_2}$ $\alpha_{e_2}^{t_2}$ $\alpha_{e_3}^{t_2}$
②	**0.59**	0.52	0.10	–	~~0.34~~	0.16	0.03	–	→	$\alpha_{e_1}^{t_1}$	$\alpha_{e_3}^{t_1}$

Figure 2: ALG algorithm example

font) and the assignments that have to be updated after the selection. Initially (i.e., ① selection), the algorithm selects the assignment with the largest score (i.e., $\alpha_{e_4}^{t_2}$). Thus, after this selection the assignments referring to e_4 have to be omitted (marked with /), and the assignments referring to t_2 have to be updated. After the second selection, the algorithm has to update only $\alpha_{e_3}^{t_1}$ since $\alpha_{e_2}^{t_1}$ is no longer feasible (marked with ×) due to location constraint. Note that, for the sake of simplicity, the resources constraint has been omitted from the running example. Finally, the schedule contains $\alpha_{e_4}^{t_2}$, $\alpha_{e_1}^{t_1}$ and $\alpha_{e_2}^{t_2}$.

3.2 Incremental Updating Algorithm (INC)

The ALG algorithm proposed in [4], has the following shortcoming: (1) each time ALG selects an assignment, it has to recompute (i.e., update) from scratch all the scores for all the assignments associated with the selected assignment's interval. This process is referred to assignment updating or simply as updates; and (2) in each step, ALG has to examine (and traverse) all the available assignments in order to perform its tasks (e.g., select assignment, perform updates).

Considering the aforementioned issues, we design the *Incremental Updating algorithm* (INC). Regarding the first issue, INC exploits an *incremental updating scheme*, performing incremental assignment updates. Incremental updating allows INC, to provide the same solution as ALG, while, in each step, INC performs only a part of the updates (i.e., score computations). Regarding the second issue, INC attempts to reduce the number of assignments that should be examined in each step, i.e., search space. To this end, we devise an *assignment organization* that takes into account the incremental updating scheme. In several cases in our experiments, INC *is more than three times faster* than the existing algorithm.

Essentially, INC follows a similar assignment selection process to ALG, selecting the top assignment in each step, in a greedy fashion. However, in INC the assignments' update process has been designed based on the introduced incremental updating scheme.

3.2.1 Incremental Updating

In the proposed scheme, the updates are computed in an incremental manner, where after each assignment selection only a part of the updates are performed. As a result, during the algorithm execution, some of the assignments may not be up-to-date.

An assignment is denoted as ***updated***, if its score has been computed by considering all the (previously) selected assignments, and ***not updated*** otherwise. In analogy, a set of assignment is referred as *updated*, when all its assignments are updated, and ***partially updated***, otherwise.

The basic idea of our scheme is that we can determine a subset of the not updated assignments that have to be updated before each selection. First we show that, from the available assignments $\mathcal{A}$, we can find a set $\mathcal{B} \subseteq \mathcal{A}$ which includes the next algorithm selection χ. Then, we also show that the not updated assignments included in $\mathcal{B}$ are the only not updated assignments that have to be updated in order to find χ.

Assignments Sorted by Score ("+" / "–" : *Updated/Not updated*)										**Select**	**Φ**	**Update**
①	$\boldsymbol{\alpha_{e_4}^{t_2+}}$	$\cancel{\alpha_{e_4}^{t_1+}}$	$\alpha_{e_1}^{t_1+}$	$\alpha_{e_2}^{t_2+}$	$\alpha_{e_1}^{t_2+}$	$\alpha_{e_2}^{t_1+}$	$\alpha_{e_3}^{t_1+}$	$\alpha_{e_3}^{t_2+}$	→	$\alpha_{e_4}^{t_2}$	$\alpha_{e_1}^{t_1}.S$	–
②	–	–	$\boldsymbol{\alpha_{e_1}^{t_1+}}$	$\alpha_{e_2}^{t_2-}$	$\cancel{\alpha_{e_1}^{t_2-}}$	$\alpha_{e_2}^{t_1+}$	$\alpha_{e_3}^{t_1+}$	$\alpha_{e_3}^{t_2-}$	→	$\alpha_{e_1}^{t_1}$	∅	$\alpha_{e_2}^{t_2}$
③	–	–	–	$\boldsymbol{\alpha_{e_2}^{t_2+}}$	–	$\xcancel{\alpha_{e_2}^{t_1+}}$	$\alpha_{e_3}^{t_1-}$	$\alpha_{e_3}^{t_2-}$	→	$\alpha_{e_2}^{t_2}$	$\alpha_{e_3}^{t_2}.S$	–

Figure 3: Incremental updating scheme example

In order to specify $\mathcal{B}$, we use a numeric *bound* Φ. As shown next, the value of Φ is the score of the *top*, *updated* and *valid* assignment of $\mathcal{A}$.

Proposition 1. Let Φ be the score of the *top*, *updated* and *valid* assignment of the available assignments $\mathcal{A}$. Then, the next selected assignment χ is one of the assignments that in $\mathcal{A}$ have score larger or equal to Φ; i.e., $\chi \in \mathcal{B}$, where $\mathcal{B} = \{\alpha_e^t \in \mathcal{A} \mid \alpha_e^t.S \geq \Phi\}$.

Proof Sketch. First, we show that the score of a not updated assignment is always larger or equal to the score of the assignment resulted by its update. Note that the proof for this is not trivial for arbitrary numbers of candidate and competing events. Based on the aforementioned, the not updated assignments of $\mathcal{A}$, having score lower than Φ, also have score lower than Φ in $\mathcal{A}'$, where $\mathcal{A}'$ be the set of assignments resulting from $\mathcal{A}$ by updating its not updated assignments. Further, the score of each updated assignment of $\mathcal{A}$ remains the same in $\mathcal{A}'$. So, both the updated and the not updated assignments of $\mathcal{A}$ have scores lower than Φ; their scores in $\mathcal{A}'$ also remain lower than Φ. Thus, the Proposition 1 holds. ■

Based on Proposition 1, since χ is included in $\mathcal{B}$, we can easily verify that, χ is the *top* assignment of $\mathcal{B}'$, where $\mathcal{B}'$ results from $\mathcal{B}$ by updating its not updated assignments. Thus, in order to find χ, we have to update the not updated assignments of $\mathcal{B}$. Based on the aforementioned, the following corollary describes the incremental updating process.

Corollary 1. In each step, in order to select the next assignment, only the not updated assignments having score larger or equal to Φ have to be updated.

Example 3. [*Incremental Updating Scheme*] Figure 3 illustrates the utilization of the incremental updating scheme. For clarity of presentation, we omit the assignment scores since these are the same as in Example 2. To better understand the procedure, in each row the assignments are presented in descending order, based on their score. The +/- notation is used to denote that the assignment is *updated*, or *not updated*, respectively. After the first selection, Φ is equal to $\alpha_{e_1}^{t_1}.S$ (i.e., top, updated and valid assignment), and all the assignments referring to t_2 change to *not updated*. Further, since all the not updated assignments have score lower than Φ, none of the assignments have to be updated. Then (② selection), after selecting $\alpha_{e_1}^{t_1}$, all the assignments become not updated; so Φ becomes unavailable. Next, the algorithm updates $\alpha_{e_2}^{t_2}$ and sets Φ equal to its score (0.16). In the last selection, since the current Φ is larger than the scores (0.10 and 0.9) of the not updated assignments $\alpha_{e_3}^{t_1}$ and $\alpha_{e_3}^{t_2}$, the algorithm does not have to update it. Compared to the ALG algorithm (Example 2) which performs four updates, our scheme performs only one.

3.2.2 Assignments Organization over Incremental Updating

In each step, the algorithm needs to examine and traverse all the available assignments, in order to perform the following main tasks: (1) select the top assignment; (2) perform updates; and (3) maintain the bound. In order to accomplish these tasks, for each of the available assignments, the algorithm has to perform numerous computations. Indicatively, it has to check validity constraints, compare scores, consider bounds and possibly compute the new assignment score, etc.

Given the above, we introduce an *interval-based assignment organization* that incorporates with our incremental updating scheme. This organization attempts to reduce the number of assignments that are accessed and examined, i.e., *search space*. Using our organization, in most cases in our experiments, INC *examines slightly more than half assignments* compared to the existing algorithm.

Search Space Reduction in Assignment Updates. Here, we describe how we reduce the assignments that should be examined in order to perform the updates. An interval-based assignment organization allows to access at the interval-level, only the assignments that should be examined for update. Adopting this organization in a simple (not incremental) updating process, like in ALG, in each step, the algorithm needs only to access the assignments of one interval in order to performs the updates. On the other hand, in the incremental updating setting, several intervals become partially updated during the execution. In this scenario, in order to identify the assignments that need to be updated, we have to examine all the assignments included in partially updated intervals. As a result, in our setting, a simple interval-based organization will not be effective, since it will allow to skip accessing only the updated intervals.

Beyond ignoring only the updated intervals, in order to further reduce the search space, we have to be able to identify (and skip) the partially updated intervals whose assignments are not going to be updated. In our organization scheme, this is addressed by defining a score over each interval. Particularly, for each interval $t \in \mathcal{T}$, a value M_t is defined, where M_t is equal to the score of the *top*, *updated* and *valid* assignment of interval t. Exploiting M_t, we can directly identify the partially updated intervals that have to be accessed through the updating process. Particularly, it is easy to verify that we have to access all the partially updated intervals $t \in \mathcal{T}$ for which $M_t \leq \Phi$.

Search Space Reduction in Assignment Selection and Bound Maintenance. The organization described so far allows to reduce the search space during the assignment updating process. However, after performing the updates, the algorithm has to accomplish also the tasks of selecting the next assignment and maintaining the bound Φ, which in turn enforce the examination of all the available assignments. In what follows, we show how to perform all the tasks without examining any further assignments beyond the ones examined during the updating process.

The intuition is that, in each step, only a subset of the assignments is updated, while the rest remain the same as in the previous step, referred here as *static*. Therefore, it is reasonable to assume that the algorithm is able to accomplish all of its tasks by utilizing "information" previously captured from the static assignments $\mathcal{W}$. So, if this "information" is known, then, after performing the updates, we can ignore $\mathcal{W}$ (i.e., avoid access). As shown next, this "information" can be captured by two numeric values I_χ and I_Φ determined from $\mathcal{W}$. Briefly, I_χ is exploited to specify the next selected assignment χ, and I_Φ to compute the new Φ.

Proposition 2. Given a set of static assignments $\mathcal{W}$. Let I_χ and I_Φ be the scores of the *first* and the *second larger top, updated* and *valid* assignment of $\mathcal{W}$, respectively. Then, if I_χ and I_Φ are know, the algorithm can ignore $\mathcal{W}$.

Algorithm 1. INC (k, $\mathcal{T}$, $\mathcal{E}$, $\mathcal{C}$, $\mathcal{U}$)

```
Input: $k$: number of scheduled events; $\mathcal{T}$: time intervals;
       $\mathcal{E}$: candidate events; $\mathcal{C}$: competing events; $\mathcal{U}$: users;
Output: $\mathcal{S}$: feasible schedule containing $k$ assignments
Variables: $\mathcal{L}_i$: assignment list for interval $i$; $\Phi$: bound; $\mathcal{M}$: top, valid and updated assign list
1  $\mathcal{S} \leftarrow \varnothing$;  $\mathcal{M} \leftarrow \varnothing$;  $\mathcal{L}_i \leftarrow \varnothing$,  $\mathcal{L}_i.U \leftarrow$ updated $1 \leq i \leq |\mathcal{T}|$
2  foreach $(e, t) \in \mathcal{E} \times \mathcal{T}$ do                                  //generate assignments
3      compute $\alpha_e^t.S$;  $\alpha_e^t.U \leftarrow$ updated;                                 //by Eq. 4
4      insert $\alpha_e^t$ into $\mathcal{L}_t$                                              //initialize assignment lists
5      $\mathcal{M}_{[t]} \leftarrow$ getBetterAssgn($\mathcal{M}_{[t]}$, $\alpha_e^t$)   //initialize $\mathcal{M}$ with the top assignment from each interval
6  while $|\mathcal{S}| < k$ do
7      $\alpha_{e_p}^{t_p} \leftarrow$ getTopAssgn($\mathcal{M}$)                     //select the top, valid & updated assignment
8      insert $\alpha_{e_p}^{t_p}$ into $\mathcal{S}$                                        //insert into schedule
9      remove $\alpha_{e_p}^{t_p}$ from $\mathcal{L}_{t_p}$;  $\mathcal{L}_{t_p}.U \leftarrow$ prtl updated;          //update $\mathcal{L}_{t_p}$ status
10     $\alpha_e^t.U \leftarrow$ prtl updated, $\forall \alpha_e^t \in \mathcal{L}_{t_p}$
11     foreach $\alpha_e^t \in \mathcal{M}$ do                        //update $\mathcal{M}$ list based on selected assignment
12         if $t = t_p$ then
13             $\alpha_e^t \leftarrow \varnothing$                                            //i.e., $\alpha_e^t.S \leftarrow -\infty$
14         else if $e = e_p$ then
15             $\alpha_e^t \leftarrow$ getTopAssgn($\mathcal{L}_i$)
16     $\Phi \leftarrow$ score of top $\mathcal{M}$                                          //set bound
17     for $i = 1$ to $|\mathcal{T}|$ do                                             //update assignments
18         if $\mathcal{L}_i.U =$ prtl updated and $\mathcal{M}_{[i]}.S \leq \Phi$ then            //check for updates
19             foreach $\alpha_e^t \in \mathcal{L}_i$ do
20                 if $\alpha_e^t$ is not valid then
21                     remove $\alpha_e^t$ from $\mathcal{L}_i$
22                 else if $\alpha_e^t.U =$ prtl updated and $\alpha_e^t.S \geq \Phi$ then
23                     compute new $\alpha_e^t.S$;  $\alpha_e^t.U \leftarrow$ updated;                  //by Eq. 4
24                     $\mathcal{M}_{[i]} \leftarrow$ getBetterAssgn($\mathcal{M}_{[i]}$, $\alpha_e^t$)          //update top assignment
25                     $\Phi \leftarrow$ getBetterAssgn($\Phi$, $\alpha_e^t.S$)                       //update bound
26             if all $\alpha_e^t \in \mathcal{L}_i$ is updated then $\mathcal{L}_i.U =$ updated;
27 return $\mathcal{S}$
```

In our interval-based scheme implementation, the static assignments $\mathcal{W}$ correspond to a set of static intervals $\mathcal{T}_\mathcal{W} \subseteq \mathcal{T}$. Both I_χ and I_Φ can be be directly computed based on the values of M_t of the static intervals $\mathcal{T}_\mathcal{W}$. Particularly, $I_\chi = \max\limits_{\forall t \in \mathcal{T}_\mathcal{W}} M_t$ and $I_\phi = \max\limits_{\forall t \in \{\mathcal{T}_\mathcal{W} \setminus t_\chi\}} M_t$, where t_χ is the interval of I_χ. Therefore, based on Proposition 2, in each step, the algorithm needs to access only intervals that have been updated (i.e., subset of partially updated intervals).

Assignment Organization Summary. To sum up, the presented organization allows: (1) the reduction of the assignments that are examined during the updating process; and (2) skipping the examination of any further assignments beyond the updated ones.

3.2.3 INC Algorithm Description & Analysis

Algorithm Description. Algorithm 1 describes the INC algorithm; INC receives the same inputs as ALG. Additionally, INC employs $|\mathcal{T}|$ lists, with each list $\mathcal{L}_i$ filled with the assignments of interval i. Further, each assignment α_e^t and list $\mathcal{L}_i$, use a flag U (denoted as $\alpha_e^t.U$) to define its update status. Finally, the algorithm uses a list $\mathcal{M}$ that holds the top, valid and updated assignments of each interval. Initially, like ALG, INC calculates the scores for all possible assignments (*loop in line* 2). At the same time, the assignments are inserted into the corresponding list $\mathcal{L}_i$ (*line* 3-4). Note that, the *getBetterAssgn* function returns the assignment with the larger score.

Then, at the beginning of each iteration (*line* 6), the algorithm selects the top assignment from $\mathcal{M}$, and inserts it into schedule (*lines* 7-8). Also, the algorithm has to revise the information related to update status (*lines* 9-10). After the assignment's selection phase, the algorithm performs score updates. Initially, the bound Φ is defined by the top updated assignment (*line* 16). Then, the algorithm traverses the lists $\mathcal{L}_i$, using as upper bound the $\mathcal{M}_{[i]}.S$, to identify the lists that have to be checked for updates (*line* 18). From the verified lists, the

	t_1	t_2		t_1	t_2		t_1	t_2
e_1	0.59	0.53	→	**0.59**	~~0.53~~	→	–	–
e_2	0.52	0.57		0.52	0.57		~~0.52~~	**0.16**
e_3	0.10	0.09		0.10	0.09		0.05	0.03
e_4	~~0.64~~	**0.66**		–	–		–	–
Select:	① $\alpha_{e_4}^{t_2}$		→	② $\alpha_{e_1}^{t_1}$		→	③ $\alpha_{e_2}^{t_2}$	
Update:			–		$\alpha_{e_3}^{t_1}$ $\alpha_{e_2}^{t_2}$ $\alpha_{e_3}^{t_2}$			

Figure 4: HOR algorithm example

Algorithm 2. HOR (k, $\mathcal{T}$, $\mathcal{E}$, C, $\mathcal{U}$)

```
Input: $k$: number of scheduled events;  $\mathcal{T}$: time intervals;
       $\mathcal{E}$: candidate events;  $C$: competing events;  $\mathcal{U}$: users;
Output: $\mathcal{S}$: feasible schedule containing $k$ assignments
Variables: $\mathcal{L}_i$: assignment lists for interval $i$;    $\mathcal{M}$: top assignments list
1  $\mathcal{S} \leftarrow \varnothing$;  $\mathcal{M} \leftarrow \varnothing$;
2  while $|\mathcal{S}| < k$ do
3      $\mathcal{L}_i \leftarrow \varnothing$;   $1 \le i \le |\mathcal{T}|$
4      foreach $(e, t) \in \{\mathcal{E} \backslash \mathcal{E}(\mathcal{S})\} \times \mathcal{T}$ do          //generate assignments
5          if $\alpha_e^t$ is valid then
6              compute $\alpha_e^t.S$;                                  //by Eq. 4
7              insert $\alpha_e^t$ into $\mathcal{L}_t$                          //initialize assignment lists
8              $\mathcal{M}_{[t]} \leftarrow$ getBetterAssgn($\mathcal{M}_{[t]}$, $\alpha_e^t$)  //insert into $\mathcal{M}$ the top assignment from each interval
9      while $\mathcal{M} \neq \varnothing$ and $|\mathcal{S}| < k$ do                //select assignments from $\mathcal{M}$
10         $\alpha_{e_p}^{t_p} \leftarrow$ popTopAssgn($\mathcal{M}$)
11         if $e_p \notin \mathcal{S}$ then
12             insert $\alpha_{e_p}^{t_p}$ into $\mathcal{S}$                            //insert into schedule
13         else          //assignment is invalid; select the top valid from $\mathcal{L}_{t_p}$ and insert it into $\mathcal{M}$
14             insert the top assignment $\alpha_{e_i}^{t_p}$ from $\mathcal{L}_{t_p}$ into $\mathcal{M}$, s.t. $e_i \notin \mathcal{S}$
15 return $\mathcal{S}$
```

algorithm performs incremental updates (*lines* 22-23), updating also $\mathcal{M}$ and Φ (*lines* 24-25).

INC vs. ALG Solution. The following proposition states that both INC and ALG, return the same solutions.

Proposition 3. INC and ALG always return the same solution.

Complexity Analysis. The cost in the first loop (*line* 2) is $O(|\mathcal{E}||\mathcal{T}||\mathcal{U}|)$. Note that, each assignment score (Eq. 4) is computed in $O(|\mathcal{U}|)$. Then, the second loop (*line* 6) performs k iterations. The overall cost for the getTopAssgn operation (*line* 7) is $O(\sum_{i=0}^{k-1} |\mathcal{T}|)$. Further, the loop in *line* 11 performs $|\mathcal{T}|$ iterations, whereas in the worst case, in $|\mathcal{T}| - 1$ of these iterations, INC performs a getTopAssgn operation which costs $O(|\mathcal{E}| - (i + 1))$, with $0 \le i \le k - 1$. Thus, the overall cost for this getTopAssgn operation is $O(\sum_{i=0}^{k-1}(|\mathcal{T}| - 1)(|\mathcal{E}| - i - 1))$. Next (*line* 17), in the worst case, all the not updated assignments are updated (same as ALG). Note that, in the *Best case*, INC does not perform any computations for assignment updates, while in ALG, in every case, the cost for updates is $O(|\mathcal{U}| \sum_{i=0}^{k-2} |\mathcal{E}| - i - 1)$.

Hence, in the worst case, the overall cost of INC is same as ALG; i.e., $O(|\mathcal{U}||C| + |\mathcal{E}||\mathcal{T}||\mathcal{U}| + k|\mathcal{E}||\mathcal{T}| + k|\mathcal{E}||\mathcal{U}| - k^2|\mathcal{T}| - k^2|\mathcal{U}|)$. Finally, the space complexity is $O(|\mathcal{E}||\mathcal{T}| + |\mathcal{T}|)$.

3.3 Horizontal Assignment Algorithm (HOR)

In this section we propose the *Horizontal Assignment algorithm* (HOR), which in general, is more efficient than the ALG and INC algorithms and in most cases in practice provides same solutions. The goal of HOR is twofold. First, to reduce the number of updates by performing only a part of the required updates; and, at the same time, minimize the impact of not regular updates, in the solution quality. In HOR both of these issues are realized by the policy that are employed to select the assignments. In our experiments, in several cases HOR *is around 5 and 3 times faster* than ALG and INC, respectively. Also, in more than 70% of our experiments, HOR reports the same solution as ALG, while in the rest cases the difference is marginal.

Horizontal Selection Policy. The key idea of HOR is that it adopts a selection policy, named *horizontal selection policy*, that selects assignments in a "horizontal" fashion. In this policy, in each iteration the algorithm selects a set of assignments consisting of one assignment from each interval. Particularly, the top assignment from each interval is selected. This way, essentially, a layer of assignments is generated in each iteration. For example, consider the scenario where $k > |\mathcal{T}|$ (and the assignments are feasible in all cases). In the first iteration, HOR will assign one event in each interval; equally, in the n^{th} iteration, n events will have been assigned in each interval.[5]

This policy allows HOR to avoid performing updates after each assignment selection. This holds, since, in each iteration at most one assignment per interval is selected. Thus, during an iteration, when an assignment is selected for an interval, the algorithm stops examining the selection of further assignments for this interval. As a result, there is no need to perform any updates until the end of each iteration, where the scores for all the assignments have to recomputed.

In what follows we outline the intuition behind the horizontal selection policy. Considering that the users' attendance is shared between the events that take place during the same or overlapping time intervals. The horizontal policy assigns the same number of events to each interval, ignoring the possibility that it may be preferable to assign a different number of events to some intervals.

Example 4. [*HOR Algorithm*] Figure 4 outlines the execution of the HOR algorithm, presenting assignments following an interval-based organization. Initially, HOR selects the assignment with the largest score. Since the first selected assignment refers to t_2, in the next selection, HOR will select the top assignment from t_1. After selecting assignments from both intervals, HOR has to update all the available assignments in order to perform the third selection. Therefore, HOR performs three updates, whereas it finds the same schedule as ALG/ INC.

Algorithm Description. Algorithm 2 presents the pseudocode of HOR. Note that, since the horizontal selection policy performs selections at the interval-level, we implement interval-based assignment organization. Finally, similarly to INC, HOR uses the $|\mathcal{T}|$ lists $\mathcal{L}_i$ and the list $\mathcal{M}$. At the beginning of each iteration the algorithm calculates the scores for all possible assignments (*loop in line* 4) and initializes $\mathcal{M}$ (*line* 8). In the next phase (*line* 9), the algorithm selects the assignments based on $\mathcal{M}$. Particularly, in each step, the top valid assignment from $\mathcal{M}$ is selected.

3.3.1 HOR Algorithm Analysis

ALG vs. HOR Score Computations Analysis. Here we study the number of score computations, comparing the ALG and the HOR algorithms. The following proposition specifies the cases where HOR performs less score computations than ALG.

Proposition 4. HOR performs less score computations than ALG when $k \le |\mathcal{T}|$ or $|\mathcal{E}| < \frac{k}{2}(3|\mathcal{T}| + 1)$.

PROOF SKETCH. In case that $k \le |\mathcal{T}|$, HOR computes only the scores for the initial assignments (i.e., $|\mathcal{T}||\mathcal{E}|$) without performing any updates. In case that $k > |\mathcal{T}|$, HOR computes the same initial assignments, as well as the scores for $\sum_{i=0}^{(k/|\mathcal{T}|)-1} |\mathcal{T}|(|\mathcal{E}| - i|\mathcal{T}| - |\mathcal{T}|)$ updates. On the other hand, in the ALG algorithm, in any case, we

[5] With an exception in the last iteration l, in which if $k \bmod |\mathcal{T}| \neq 0$, then, $|\mathcal{T}| - (k \bmod |\mathcal{T}|)$ intervals will have $l - 1$ events.

have to compute the same number of initial assignments as in HOR, as well as $k|\mathcal{E}| + \frac{k}{2} - \frac{k^2}{2} - |\mathcal{E}|$ updates. ■

From Proposition 4 we can infer that in "rational/typical" (i.e., real-world) scenarios, HOR perform fewer computations than ALG. Particularly, even in cases that $k > |\mathcal{T}|$, it should also hold that $|\mathcal{E}| \geq \frac{k}{2}(3|\mathcal{T}| + 1)$ in order for HOR to perform more computations. Considering the setting of our problem, the second relation is difficult to hold in practice. For example, consider the scenario where $|\mathcal{T}| = 10$ and $k = 20$. Then, in order for HOR to perform more computations, it should hold that $|\mathcal{E}| \geq 301$, which seems unrealistic due to the noticeable difference between the number of scheduled ($k = 10$) and candidate events ($|\mathcal{E}| \geq 301$).

Worst Case w.r.t. k and $|\mathcal{T}|$. Considering the horizontal selection policy, beyond the size of the input (e.g., $|\mathcal{E}|$, $|\mathcal{U}|$, k), the number of computations in HOR is also influenced by the ratio between parameters k and $|\mathcal{T}|$. During the execution, HOR performs $\lceil k/|\mathcal{T}| \rceil$ iterations. At the beginning of each iteration, it computes the scores according to which $|\mathcal{T}|$ assignments are selected. In the last iteration, if $k \bmod |\mathcal{T}| \neq 0$, then only $k \bmod |\mathcal{T}|$ assignments need to be selected, while the algorithm has already performed the computations that are required to select $|\mathcal{T}|$ assignments. Thus, in this case, HOR has performed more computations than the ones required for selecting its assignments. For example, assume that we have $|\mathcal{T}| = 10$ and $k = 11$. In this case, the score computations performed by HOR are the same as in the case that we have $k = 20$.

The case in which the difference between the number of computed assignment selections and the number of the selections that need to be performed is maximized, is referred as *worst case w.r.t. k and T*. Note that, even in the worst case, in our experiments, HOR outperforms INC in several cases.

Proposition 5. In HOR, the worst case w.r.t. k and $|\mathcal{T}|$ occurs when $k > |T|$ and $k \bmod |\mathcal{T}| = 1$.

Complexity Analysis. In the first while loop (*line* 2), HOR performs $\lceil k/|\mathcal{T}| \rceil$ iterations. In each iteration, in the worst case, there are $|\mathcal{E}| - i|\mathcal{T}|$ available events, where $0 \leq i \leq \frac{k}{|\mathcal{T}|}$. Thus, in each iteration, it computes $|\mathcal{T}|(|\mathcal{E}| - i|\mathcal{T}|)$ assignments (*line* 6). The overall cost for computing the assignments is $O(|\mathcal{U}| \sum_{i=0}^{k/|\mathcal{T}|} |\mathcal{T}|(|\mathcal{E}| - i|\mathcal{T}|))$. Further, in each iteration of the first loop (*line* 2), the nested loop (*line* 9) performs $|\mathcal{T}|$ iterations (referred as nested iterations). In each nested iteration, in the worst case, HOR performs two popTopAssgn operations (*lines* 10 & 14). The cost for the first and the second popTopAssgn operations is $O(|\mathcal{T}|)$ and $O(|\mathcal{E}| - i|\mathcal{T}|)$, respectively. Hence, in sum, the cost for popTopAssgn operations is $O(\sum_{i=0}^{k/|\mathcal{T}|} |\mathcal{T}|(|\mathcal{T}| + |\mathcal{E}| - i|\mathcal{T}|))$. The worst case can occur when all the assignments contained in $\mathcal{M}$ refer to the same event.

Thus, the overall cost of HOR is $O(|\mathcal{U}||C| + |\mathcal{E}||\mathcal{T}||\mathcal{U}| + k|\mathcal{E}||\mathcal{U}| + |\mathcal{T}|^2 - k|\mathcal{T}||\mathcal{U}| - k^2|\mathcal{U}|)$. Finally, the space complexity is $O(|\mathcal{E}||\mathcal{T}| + |\mathcal{T}|)$.

3.4 Horizontal Assignment with Incremental Updating Algorithm (HOR-I)

This section introduces the *Horizontal Assignment with Incremental Updating algorithm* (HOR-I). HOR-I combines the basic concepts from the INC and HOR algorithms, in order to further reduce the computations performed by HOR. Particularly, HOR-I adopts an incremental updating scheme, similar to INC (Sect. 3.2.1), as well as the horizontal selection policy employed by HOR (Sect. 3.3). Note that, in several cases, in our experiment HOR-I *performs about half computations and is up to two times faster compared to* HOR.

Algorithm 3. HOR-I (k, $\mathcal{T}$, $\mathcal{E}$, C, $\mathcal{U}$)

```
Input: $k$: number of scheduled events;  $\mathcal{T}$: time intervals;
       $\mathcal{E}$: candidate events;  $C$: competing events;  $\mathcal{U}$: users;
Output: $\mathcal{S}$: feasible schedule containing $k$ assignments
Variables: $\mathcal{L}_i$: assignment lists for interval $i$;   $\Phi$: bound; $\mathcal{M}$: top assignments list

1  $\mathcal{S} \leftarrow \varnothing$;  $\mathcal{M} \leftarrow \varnothing$;  $\mathcal{L}_i \leftarrow \varnothing \;\; 1 \leq i \leq |\mathcal{T}|$
2  while $|\mathcal{S}| < k$ do
3      if $\mathcal{S} = \varnothing$ then                                         //first iteration
4          foreach $(e, t) \in \{\mathcal{E} \backslash \mathcal{E}(\mathcal{S})\} \times \mathcal{T}$ do                //generate assignments
5              compute $\alpha_e^t.S$;   $\alpha_e^t.U \leftarrow$ updated;                      //by Eq. 4
6              insert $\alpha_e^t$ into $\mathcal{L}_t$                           //initialize assignment lists
7              $\mathcal{M}_{[t]} \leftarrow$ getBetterAssgn($\mathcal{M}_{[t]}$, $\alpha_e^t$)
8      else                                            //incremental assignments updating
9          for $i = 1$ to $|\mathcal{T}|$ do
10             $\Phi \leftarrow 0$                                              //initialize bound
11             foreach $\alpha_e^t \in \mathcal{L}_i$ do
12                 if $\alpha_e^t$ is valid then
13                     if $\alpha_e^t.S \geq \Phi$ then
14                         compute new $\alpha_e^t.S$;   $\alpha_e^t.U \leftarrow$ updated;
15                         $\Phi \leftarrow$ getBetterAssgn($\Phi$, $\alpha_e^t.S$)              //update bound
16                     else
17                         $\alpha_e^t.U \leftarrow$ prtl updated                      //partially updated
18                 else
19                     remove $\alpha_e^t$ from $\mathcal{L}_i$
20             $\mathcal{M}_{[i]} \leftarrow \Phi$                                  //update top assignment
21     while $\mathcal{M} \neq \varnothing$ and $|\mathcal{S}| < k$ do                  //select assignments from $\mathcal{M}$
22         $\alpha_{e_p}^{t_p} \leftarrow$ popTopAssgn($\mathcal{M}$)
23         if $e_p \notin \mathcal{S}$ then
24             insert $\alpha_{e_p}^{t_p}$ into $\mathcal{S}$                              //insert into schedule
25         else           //select the top, valid & updated from $\mathcal{L}_{t_p}$ and insert it into $\mathcal{M}$
26             $\alpha_{e_p}^{t_p} \leftarrow$ top & updated assignment from $\mathcal{L}_{t_p}$, s.t. $e_p \notin \mathcal{S}$
27             if $\alpha_{e_p}^{t_p} = \varnothing$ and $\exists \alpha_e^t \in \mathcal{L}_{t_p}$ s.t. $\alpha_e^t$ is valid then
28                     ·                                   //incremental updates in interval $p$
29                     ·  Same as lines 10 to 20, with $i = p$
30                     ·
31 return $\mathcal{S}$
```

Recall that, at the beginning of each iteration, HOR calculates the scores for all available assignments. Particularly, in the first iteration, the algorithm generates the assignments and calculates their (initial) scores, while in each of the following iterations the scores for all the assignments are updated. On the other hand, after the first iteration, HOR-I instead of updating all the assignments, uses an incremental updating scheme. This way, in each iteration, a reduced number of updates are performed.

Note that since the updates are performed after the first iteration, it is obvious that HOR-I is identical to HOR in cases where only one iteration is required (i.e., $k \leq |\mathcal{T}|$).

Example 5. [*HOR-I Algorithm*] The difference between HOR-I and HOR example (Example 4), appears at the third selection, where from t_2 only the $\alpha_{e_2}^{t_2}$ is updated. This happens because after updating $\alpha_{e_2}^{t_2}$, its score (0.16) is the current bound for this interval. Then, when checking $\alpha_{e_3}^{t_2}$ for update, its score (0.09) is lower than the bound, so there is no need to update it. Hence, HOR-I performs two of the three updates performed by HOR.

Algorithm Description. Algorithm 3 presents HOR-I; HOR-I uses the same structures as HOR, as well as a bound Φ. At the first iteration (*loop in line* 4), as is the case with HOR, HOR-I generates the assignments and initializes $\mathcal{M}$. In the next iterations (*loop in line* 9), it performs incremental updates for each interval, determining a different bound Φ for each interval. Then, similarly to HOR, HOR-I performs the assignment selection based on $\mathcal{M}$ (*loop in line* 21). In contrast to HOR, HOR-I has also to examine the update status of the assignments. In case that there is not a valid and updated assignment left on an interval (*lines* 27-30), HOR-I has to perform incremental updates in this interval.

3.4.1 HOR-I Algorithm Analysis

HOR-I Solution & Worst Case w.r.t. k and $|\mathcal{T}|$. The following propositions state that both HOR-I and HOR return the same solutions and also have the same worst case w.r.t. k and $|\mathcal{T}|$.

Proposition 6. HOR-I and HOR always return the same solution.

Proposition 7. In HOR-I, the worst case w.r.t. k and $|\mathcal{T}|$ occurs when $k > |T|$ and $k \bmod |\mathcal{T}| = 1$.

Complexity Analysis. In the worst case, the computation cost in HOR-I, is the same as HOR. Particularity, in the worst case, the bound employed by HOR-I cannot prevent any of the assignment updates (*line* 9). This case arises, when the assignments in each interval list $\mathcal{L}_i$ are sorted in ascending order by its score, and there are no assignments having the same score. Thus, the computation cost for HOR-I is $O(|\mathcal{U}||C| + |\mathcal{E}||\mathcal{T}||\mathcal{U}| + k|\mathcal{E}||\mathcal{U}| + |\mathcal{T}|^2 - k|\mathcal{T}||\mathcal{U}| - k^2|\mathcal{U}|)$. Note that, in the *Best case* HOR-I does not perform any computations for updates, while in HOR, in any case (where $k > |\mathcal{T}|$), the cost for updates is $O(\sum_{i=0}^{(k/|\mathcal{T}|)-1} |\mathcal{U}||\mathcal{T}|(|\mathcal{E}| - i|\mathcal{T}| - |\mathcal{T}|))$. Finally, the space complexity is $O(|\mathcal{E}||\mathcal{T}| + |\mathcal{T}|)$.

4 EXPERIMENTAL ANALYSIS

4.1 Setup

Datasets. In our experimental evaluation we present the results from four datasets, *two real* and *two synthetic*. The *first real* is the *Meetup dataset* (Meetup) from [21], which contains data from California, and is the dataset used in [4]. We follow the same approach as in [4, 26–28, 31], in order to define the interest of a user to an event. After preprocessing, we have the Meetup dataset containing 42,444 users and about 16K events.

The next *real dataset* (Concerts) which is the largest, is related to music and provided from Yahoo! ("Music user ratings of musical tracks, albums, artists and genres dataset"). Concerts is used to demonstrate the scenario of music festival organization. Particularly, Concerts contains data for several music entities (i.e., tracks, albums, artists, genres), as well as ratings of users over these entities. In this dataset, we consider albums to represent the events (i.e., music concerts). We select the albums that are associated with at least one genre, which results to 89K albums. Further, as users we select the users that have rated at least 10 genres, which result to 379,391 users.

In order to compute user interest over the albums, we consider the users ratings over the music genres, as well as the genres that are associated with the music albums. Let a user u, R_u denote the set of ratings r_i over genres, where $r_i \in [0, 1]$ is the rating over the i genre. Also, let G_a be a set of genres associated with a music album a. Here, we define the interest of a user u over the album a as $(\sum_{\forall g \in G_a} r_g)/|G_a|$, where $r_g = 1$ if the genre g is not specified in R_u. Note that, similar results are reported using alternative methods, such as setting $r_g = 0$ for genres not specified in R_u, or considering only the common user-album genres.

Finally, regarding *synthetic datasets* (Table 1), we generate the users' *interest values* for the events, following the *three distribution types* examined in the related literature [12, 26–28, 31]: *Uniform* (Unf), *Normal* (Nrm) and *Zipfian* (Zip). Note that, for brevity, the results for the Normal distribution are not presented here since they are similar to Uniform. Further for Zipfian, we present only the results with parameter equal to 2 which are similar to those of 1 and 3.

Table 1: Parameters

Description (Parameter)	Values
Synthetic & Real Datasets	
Num of scheduled events (k)	50, 70, **100**, 200, 500
Num of candidate events ($\|\mathcal{E}\|$)	k, $\mathbf{2k}$, $3k$, $5k$, $10k$
Num of time intervals ($\|\mathcal{T}\|$)	$\frac{k}{5}$, $\frac{k}{2}$, k, $\mathbf{\frac{3k}{2}}$, $2k$, $3k$
Competing events per interval	Uniform: [1, 4], [1, 8], **[1, 16]**, [1, 32], [1, 64]
Num of available locations	5, 10, **25**, 50, 70
Num of available resources (θ)	10, **20**, 30, 50, 100
Num of required resources per event (ξ_e)	Uniform: $[1, \frac{\theta}{4}]$, $\mathbf{[1, \frac{\theta}{3}]}$, $[1, \frac{\theta}{2}]$, $[1, \frac{3\theta}{4}]$, $[1, \theta]$
Distribution of social activity probability (σ_u^t)	**Uniform**, Normal (0.5, 0.25)
Synthetic Datasets	
Num of users ($\|\mathcal{U}\|$)	10K, **50K**, 100K, 500K, 1M
Distribution of interest ($\mu_{u,e}$)	Uniform, Normal (0.5, 0.25), Zipfian: 1, 2, 3

Parameters. Table 1 summarizes the parameters that we vary and the range of values examined; default values are presented in bold.

Adopting the same setting as in the related works [4, 12, 26–28, 31], we set the the default and maximum value of the of *scheduled events* k, to 100 and 500, respectively. In order to select the values for the number of *competing events per interval*, we analyze the two Meetup datasets used in our evaluation [21]. Particularly, we are interested in the number of events taking place during overlapped time intervals. As event interval we consider the period spanning from one hour before to two hours after the event's scheduled time. From the analysis, we found that, on average, 8.1 events are taking place during overlapping intervals. Therefore, in the default setting the number of competing events per interval is selected by a uniform distribution having 8.1 as mean value. Further, we vary the mean value from 2 to 32 (Table 1). In our experiments, the reported results are similar to the default setting, with the utility score being slightly lower for larger numbers of competing events, as expected (results are omitted due to lack of space).

In order to select the default and the examined values for the *number of available events' locations*, we consider the percentage of pairs of events that are spatio-temporally conflicting, as specified in [26]. Also, we vary the *number of required resources* for each event, as well as the number of *available resources* (Table 1). Here, as resources we consider agents (i.e., organizer's staff). In the aforementioned experiment, the methods are marginally affected by the examined parameters. Thus, due to lack of space, the results are omitted. Finally, regarding the *social activity probability*, we use Uniform and Normal distribution. Note that, the results for Normal distribution are not presented here, since they are the same as in Uniform.

Methods. In our evaluation we study the three proposed algorithms (INC, HOR, HOR-I), as well as the ALG algorithm proposed in [4]. Further, we include the baselines used in [4]. The first, denoted as TOP, computes the assignment scores for all the events and selects the events with top-k score values. Since TOP computes the scores only once, TOP is always performing the minimum number of computations. The second, RAND assigns events to intervals, randomly. Note that, since the objective, the solution and the setting of our problem are substantially different (see Sect. 1) from the related works [6, 12, 26–29, 31], the existing methods cannot be used to solve the SES problem.

Metrics & Implementation. In each experiment, we measure: (1) the *total utility score*; (2) the *execution time*; and (3) the *number of computations* for assignment scores ($|\mathcal{U}|$ per assignment score). All algorithms were written in C++ and the experiments were performed on an 2.67GHz Intel Xeon E5640 with 32GB of RAM.

4.2 Results

Recall that, the HOR and HOR-I algorithms return the same solutions (i.e., equal utilities); the same also holds for the ALG and INC algorithms. Hence, only the former utility plots are presented. Further, in cases where $k < |\mathcal{T}|$, the HOR-I algorithm is identical to HOR (Sect. 3.4); thus, in these cases only the HOR results are included in the plots.

4.2.1 Effect of the Number of Scheduled Events

In the first experiment, we study the effect of varying the number of scheduled events k.

Utility. In terms of utility (Fig. 5a–5d), we observe that, in all cases, our HOR method has the same utility score as the ALG (details are presented in Sect. 4.2.8). Further, the difference between RAND and the other methods increases, as k increases. This is reasonable considering the fact that the larger the k, the larger the number of "better", compared to random, selected assignments.

Regarding the Unf dataset (Fig. 5c), we observe the following. First, the difference between the random and the other methods is the smallest one, compared to the other datasets. Second, the difference between the methods is roughly the same for all k values. The reason for the aforementioned is that the uniform distribution results to utility values being very close, for all assignments. Thus, an effective assignment selection cannot significantly improve the overall utility.

Finally, we can observe that TOP reports considerably low utility scores in all cases (which is also observed in the following experiments). The reason is that TOP assigns the events to a small number of intervals. This results to a large number of parallel events which "share" assigned interval's utility.

Computations. Regarding the number of computations (Fig. 5e–5h), we should mention that, the computations that are performed due to updates increases with k, while the number of initially computed scores is the same for all k. Thus, the difference between the ALG and our methods increases with k. Overall, we can observe that, in all cases, ALG reports the larger number of computations, while HOR-I the lower (excluding the TOP baseline).

Regarding our methods, comparing HOR with HOR-I, we can observe that the difference between our HOR versions increases with k, with HOR-I performing noticeably less computations compared to HOR for large k. An exception is reported in Unf dataset (Fig. 5g), in which all bound-based methods (INC, HOR-I) report poor performance (as explained later).

Further, comparing the HOR with INC, for $k < 200$, HOR performs less computations than INC. However, in the remaining cases where $k \geq 200$, INC outperforms HOR (with an exception in Unf). The reason why INC performs better than HOR for $k \geq 200$ is that, in these cases HOR performs update computations; while, for the cases where $k \leq |\mathcal{T}|$ only the initial computations are performed.

In the Unf dataset (Fig. 5g), we can observe that the bound-based methods (i.e., INC, HOR-I) demonstrate poor performance, with HOR-I performing same as HOR, and INC performing worse than both of them. The reason lies to the uniform distribution, where, as previously stated, the scores are very close for all assignments. As

(f) Time (Concerts)

(g) Time (Unf)

(h) Time (Zip)

Figure 6: Varying the number of time intervals $|\mathcal{T}|$

a result, the values of the bounds are larger than a small number of assignments' scores. Hence, a small number of score updates can be avoided by exploiting bounds.

Time. In terms of execution time (Fig. 5i–5l), we can observe that time is determined by the number of computations performed. HOR-I outperforms the other methods in all cases with HOR-I being around 4 times faster than ALG (for large k in real datasets).

4.2.2 Effect of the Number of Time Intervals

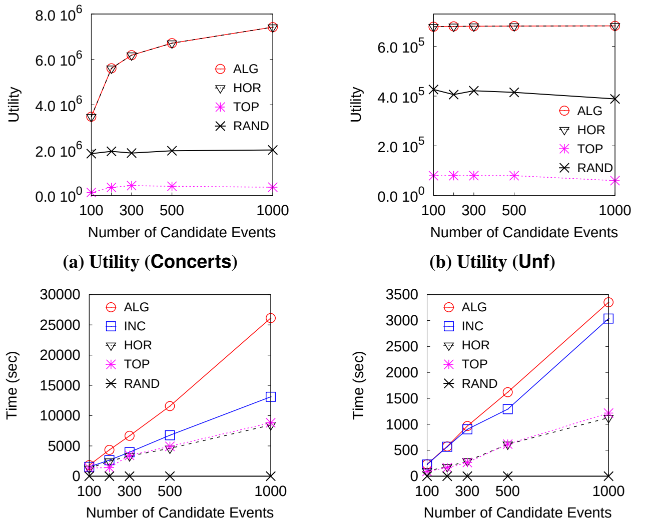
In this experiment (Fig. 6), we vary the number of time intervals $|\mathcal{T}|$. Due to lack of space, for this and the following experiments, the plots presenting the number of computations are omitted.

Utility. Regarding utility (Fig. 6a –6d), similarly to the previous experiment, our HOR algorithm performs the same as the ALG. We observe that, as the number of intervals increases, the utility of all methods increases too. This happens since the increase of available intervals results to a smaller number of events assigned in the same interval, as well as to a larger number of candidate assignments. The former results to the assignment scores (in general) being larger in cases where fewer parallel events take place. The latter offers more options, which possibly result to better assignments.

Time. As for execution time (Fig. 6e–6h), excluding TOP, the HOR-I is the most efficient in the cases which differs from HOR (i.e., $|\mathcal{T}| < 100$); while in the rest cases, HOR is the most efficient. Notice that, in general, HOR performs very close to TOP. Overall, HOR and HOR-I are about 2 to 4 times faster than the ALG, and around 5 times faster for a small number of intervals. Finally, as explained in the previous experiment, we can observe that, also in this experiment, the bound-based methods (i.e., INC, HOR-I) are less effective in Unf.

4.2.3 Effect of the Number of Candidate Events

We next study the effect of varying the number of candidate events $|\mathcal{E}|$. Note that, in this experiment, since $k < |\mathcal{T}|$, HOR-I is identical to HOR. Due to lack of space, in this experiment, the plots for the Meetup and Zip are not presented, since they are similar to Concerts.



(a) Utility (Concerts)

(b) Utility (Unf)

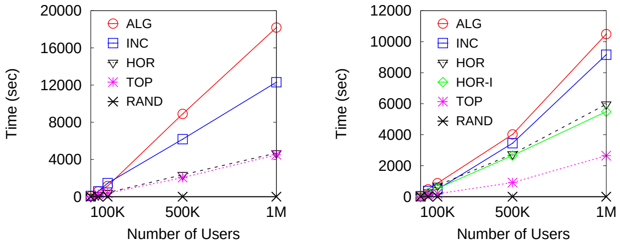
(c) Time (Concerts)

(d) Time (Unf)

Figure 7: Varying the number of candidate events $|\mathcal{E}|$

Utility. Also in this experiment (Fig. 7a–7b) our HOR method has the same utility score as the ALG in all cases. We observe that the utility of ALG and HOR increases with $|\mathcal{E}|$ (with an exception in Unf). On the other hand, for RAND it is either stable or is decreasing. This happens since the increase of $|\mathcal{E}|$ results to more candidate assignments. So, there are more options for the ALG and HOR methods, while for RAND it is less possible to select "good" assignments. Notice that, in the Unf case (Fig. 7b), the utility for the non-random methods remains stable. The reason is that increasing the number of "similar" events (as previously explained) cannot result to better assignments.

Time. Also in this experiment (Fig. 7c–7d), our HOR method outperforms the other, with INC having noticeably bad performance in Unf, compared to HOR (as in the previous experiments). Further, the difference between ALG and our methods increases with $|\mathcal{E}|$, due to the increasing number of update computations. Overall, in general HOR is around 3 to 4 times faster than ALG, and up to 5 times faster in Zip dataset specifically.



(a) Time ($|\mathcal{T}| = 150$) **(b) Time ($|\mathcal{T}| = 65$)**

Figure 8: Varying the number of users $|\mathcal{U}|$ (Unf Dataset)

4.2.4 Effect of the Number of Users

We then study the effect of varying the number of users (Fig. 8). Results for the Zip dataset are omitted since they are similar to the ones reported for Unf. Here, the HOR-I algorithm cannot be defined with the default parameters setting ($k = 100, \mathcal{T} = 150$). Hence, in order to also study HOR-I, we examine a supplementary experiment (Fig. 8b), where $\mathcal{T} = 65$. Note that, this setting ($k = 100, \mathcal{T} = 65$) corresponds to the average case for the HOR and HOR-I algorithms (w.r.t. the relation between k and $|\mathcal{T}|$; see Sect. 3.3.1 & 3.4.1).

In terms of utility (the plot is omitted due to lack of space), as expected, the utility increases with the number of users. The HOR and ALG methods have the same utility scores in all cases. Regarding performance, in the first experiment (Fig. 8a), HOR performs increasingly better than INC and ALG, as the number of users increases. In the second experiment (Fig. 8b), for larger numbers of users (i.e., $|\mathcal{U}| > 100$K), INC performs close to ALG. On the other hand, HOR and HOR-I outperforms INC, with the difference increases with $|\mathcal{U}|$. Overall, in the first experiment, HOR is around 3 to 4 times faster than ALG; in the second one, HOR and HOR-I are around 2 times faster than ALG.

4.2.5 Effect of the Number of Available Locations

In this experiment we vary the number of available locations of each candidate event (Fig. 9). The results correspond to the Unf dataset; though, similar results are reported in all datasets. We can observe, that the utility score (Fig. 9a) remains almost unaffected for the ALG and HOR methods, while TOP and RAND perform slightly better in 5 locations. This is expected, since, as the number of locations decreases, the number of feasible assignments decreases too. Regarding the execution time (Fig. 9b), in all methods, increases with number of locations. This is due to the fact that the number of feasible assignments (as well as the computations) increases too.

4.2.6 HOR & HOR-I Worst Case w.r.t. k and $|\mathcal{T}|$

Here, we consider the setting that corresponds to the worst case w.r.t. k and $|\mathcal{T}|$ for the HOR and HOR-I algorithms (Sect. 3.3.1 & 3.4.1). Thus, for $k = 100$, the worst case corresponds to $|\mathcal{T}| = 99$. Fig. 10a presents the execution time for all datasets. We can observe that even in the worst case, HOR-I outperforms all methods in all cases (excluding the TOP). Also, in synthetic datasets, where the INC demonstrates poor performance, HOR is more efficient.

4.2.7 Search Space

In this experiment (Fig. 10b) we study the effectiveness of the proposed assignment organization (Sect. 3.2.2). We measure the number of assignments examined by the ALG and our INC algorithm, varying the main parameters (k, $|\mathcal{T}|$, $|\mathcal{E}|$). In all cases, INC accesses noticeable less assignments. Also, in each parameter, the differences between INC and ALG increases in large parameter values. Overall, in most cases, INC examines slightly more than half assignments that ALG accesses.

(a) HOR & HOR-I worst case **(b) ALG & INC search space**

Figure 10: HOR/-I worst case and ALG/INC search space

4.2.8 Summary

In what follows, we summarize our findings: (1) *Between the datasets used*, with the exception of Unf, all the methods report similar results. In the Unf dataset, the bound-based methods (INC & HOR-I) demonstrate lower performance than in other datasets.

(2) *Regarding utility score*, in all cases, our HOR (and HOR-I) algorithm achieves almost the same utility score as ALG. Particularly, in more than 70% of the performed experiments (including the experiments omitted from the manuscript), HOR and ALG report the same utility scores, while in the rest of the cases, the difference in utility is on average 0.008%; with the largest difference being 1.3%. Recall that, the INC algorithm always return the same solution as ALG.

(3) *Comparing* ALG [4] *with our methods*, in several cases: (*i*) our HOR and HOR-I methods are around 5× faster and perform less than half of the computations. (*ii*) INC is more than 3× faster, performs less than half of the computations.

(4) *Comparing our methods*: (*i*) HOR-I is always faster than the other methods. In several cases, HOR-I is around 3 and 2 times faster than INC and HOR, respectively. (*ii*) HOR outperforms INC in terms of time and computations, with some exceptions, in cases where $k > |\mathcal{T}|$. Overall, in several cases, HOR is around 3× faster than INC.

5 RELATED WORK

Event Management & Mining. The SES problem studied in this work was recently introduced in [4], where a simple greedy algorithm was proposed. Compared to [4], here we show that SES is hard to be approximated over a factor and we design three efficient and scalable algorithms which perform on average half the computations compared the method presented in [4] and, in most cases, are 3 to 5 times faster (more details in Sect. 1).

Recently, a number of studies have been proposed in the context of event-participant planing. These works examine the problem of finding assignments between a set of users and a set of pre-scheduled events. The determined assignments aim to maximize the satisfaction of the users while satisfying several constraints. Particularly, [12] assigns one event to each user, based on her interests and social relations. [27] finds an user-event arrangement by assigning users to events. The latter work is extended in [28], where the online setting of the problem is examined. A similar user-event arrangement problem is defined in a more advanced setting [26], where more factors are considered (e.g., complex spatio-temporal factors, travel cost). This work is extended in [6], in which participation lower bounds on event and potential changes induced either by event organizer or by users (e.g., changes on event location) are considered. In the same context, [31] tries to maximize the satisfaction of the least satisfied user. In an online scenario, [29] exploits the user feedback (i.e., accept or reject the assigned events) in order to adaptively learn user interests. This work tries to maximize the number of accepted assigned events. Compared to our work, as discussed in Sect. 1, the objective, the solution and the setting of our problem substantially differ from the aforementioned approaches.

In a different context, [8, 9] attempt to find influential event organizers and promoters from online social networks. [25] studies the influence of early respondents in online event scheduling process. Further, a number of works [5, 7, 36, 41] analyze several factors form (Event-based) Social Networks data in order to study user attendance and provide event recommendations. Our work studies a different problem compared to the aforementioned approaches. However, some of the aforementioned methods can be exploited in our problem to estimate the user attendance probability.

Assignment & Matching Problems. The problem studied shares common characteristics with the Generalized assignment (GAP) and Multiple knapsack (MKP) problems. Particularly, our problem is a generalized case of the GAP and MKP problems with identical bin capacities [18]. A major difference of SES compared to GAP and MKP is that in SES the expected attendance (resp. profit) of assigning an event (resp. item) to an interval (resp. bin) is determined based on the other events assigned to this interval. Also, beyond the event and interval entities which are also considered in the aforementioned problems, in our problem further core entities are involved (e.g., users, organizer, competing events). Additionally, assignment/matching problems (similar to bipartite matching) have been studied in spatial context [16, 30, 32, 35]. In general, the main differences of these works compared to SES, are the same as the ones that hold in GAP and MKP problems (see above).

Recommender Systems. Numerous approaches have been proposed in the context of location and event recommendations. Particularly, several works recommend events to users [13, 19, 21, 37, 40], while others offer location-based recommendations [2, 11, 14, 15, 34, 38, 39]. Further, in a more general setting, approaches have been proposed for recommending locations or items to groups of people (i.e., group recommendations) [1, 3, 20, 22–24, 33]. Compared to our work, the aforementioned approaches study a different problem, that is, recommending objects (e.g., venues, events) to users.

6 CONCLUSIONS

This paper studied the *Social Event Scheduling* (SES) problem, which assigns a set of events to time intervals, so that the number of attendees is maximized. We showed that SES is NP-hard to be approximated over a factor, and we proposed three efficient and scalable algorithms. The proposed algorithms are evaluated over several real and synthetic datasets, outperforming the existing solution three to five times in several of cases.

ABSTRACT

We present GroupTravel, a framework that generates customized travel packages (TPs) for a group of individuals. GroupTravel implements different consensus functions proposed in group recommendation to reach agreement among members. Given a group whose members provide a travel query, GroupTravel returns k Composite Items (CIs) of Points Of Interest (POIs) that are *valid*, *representative*, *cohesive* and *personalized*. Validity is achieved by satisfying the query expressed by the group. Representativity ensures good coverage of a city. Cohesiveness reflects geographic proximity of POIs forming a CI. Personalization is achieved by choosing POIs that best match the travel preferences of group members. Additionally, group members can interact with generated TPs to customize them. With extensive synthetic experiments and user studies, we examine the benefit of personalization and the impact of different group consensus on user satisfaction. We also show that providing the ability to interact with TPs and reflecting that in the consensus yields better TPs.

1 INTRODUCTION

The ability to generate a travel package (TP) that best fits a traveler's profile is a longstanding problem that has been studied for years (e.g., [1–3]). In this work, we develop GroupTravel, a framework that generates TPs for a group of individuals traveling together. A TP is a set of k Composite Items (CIs), each of which is formed by Points of Interest (POIs) in a city. GroupTravel personalizes TPs based on a group profile that is computed as an aggregation of its members' preferences. GroupTravel allows travelers in a group to further customize the proposed TP via interaction. GroupTravel extends recent work that focused on a single traveler at a time [4] to reach consensus between multiple travelers [5, 6].

Travel Packages as Composite Items. A TP is a set of k CIs. CIs are useful in planning a city tour, selecting books for a reading club, or organizing a movie rating contest [1, 7–15]. Each CI satisfies a query that specifies desired POI categories and a budget constraint [13]. An objective function is defined to build a TP containing k *valid*, *representative*, *cohesive*, and *personalized* CIs. Validity ensures that each CI satisfies the query. Representativity enforces that the k CIs "cover" the city. Cohesiveness forms CIs containing geographically close POIs. Finally, personalization ensures that the CIs contain POIs that match the members' travel preferences. We use a fuzzy clustering algorithm to find the best k CIs forming a TP.

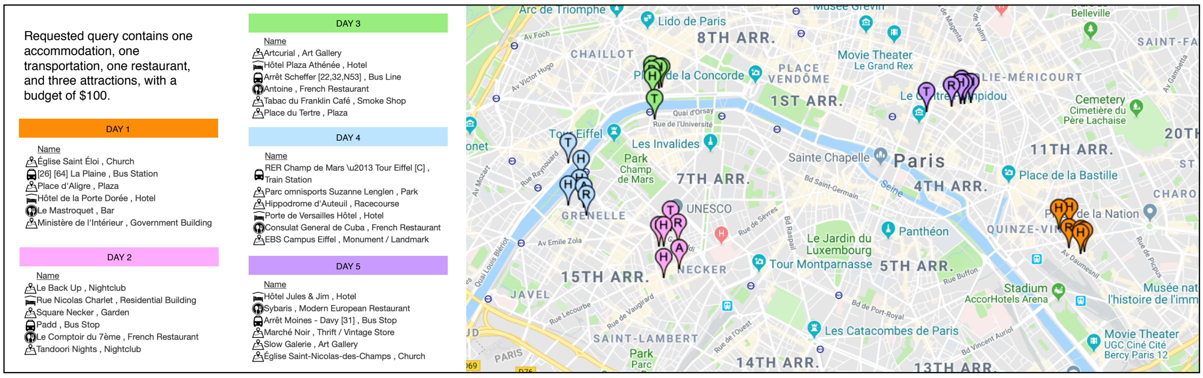
For example, a group wishing to visit Paris may request a TP consisting of five CIs, one per day. The group specifies a query which dictates CI validity: each CI must contain an accommodation, a restaurant, three attractions and one transportation mode, and such that the overall cost of visiting POIs in a CI is no more than $100. Figure 1 shows the TP returned by GroupTravel. Each CI contains a set of co-located POIs that can be visited in one day. In addition, the TP formed by the set of 5 CIs, provides a good coverage of Paris and the POIs in each CI match the group members' travel preferences.

In this paper, we make three contributions. We formalize the problem of building a TP for a group of travelers. We define how group members can interact with the generated TP to further customize it. We run synthetic experiments and user studies to validate GroupTravel's effectiveness in generating a satisfying TP for groups.

First contribution: TPs for groups. GroupTravel takes as input a query and individual travel profiles. It outputs a *personalized* TP for the group. The preference of a group for an item must *reflect the degree to which the item is preferred by all group members*. The group preference must also *capture the level at which members disagree or agree with each other*. All other conditions being equal, an item that draws high agreement should have a higher score than an item with a lower overall group agreement. The different ways of aggregating *group preference* and *group disagreement* result in different *group consensus methods* ranging from *average preference*, to *least misery* and *disagreement-based* methods [16–18]. We leverage those definitions to generate a group travel profile from individual preferences.

Second contribution: interactive TPs. In [4], we examined the benefits of letting a user interact with a TP to customize it. The rationale is that even though the k CIs are valid, representative, cohesive, and personalized, a user may still want to intervene after seeing the travel options available in a city. We showed that providing interaction primitives to the user enabled expressing additional contextual preferences such as exploring some neighborhoods in a city or requesting a new CI which contains a specific POI. In this paper, we examine the benefit of interactivity in GroupTravel, i.e., for a group of individuals traveling together. To achieve that, we define the impact of each operation on a TP and on the profile of a group.

Figure 2 illustrates the flow of GroupTravel. Given a group of travelers and a consensus function, a group profile is generated from individual profiles. Our fuzzy clustering algorithm admits a geographic region (e.g., a city), a query and the group profile. It generates a TP that is shown to the travelers who can modify CIs, delete CIs, or generate new CIs. This interaction is reflected in the group's profile by updating the overall group preferences according to the



Requested query contains one accommodation, one transportation, one restaurant, and three attractions, with a budget of $100.

requested changes. The new group profile can then be used to generate other TPs in the same or in a different city and test the "robustness" of the updated profile across cities.

Third contribution: experiments. The purpose of our experiments is two-fold: (1) study the utility of consensus functions from group recommendation in the context of GroupTravel, and (2) examine the benefit of interactive customization for groups. We run two extensive sets of experiments. In the first, we generate synthetic data to examine the relationship between group characteristics (group size, agreement between members, and consensus methods) and optimization dimensions (representativity, cohesiveness, and personalization). In the second, we run an extensive user study with real users from Figure-Eight[1] and Amazon Mechanical Turk[2]. Our study evaluates the usefulness of GroupTravel by asking actual users about their satisfaction with TPs before and after customization.

Our findings extend previous work for single travelers [4] and in group recommendation [5, 6]. In particular, we find that customization makes travel profiles more robust. Additionally, we find that disagreement-based consensus performs best in terms of all optimization dimensions, and for all different group variants (uniform and non-uniform as well as small, medium and large). Least misery, on the other hand, is more successful at satisfying the median user in larger groups with diverse tastes.

We also observe that TPs for non-uniform groups are more cohesive than TPs for uniform groups. This result generalizes previous work where a tension between personalization and cohesiveness was observed for individual users: the more personalized a TP is, the less likely it is to be cohesive, and vice versa [4]. Non-uniform groups contain members with diverse preferences. This diversity dilutes personalization (the aggregated profile expresses lower preferences than individual profiles). Given that, cohesiveness is likely to be higher for non-uniform groups. Similarly, the cohesiveness of uniform groups increases with group size, while their personalization decreases.

Our user study validates our objective function by showing that personalized TPs perform well and are liked better than non-personalized and random TPs. We also find that TPs obtained using average preference and least misery are best for uniform groups, whereas TPs obtained using disagreement-based methods are best for non-uniform groups. Similarly, incorporating inter-member disagreements is shown to be the best way to reach a consensus within diverse groups.

The paper is organized as follows. In Section 2, we describe our data model. Our approach for building group travel packages and interacting with them is described in Section 3. Experiments are reported in Section 4. The related work is reviewed in Section 5. We conclude with a summary of our work and a discussion of future work in Section 6.

Table 1: Sample Points Of Interest in Paris

2 DATA MODEL

2.1 Items

Our travel packages are built using Points Of Interest (POIs) in a city. Table 1 shows sample POIs in Paris. In our experiments, we use the TourPedia dataset.[3] It consists of POIs in eight cities which are divided into four main categories (*cat* for short): (1) accommodation (*acco*), (2) transportation ($trans$), (3) restaurant ($rest$) and (4) attraction ($attr$). Each POI or item i has a unique id, a name, a longitude and a latitude. To be able to set the rest of the attributes for the items in our dataset, we augment it with additional information extracted from Foursquare.[4] Using the Foursquare API, we retrieved the type of each item i. For instance, in the case of an accommodation item i, $i.type$ will be set to either a hotel, a hostel, a motel, a college residence hall, etc. Similarly, for a transportation item i, we set $i.type$ to its transportation mode which can be a tram station, a train station, a car rental, a bike rental, and so on. To set $i.tags$ for an item i, we retrieved all the tags provided by users on Foursquare for item i. Finally, there are may ways of setting the cost of visiting an item i or $i.cost$ including declarative data.

2.2 User Profile

Our goal is to provide a group of users with personalized travel packages. To do that, we build a group travel profile which captures the preferences of group members for different types of POIs. We start by defining a single-user profile and then explain how we aggregate the profiles of different users to generate a group profile.

Each user u is associated with a profile for each POI category c (i.e., *acco*, *trans*, *rest* or *attr*), which is a vector defined as follows:

$$\vec{u} = \langle u_1, \cdots, u_n \rangle$$

where n is the number of different POI types in category c and each $u_j, 1 \leq j \leq n$ is a score between 0 and 1.

To simplify our notation, c does not appear in $\vec{u}$. One way to set the vector $\vec{u}$ is to ask the user to state her preferences for the different types of POIs. In case the POI types are not sufficient to capture all the dimensions of travel preferences for users, we can try to learn these other dimensions from the data. For accommodation and transportation, the types are well-defined (e.g., Bicycle, Bus, Tram for transportation, and Hotel, Hostel, Resort for accommodation). For restaurants and attractions, we leverage their tags to capture information such as cuisine and ambiance for restaurants, or type and entrance fee for attractions. Particularly, we rely on Latent Dirichlet Allocation (LDA) applied to tags to identify latent topics for restaurants and attractions [19]. This results in several types such as "art gallery, museum, library" and "garden, park, event hall" for attractions, and "Japanese, sushi" and "beer, wine, bistro" for restaurants.

To set the individual components of the vector $\vec{u}$, we do the following. For the case of transportation and accommodation, we ask the user to provide a rating r_j between 0 and 5 for each accommodation or transportation type s_j. Similarly, for restaurants and attractions, we ask the user to provide a rating r_j between 0 and 5 for each latent topic s_j where each topic is represented by representative tags. Finally, we set the score u_j in the user profile as the normalized rating over all types or topics, i.e.,

$$u_j = \frac{r_j}{\sum_{k=1}^{n} r_k}$$

2.3 Group Profile

Similar to users, a group of users $\mathcal{G}$ is associated with a group profile for each POI category c (i.e., *acco*, *trans*, *rest* or *attr*), which is a vector defined as follows:

$$\vec{g} = \langle g_1, \cdots, g_n \rangle$$

where n is the number of different POI types in category c, and each $g_j, 1 \leq j \leq n$ is a score between 0 and 1. The value g_j reflects the preference of group $\mathcal{G}$ for a POI type by aggregating the preferences of group members.

To compute each g_j, we need to aggregate the preferences u_j of each user $u \in \mathcal{G}$. To do so, we leverage *consensus functions* that were previously proposed in the context of group recommendation [17, 18]. A consensus function is used to aggregate two components: *group preference* and *group disagreement*. Intuitively, to compute g_j, we need to *reflect the degree to which the j^{th} POI type in a given category is preferred by all group members*, and *capture the level at which members disagree or agree with each other about the j^{th} POI type in a given category.* All other conditions being equal, a POI that draws high agreement should have a higher score than a POI with a lower overall group agreement. We revisit the definitions we introduced in [16] to compute group consensus as a combination of group preference and group disagreement.

Group preference. The degree to which the j^{th} POI type in a given category is preferred by all group members is denoted p_j, and is computed using one of two common preference aggregation functions:

[3] *http://tour-pedia.org/about/*

[4] *https://foursquare.com/*

(1) *Average Preference:* $p_j = \frac{1}{|\mathcal{G}|} \sum_{u \in \mathcal{G}} u_j$

(2) *Least-Misery Preference:* $p_j = \min_{u \in \mathcal{G}} u_j$

Group disagreement. The level at which members disagree or agree with each other about the j^{th} POI type in a given category is denoted d_j, and is computed using one of two common disagreement computation functions:

(1) *Average Pair-wise Disagreement:*
$d_j = \frac{2}{|\mathcal{G}|(|\mathcal{G}|-1)} \sum_{u,v \in \mathcal{G}} (|u_j - v_j|)$,

(2) *Disagreement Variance:*
$d_j = \frac{1}{|\mathcal{G}|} \sum_{u \in \mathcal{G}} (u_j - \mu_j)^2$ where $\mu_j = \frac{1}{|\mathcal{G}|} \sum_{u \in \mathcal{G}} u_j$

The average pair-wise disagreement function computes the average of pair-wise differences in individual preferences for the j^{th} POI type among group members, while the variance disagreement function computes the mathematical variance of individual preferences. Intuitively, the closer the preferences between users u and v, the lower their disagreement.

Group consensus. We are now ready to compute a single group consensus score g_j for the j^{th} POI type in a given category. We do that by combining group preference and disagreement as follows:

$$g_j = w_1 \times p_j + w_2 \times (1 - d_j)$$

where $0 \leq w_1, w_2 \leq 1$, $w_1 + w_2 = 1$, and they specify the relative importance of preference and disagreement in the overall group consensus, respectively. We hence have four possible consensus functions that combine preference and disagreement to compute a single score g_j in the group profile.

Example. Consider a family (a couple with three kids) which forms a travel group $\mathcal{G}$ of size 4. Their preferences for visiting museums are 0.8, 1.0, 0.6, and 0.2, for the father, mother, the teenage child, and the kid, respectively, where 1.0 reflects the highest preference. Using average preference method, the group preference for this POI type is $p = 0.65$. However the group preference towards museums gets as low as 0.2 using the least misery method. Least misery favors the most unhappy user in the group, hence the preference of the kid dominates others'. On the other hand, the average pair-wise disagreement between $\mathcal{G}$'s members is $d = 0.43$. Also, the disagreement variance is $d = 0.088$. Given $w_1 = 0.5$ (hence $w_2 = 0.5$), $\mathcal{G}$'s consensus for museums is $g = 0.61$ by considering average preference and average pair-wise disagreement as the group preference and group disagreement components, respectively.

3 BUILDING GROUP TRAVEL PACKAGES

In this section, we define and solve the problem of building personalized travel packages for groups. We start by introducing Composite Items (CIs) and Travel Packages (TPs), and formulate building travel packages as a fuzzy clustering problem. We then discuss how groups can interact with travel packages to customize them using GroupTravel.

3.1 Composite Items

A Composite Item is a set of POIs of different categories. To be able to define what constitutes a CI, we rely on a group query which is a vector defined as follows:

$$\vec{q} = \langle \#c_1, \cdots, \#c_m, B \rangle$$

where m is the number of POI categories (4 in our dataset), $\#c_j, 1 \leq j \leq m$ specifies the number of items for POI category c_j, and B is a total budget.

A query indicates which categories of POIs, and how many of them, should constitute a CI. For example, the query $\vec{q} = \langle 1\ acco, 1\ trans, 2\ rest, 1\ attr, \$120 \rangle$ represents a CI with 1 accommodation, 1 transportation, 2 restaurants and 1 attraction for a daily budget of $120.

The query is used to define valid CIs as follows. Given a set of items $\mathcal{I}$ and a query $\vec{q} = \langle \#c_1, \cdots, \#c_m, B \rangle$, a valid $CI \subseteq \mathcal{I}$ is a set of items such that (1) their categories correspond to the requested categories in the group query, and (2) the total budget of items forming the CI is at most B, i.e.,

$$\begin{cases} (i)\ \forall j \in \{1, \cdots, m\}, \ \sum_{i \in CI} \mathbb{1}(i.cat, c_j) = \#c_j \\ (ii)\ \sum_{i \in CI} i.cost \leq B \end{cases}$$

where $\mathbb{1}$ is an indicator function which is equal to 1 if the category of item i is c_j and 0 otherwise. We refer to the set of valid CIs as $\mathcal{V}$.

3.2 Travel Packages

We are now ready to define the notion of a group travel package and formulate building travel packages as a fuzzy clustering problem. Given a group $\mathcal{G}$, a set of items $\mathcal{I}$, and a query $\vec{q}$, we define a group travel package as a set of k Composite Items $\mathsf{TP} = \{CI_1, CI_2, \cdots, CI_k\}$ where each $CI_j \subseteq \mathcal{I}$ is a valid Composite Item.

A travel package is formed by *valid* and *cohesive* CIs that are *representative* of the set of available items in the city. The validity of a CI is expressed in terms of a query $\vec{q}$ as defined in Section 3.1. Its cohesiveness must reflect how close the items forming a CI are to each other. The intuition is that each CI represents things to do in a given area of a city and must thus have POIs that are geographically close to each other. Finally, the representativity of a travel package serves the purpose of providing a good coverage of the city [13]. KFC, the algorithm that solves that problem in [13], relies on fuzzy clustering to position k centroids that "cover" the whole dataset. CIs are then formed in the vicinity of these centroids, which ensures that they provide a good summary of the dataset. In the context of this work, we may want to see a given item in different CIs. For example, a user's hotel could belong to multiple CIs. The same applies to a museum if the user wants to go back to the museum (as is the case for the "Louvre museum" in Paris that requires more than one visit). Contrary to *hard* clustering, *fuzzy* clustering allows each data point to participate in multiple clusters [20]. Thus, KFC is a natural choice for us to generate travel packages.

To be able to generate CIs, we define an item vector for each POI i as follows:

$$\vec{i} = \langle i_1, \cdots, i_n \rangle$$

where n is the number of types for the POI category that item i belongs to, and each $i_j, 1 \leq j \leq n$ is a score between 0 and 1. The item vector $\vec{i}$ is set based on the category of the item i. For accommodation and transportation items (i.e., $i.cat = acco$ or $i.cat = trans$), we set i_j as follows:

$$i_j = \begin{cases} 1, & \text{if } i.type = t_j \\ 0, & \text{otherwise} \end{cases}$$

where t_j is the j^{th} type in the category that item i belongs to. For restaurants and attractions, the item vector $\vec{i}$ is set to the topic distribution vector for item i obtained from applying LDA.

To generate a personalized travel package TP for a group $\mathcal{G}$, we optimize the following objective function:

$$\begin{aligned} &\underset{M,W}{argmax}\ \alpha \sum_{j=1}^{k} \sum_{i \in \mathcal{I}} w_{ij}^{f}\ (1 - Euclidean(i, \mu_j)) + \\ &\sum_{j=1}^{k} \max_{CI_j \in \mathcal{V}} \Bigg(\beta \sum_{i \in CI_j} (1 - Euclidean(i, \mu_j)) + \\ &\qquad\qquad \gamma \sum_{i \in CI_j} Cosine(\vec{i}, \vec{g}) \Bigg) \\ &s.t.\ \forall i \in \mathcal{I},\ \sum_{j=1}^{k} w_{ij} = 1 \end{aligned} \tag{1}$$

In Equation 1, we use a normalized geographic Euclidean distance between two items, and Cosine similarity between an item vector and the group profile vector for the category the item belongs to. Euclidean distance is an an approximation of Haversine calculations on a spherical space (to measure the distance in miles/kilometers between two latitudes and longitudes) with Equirectangular calculations on a Euclidean space to gain performance. This approximation makes sense for short distances within a city as we have experimentally observed that our performance gain is 30x with only 0.1% of precision loss. To obtain a normalized Euclidean distance, we divide all distance values by the largest observed distance value. $M = \{\mu_1, \mu_2, \cdots, \mu_k\}$ is a set of k centroids, W is a weight matrix of size $|\mathcal{I}| \times k$ which contains the w_{ij} weights indicating which item belongs to which cluster. α and β are user-dependent parameters controlling the weight of the optimization objectives, and $f \leq 1$ is the weighting exponent used in fuzzy clustering.

The two components of the objective function are inherited from KFC [13] and capture cohesiveness and representativity by choosing items i that are close to the centroid μ_j of each of the k clusters, where closeness is based on the geographic distance. Those components serve to identify cluster centroids μ_j that are representative of the complete dataset, while ensuring that the centroids obtained are close to some valid CI (i.e., $\in \mathcal{V}$). Maximizing the sum of the similarities of all items in a CI to its centroid additionally ensures the cohesiveness of the valid CI considered.

The last component, weighted with γ, captures personalization by comparing the similarity of the group's profile vector $\vec{g}$ to the item vector $\vec{i}$. This allows the algorithm to focus on producing CIs that are valid, cohesive and that contain personalized items that matter to the group, rather than any items.

3.3 Customizing Travel Packages

In order to customize travel packages, we provide group members with a GUI where all the CIs forming a travel package are displayed on an interactive map of the city. We define five atomic operations to allow groups to refine their preferences and produce customized TPs. Our operations are:

1. REMOVE(i,CI): remove POI i from Composite Item CI.
2. ADD(i,CI): add POI i to a Composite Item CI. The user can filter the POIs by category and type and the closest items to CI satisfying the user filter are displayed for the user to choose from.
3. REPLACE(i,CI): replace POI i in CI with another POI. In that case, the system recommends to the user the closest POI j in terms of geographic distance and such that $i.cat = j.cat$.
4. GENERATE(RECTANGL$E(x, y, w, h)$): generate a new CI that is centered in the area enclosed by a rectangle whose upper-left point is (x, y), and with width w and height h. The generated CI is both *valid* and *cohesive*.

Using the above set of operations, group members can customize the generated travel package until they are satisfied with it. For example, a member can drop or add a set of POIs in a given CI. She can also replace POIs with others that the system recommends to ensure that the CI remains as cohesive as possible. Finally, a group member can completely delete a CI by iteratively removing items in that CI until it is empty. Similarly, a group member can generate a new CI by selecting an area in the map. The group interactions with the CIs provide us with additional information about the group travel preferences. Particularly, they are useful in refining the group travel profile.

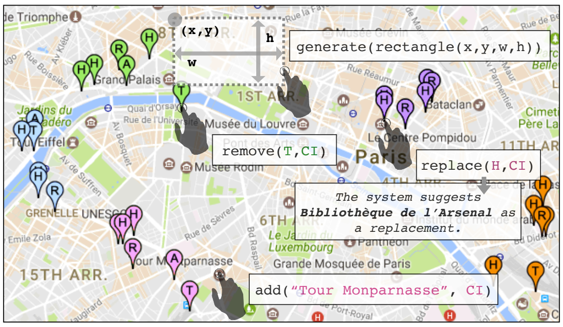

Figure 3: Customization operators

Figure 3 illustrates examples of customization operators in Paris. For instance, a REMOVE operator is requested to discard a bus stop in the area of "Invalides". It is also requested to ADD "Monparnasse tower" to the travel package as an attraction. In response to a REPLACE operator, the system suggests "Arsenal library" to replace "Pompidou library". Also a GENERATE operation is requested by defining an area from "L'église de la Madeleine" to "Palais Royal", where a potential attraction POI is "Place Vendôme".

Refining the group profile. The interactions of group members with the provided CIs serve as implicit feedback that can be used to update the group's travel profile. This refinement serves two purposes: *(1) make the group profile robust so that fewer interactions will be needed in the future including in other cities, (2) build long-lasting profiles for non-ephemeral groups.* We define two strategies for updating the group profile: individual and batch strategies. The *individual strategy* was defined for single travelers [4]. It first refines each group member profile based on that member's interactions with the TP, if that member customized the TP. It then aggregates all individual profiles into a new group profile. The *batch strategy* gathers interactions performed by all group members and directly refines the group profile. We describe the batch strategy that is a direct adaptation of the individual strategy.

Let $\vec{g}$ be the current group profile for POI category c. Furthermore, assume a group member added a set of POIs I^+ that belong to category c. Also, assume a group member removed a set of POIs I^- that belong to category c. Now the group vector $\vec{g}$ for category c can be updated as follows:

$$\vec{g} = \vec{g} + \vec{g}^+ - \vec{g}^-$$

where

$$\vec{g}^+ = \frac{1}{|I^+|} \sum_{i \in I^+} \vec{i}$$

and $\vec{i}$ is the item vector of item i as defined in Section 3.2.

The value $\vec{g}^-$ will be set the exact same way as $\vec{g}^+$ by replacing I^+ with I^- above. Finally, if any of the components of the updated vector $\vec{g}$ falls below 0, the value of this component will be set to 0.

4 EXPERIMENTS

We provide two sets of experiments. First, we generate synthetic data to examine the relationship between group characteristics (group size, uniformity, and consensus methods) and optimization dimensions (representativity, cohesiveness, and personalization). As we do not recruit real participants in this experiment, we focus on dissecting the objective function of GroupTravel. In the second experiment, we describe our user study which evaluates the usefulness of GroupTravel by asking group members about their satisfaction with the generated travel packages, before and after customization.

4.1 Setup

Group composition. We build groups by aggregating profiles of individual users. In our synthetic experiment, user profiles are generated at random. In our user study, user profiles capture the travel preferences of the participants.

We form different groups by varying their *size* (the number of users in a group) and *uniformity*. Intuitively, a group is more uniform if its members have similar preferences with respect to POI types. The uniformity of a group $\mathcal{G}$ is a value between 0 and 1 and is computed as the average pairwise Cosine similarity between profile vectors of all $\mathcal{G}$'s members, i.e.,

$$uniformity(\mathcal{G}) = \frac{2}{|\mathcal{G}||\mathcal{G}-1|} \sum_{u,v \in \mathcal{G}} Cosine(\vec{u}, \vec{v})$$

We consider three categories of group sizes, i.e., *small* groups having 5 members, *medium* groups having 10 members, and *large* groups having 100 members. We also consider two categories of group uniformity, i.e., *uniform* groups having a uniformity value larger then 0.85, and *non-uniform* groups having a uniformity value smaller than 0.20.

Group consensus. Recall from Section 2.3 that for a group $\mathcal{G}$, we aggregate the individual user profiles to generate a group profile by applying a group consensus as follows:

$$g_j = w_1 \times p_j + w_2 \times (1 - d_j)$$

where p_j represents a group preference for POI type j and d_j represents group disagreement for POI type j. We employ the following variants of group consensus in our experiments:

- *Average preference*, where p_j is *average preference* and $w_1 = 1.0$ (i.e., group disagreement is not considered).
- *Least misery*, where p_j is *least misery* and $w_1 = 1.0$ (i.e., again group disagreement is not considered).
- *Average preference with average disagreement*, where p_j is *average preference*, d_j is *average pair-wise disagreement* and $w_1 = 0.5$. Hereinafter, we call this method "pair-wise disagreement" for simplicity.
- *Average preference with disagreement variance*, where p_j is *average preference*, d_j is *disagreement variance* and $w_1 = 0.5$. Hereinafter, we call this method "disagreement variance" for simplicity.

4.2 Optimization dimensions

Once a TP is computed for a group, we measure each component of our optimization objective, representativity, cohesiveness and personalization (Section 3.2).

Representativity measures the collective coverage of POIs in a TP over a region of interest, e.g., a city. The farther CIs in a TP are from each other, the higher the TP's representativity. Representativity is measured as follows:

$$representativity(\mathsf{TP}) = \sum_{l=1}^{k} \sum_{j=l}^{k} Euclidean(\mu_l, \mu_j) \qquad (2)$$

where μ_l is the centroid of the composite item C_l, and $Euclidean(\mu_l, \mu_j)$ measures the Euclidean distance between the centroids μ_l and μ_j. Recall from Section 3.2 that the Euclidean distance is an an approximation of Haversine calculations.

Cohesiveness measures the geographical compactness of CIs in a TP, i.e., how close the POIs in a CI are to each other. It is measured as follows:

$$cohesiveness(\mathsf{TP}) = \mathcal{S} - \left(\sum_{CI \in \mathsf{TP}} \sum_{i,j \in CI} Euclidean(i, j) \right) \qquad (3)$$

where $Euclidean(i, j)$ measures the Euclidean distance between the geographical coordinates of POIs i and j. The constant $\mathcal{S}$ defines the maximum possible sum of distances over CIs in a TP. In our synthetic experiment, we set $\mathcal{S} = 221.79$ as the largest observed value for aggregated distances.

While representativity and cohesiveness evaluate TPs in a geographical domain, personalization evaluates them in terms of preferences (using the profile vector $\vec{g}$ for the group $\mathcal{G}$). Personalization is measured as follows:

$$personalization(\mathsf{TP}, \mathcal{G}) = \sum_{CI \in \mathsf{TP}} \sum_{i \in CI} Cosine(\vec{i}, \vec{g}) \qquad (4)$$

		average preference			**least misery**			**pair-wise disagreement**			**disagreement variance**		
		R	C	P	R	C	P	R	C	P	R	C	P
uniform groups	**small**	100%	69%	95%	38%	0%	74%	100%	74%	99%	99%	79%	100%
	medium	94%	70%	94%	75%	57%	73%	95%	77%	98%	96%	80%	98%
	large	85%	73%	72%	76%	76%	68%	96%	87%	97%	97%	84%	96%

Table 2: Synthetic experiment for travel groups. Optimization dimensions are abbreviated as R for representativity, C for cohesiveness, and P for personalization.

4.3 Synthetic Data Experiment

Our goal in the synthetic data experiment is to examine the relationship between group characteristics and our optimization dimensions. Preferences of real people will be verified later in the user study (Section 4.4). Groups are characterized by their *uniformity*, i.e., similarity between members, *size*, and the *consensus function* used to aggregate individual preferences.

4.3.1 Setup. We describe how we generate user and group profiles and other settings in the synthetic experiments.

Group profiles. We generate user profiles in an independent roll-and-dice process. Each profile is a vector whose cells contain preference values for different types of POIs. We assign a random value between 0 and 1 to each cell in the user profile vector. A group $\mathcal{G}$ is a matrix of $|\mathcal{G}|$ user profiles, where $|\mathcal{G}| \in \{5, 10, 100\}$. For each combination of group size and group uniformity (uniform and non-uniform), we generated 100 different random groups. For each generated group, we computed a group profile using the four different consensus methods. As a result, we obtained 2400 distinct group profiles in total.

Query and objective function. We generate a TP for each group profile. Each TP contains exactly 5 CIs that are valid with respect to a default query, i.e., $\langle 1$ *acco*, 1 *trans*, 1 *rest*, 3 *attr*$\rangle$. Also, we specify *an infinite budget* to ensure that all popular POIs are included in the CIs. Regarding the weights in our objective function (Equation 1), we always set $\gamma = 1.0$ for personalization, and we assign random values to α and β in the range $[0, 1]$ for representativity and cohesiveness, respectively, in order to prevent bias towards an optimization objective.

Optimization dimensions. For the TPs generated for group profiles, we report representativity, cohesiveness, and personalization as defined in Equations 2, 3, and 4, respectively. The values obtained for all dimensions are normalized in the range $[0, 1]$ in min-max style:

$$normalized\_value(o) = \frac{value(o) - min(o)}{max(o) - min(o)}$$

where $min(o)$ and $max(o)$ are the smallest and highest values of an optimization dimension o, respectively. Before normalization, the values of representativity, cohesiveness, and personalization were spread in the ranges $[0.03, 41.39]$, $[19.29, 221.79]$, and $[0.01, 0.16]$, respectively.

Validation of observations. We validate all our observations on optimization dimensions in terms of statistical significance using the One-way ANOVA procedure, with the $\mathcal{F}$-measure of MSB/MSE[5] and the significance level of $p = 0.05$. ANOVA results are reported as $\mathcal{F}(n, k) = x$ given $p < 0.05$, where n and k are the first and second degrees of freedom, respectively, and x is the value obtained for the $\mathcal{F}$-measure. Fully-independent generation of user and group profiles ensures that the $\mathcal{F}$-measure captures truly significant results.

We also compute the Pearson correlation coefficient (PCC) to validate linear correlations between attributes. PCC has a value between $+1$ and -1, where $+1$ reflects a totally positive linear correlation, 0 means no linear correlation, and -1 represents a totally negative linear correlation.

4.3.2 Summary of results. Table 2 reports the values of the optimization dimensions averaged over 100 generated groups. Overall, we observe that disagreement-based consensus functions, whether pair-wise or variance, perform best in terms of all optimization dimensions, and for all different group variants. Least misery appears to be the worst aggregation method. We also observe that TPs for non-uniform groups are more cohesive than uniform groups. However, the cohesiveness of uniform groups increases with group size, while their personalization decreases. We also note that there is a tension between personalization and cohesiveness where more personalized TPs are less likely to be cohesive.

Additionally, we report the similarity between the TP of a group and its median user (Table 3). Overall, we observe that the similarity decreases in larger groups. For non-uniform groups, the best similarity values are achieved using least misery, while for uniform groups, disagreement-based methods are superior.

4.3.3 Interpretation of results. We discuss the influence of consensus functions, group uniformity, and group size, on the optimization dimensions and the agreement between individuals and groups.

Influence of consensus functions. We observe in Table 2 that TPs are generally more personalized when their associated group profile is built using a disagreement-based consensus (variance disagreement and pair-wise disagreement). Least misery is the worst consensus method for personalization. This shows that optimizing towards one single group member is not an effective personalization strategy. Incorporating inter-member disagreements is therefore the

[5] *MSB: Mean Square Between, MSE: Mean Square Error*

		average preference			least misery			pair-wise disagreement			disagreement variance		
		R	C	P	R	C	P	R	C	P	R	C	P
uniform groups	**small**	99%	31%	93%	38%	98%	75%	98%	26%	99%	98%	20%	99%
	medium	86%	55%	85%	93%	66%	75%	87%	47%	99%	98%	45%	99%
	large	99%	71%	94%	98%	68%	71%	98%	57%	99%	97%	61%	99%
non-uniform groups	**small**	15%	73%	59%	83%	76%	64%	13%	74%	38%	14%	72%	37%
	medium	21%	67%	28%	83%	81%	88%	21%	59%	14%	21%	63%	14%
	large	5%	26%	2%	48%	44%	54%	2%	22%	1%	2%	23%	5%

Table 3: Agreement between median users and groups, where the value 100% represents the highest degree of agreement. The symbol R stands for representativity, C for cohesiveness, and P for personalization.

best way to obtain POIs that satisfy everyone in a group, regardless of group uniformity. We also observe that average preference and disagreement-based methods result in similar representativity values, validating that fuzzy clustering achieves good representativity overall by strategically placing centroids on a map.

Influence of group uniformity. We observe in Table 2 that TPs for non-uniform groups are always more cohesive than TPs for uniform groups. This result generalizes previous work where a tension between personalization and cohesiveness was observed for single-member groups: the more personalized a TP is, the less likely it is to be cohesive [4]. Non-uniform groups contain members with diverse preferences. This diversity makes personalization weaker (the aggregated profile expresses lower preferences than individual profiles). Given that, cohesiveness is likely to be higher for non-uniform groups.

Influence of group size. In Table 2, we observe that regardless of the consensus function, cohesiveness increases as uniform groups grow in size. The values of PCC are $+0.98$, $+0.73$, $+0.73$, and $+0.99$ for average preference, least misery, variance disagreement, and pair-wise disagreement, respectively. As groups grow in size, their uniformity decreases yielding a weaker personalization effect, which in turn favors cohesiveness. We also observe an inverse correlation between personalization and group size for uniform groups. The values of PCC are -0.99, -0.99, -0.89, and -0.89 for average preference, least misery, variance disagreement, and pair-wise disagreement, respectively. That is explained by the fact that in larger groups, the preferences of individuals fade out and personalization decreases. This is also compatible with the previous single-user study [4].

Agreement between individuals and groups. Table 3 reports the similarity of individuals (the median user in each group) and groups they belong to. The goal is to measure the *sacrifice of individuals when joining groups.* For this aim, we compute a median profile for each of the 600 previously generated groups. The sum of Cosine values between the profile of the median user u and all other members of u's group is the highest. We generate a TP for each median user and compute the optimization dimensions for that TP. Table 3 reports the similarity between the values of optimization dimensions of a group and its median user. The higher that value, the better it is from that median user's perspective.

A general observation is that group size and group uniformity play an important role. In large groups, preferences of individuals fade out and returned TPs are farther from the the median user's preferences. Concerning cohesiveness, the highest similarity is obtained with least misery. It is also the case for personalization. Least misery yields higher similarity between the median user and the group for non-uniform groups. Both findings are consistent with previous work on group recommendation [5, 6], where least misery is more successful at satisfying the median user in larger groups with diverse tastes. For uniform groups, disagreement-based methods are best for personalization.

4.4 User Study

The goal of our user study is to observe how GroupTravel helps users obtain and refine a TP when traveling with others. The study consists of two parts. First, we focus on personalization aspects of GroupTravel and compare personalized and non-personalized TPs together. Second, we shed light on customization and observe how enabling interaction with TPs and their refinement can help improve the group travel profile, which consequently means more satisfactory TPs.

4.4.1 Setup. We recruited 3000 participants for our user study. To ensure diversity, we gathered 2000 of them from Figure-Eight platform[6], and the remaining 1000 from Amazon Mechanical Turk[7]. After pruning profiles with invalid email addresses and/or identifiers, we retained 90.1% and 96.6% of the participants in the aforesaid platforms, respectively. We based our choice for the number of study participants on Equation 5, that uses the central limit theorem [21].

$$Sample\ size = \frac{\frac{z^2 \times p(1-p)}{e^2}}{1 + (\frac{z^2 \times p(1-p)}{e^2 N})} \tag{5}$$

We describe the parameters in Equation 5 as follows.

- $N = 200,000$ is the population size, i.e., the number of contributors on Figure-Eight and Amazon Mechanical Turk platforms [22].
- $e = 3\%$ is the margin of error, i.e., the percentage of deviation in result in the sample size compared with the total population.
- $z = 95\%$ is the confidence level, i.e., if the job is repeated 100 times, 95 times out of 100 the result would lie within the margin of error.

	large	3.05	3.00	3.14	2.84	3.09	3.12

Table 4: Independent evaluation of user study

- $p = 50\%$ is the percentage value, i.e., the expected result value of the experiment. It is advised to put it at 50% when the result is not known.

Our sample size rounded up to at least 1062 participants based on the above formula. We recruited almost three times more participants to allow flexibility in forming groups and account for contributors who might quit the study before fully completing it.

We built travel profiles for the recruited participants by asking them to state their preferences on POI categories using Google Forms[8]. We then used the generated user profiles to build groups with varying characteristics, i.e., size and uniformity. For uniform groups, we generated 5 groups of each size (small, medium, and large). We gathered assessments from all members of small and medium groups, and from 30 random members for large groups. For non-uniform groups, we generated 3 groups for each size, and gathered assessments from all members of small and medium groups, and between 19 and 30 members for large groups. Each participant was paid \$0.01 for profile collection and \$0.50 for evaluating TPs.

4.4.2 Summary of results. Regarding personalization, we observe that participants liked personalized TPs more than non-personalized and random TPs. We also observe that TPs associated with average preference and least misery are the best performers for uniform groups, and TPs associated with disagreement-based methods are highly appreciated by members of non-uniform groups. Regarding customization, we noticed the supremacy of the batch strategy over the individual strategy in almost all cases.

4.4.3 Exploring personalization. In this part of the study, we aim to evaluate how satisfied users are with personalized TPs. We build personalized packages in the city of Paris. Similarly to the synthetic data experiment, each TP contains exactly 5 CIs that are valid with respect to a default query, i.e., ⟨1 *acco*, 1 *trans*, 1 *rest*, 3 *attr*⟩. Also, we specify *an infinite budget* to ensure that all popular POIs are included in the CIs. We conduct two evaluations, *independent* and *comparative*.

Independent evaluation. We asked members of the formed groups to evaluate TPs. The TPs under evaluation were either *non-personalized*, or *personalized* with one of the four group consensus methods. Non-personalized TPs were generated by setting the weight of the personalization dimension to 0 in the objective function. In addition, to filter undesired participants, we injected a random TP which included *invalid* CIs, and discarded input from participants who preferred that TP (23 participants). For each TP out of the 6 TPs to be evaluated (random, non-personalized, and personalized with the four different consensus methods), we asked the remaining 326 participants to indicate their interest in visiting POIs in the TP *with other members of the group*, using a score between 1 and 5. A score of 1 means that there are very few POIs that the participant is interested in, and a score of 5 means that the participant is interested in almost all of the POIs. To prevent bias, we did not share with participants any details about the characteristics and members of the group they are involved in.

Table 4 illustrates the results of our independent evaluation. The average interest of participants who were not filtered out is reported for groups with different sizes and uniformity categories. The results validate our objective function (Equation 1), because they show that personalized TPs perform well and are liked better than non-personalized and random TPs. We also observe that scores for uniform groups remain fairly stable as groups become larger. However for non-uniform groups, scores decrease by group size. This is in-line with our findings in the synthetic experiment where the preferences of individual members in non-uniform groups fade out as groups grow in size, resulting in less-personalized TPs.

Comparative evaluation. We also presented the participants of our study with a pair of TPs among the 6 aforementioned TPs, and asked them to choose the one that they prefer the most, and to state a reason behind their choice. Table 5 reports results for each pair-wise comparison in terms of the percentage of supremacy. For instance, for small uniform groups, **AVTP** is preferred over **LMTP** in 48% of the time implying that **LMTP** is preferred over **AVTP** in 52% of the time. We observe that TPs associated with average preference and least misery (**AVTP** and **LMTP** in Table 5) are winners for uniform groups, whereas TPs associated with disagreement-based methods (**ADTP** and **DVTP**) are winners for non-uniform groups. This finding is in-line with previous work on group recommendation [5, 6], where recommendations aggregated with either average preference or least misery are preferred for uniform groups where preferences are homogeneous. Similarly, incorporating inter-member disagreements is shown to be the best way to reach a consensus within diverse groups.

We also reviewed the statements that the participants provided to justify their choices. First we focused on cases where personalized TPs are not preferred. In these cases, participants often justified their choice only as a tie-breaker: *"I like this TP a little more"*, *"I think this TP is a bit better"*. For uniform groups, participants mentioned that they prefer TPs with average preference and least misery because those

[8] *https://docs.google.com/forms*

		AVTP vs.				**LMTP** vs.			**ADTP** vs.		**DVTP** vs.
		LMTP	**ADTP**	**DVTP**	**NPTP**	**ADTP**	**DVTP**	**NPTP**	**DVTP**	**NPTP**	**NPTP**
uniform	**small**	48%	56%	64%	48%	56%	56%	64%	36%	36%	40%
	medium	56%	42%	42%	54%	62%	56%	70%	42%	56%	42%
	large	47%	52%	44%	50%	51%	54%	55%	46%	52%	55%
non-uniform	**small**	27%	27%	66%	60%	40%	73%	40%	60%	60%	47%
	medium	43%	73%	46%	53%	73%	66%	67%	46%	43%	67%
	large	54%	42%	48%	49%	51%	36%	42%	64%	57%	48%

Table 5: Comparative evaluation of user study. AVTP, LMTP, ADTP, and DVTP refer to personalized TPs obtained with average preference, least misery, average disagreement, and disagreement variance, respectively, and NPTP refers to the non-personalized TP.

TPs reflect their personal preferences better: *"this TP seems to me more interesting for my taste"*, *"with this TP, I can move around the city more"*. We observe the same type of statements for non-uniform groups in case of disagreement-based methods, e.g., *"there are types of places in this TP that I want to visit"*.

4.4.4 *Exploring customization.*

In this experiment, we aim to validate the benefit of customization by allowing group members to interact with travel packages. More precisely, we want to assess if interacting with personalized TPs will refine the group profile in such a way that subsequent TPs are more relevant. To do so, we displayed personalized TPs on the map of Paris and asked participants to interact with the CIs forming those TPs by adding, removing, replacing POIs or generating new CIs (see the interface in Figure 3). We then refined the group profile based on the interactions of all group members. We compare the *individual* and *batch* strategies defined in Section 3.3.

With the refined group profile in Paris using either strategy, we built a customized travel package in a comparable city, namely Barcelona. We then asked our participants to evaluate the generated TP for Barcelona both in independent and comparative evaluations. Similar to the personalization study case in Section 4.4.3, to filter undesired participants, we injected a random TP which included *invalid* CIs, and discarded input from participants who preferred that TP. Participants were asked to rate the TPs in a scale of 1 to 5. A total of 18 workers participated in this study. That allowed us to build one uniform group with 11 members and one non-uniform group with 7 members. We recruited workers with an approval rate superior to 90%.

Independent evaluation. Participants in each group were asked to evaluate three different TPs in Barcelona: the first one was non-personalized, the second personalized and customized using the individual strategy, and the third personalized and customized with the batch strategy. Table 6 reports average ratings. Results are comparable across TPs. Overall, all travelers were equally satisfied with the POIs in all the TPs.

Comparative evaluation. Participants in each group were asked to compare a pair of TPs built from a non-personalized TP, a personalized and customized TP using the individual strategy, and a personalized and customized TP with the batch strategy. Table 6 reports results for each pair-wise comparison in terms of the percentage of supremacy. For instance, the batch strategy is preferred over the individual one in 82% of the time for uniform groups, implying that the individual strategy is preferred over the batch one only 18% of the time. The batch strategy is by far the best. That is particularly true for uniform groups. That is in-lined with the independent study. The intuition is that refining group profiles directly yields better TPs.

5 RELATED WORK

5.1 Itineraries and Personalization

The extraction of travel itineraries from Flickr photos was first proposed in [1] and their personalization in [2] to build customized city tours. Tailored itineraries are extracted from Flickr using an objective function that combines POI popularity with the actual user preferences over POI categories. This approach is not directly applicable to ours, since the personalization is merely a filtering of extracted trajectories. In our case, it is the POI composition itself that is personalized using the query and travel profile. That makes our problem computationally more challenging. Another difference is that unlike itineraries, POIs forming a CI are not ordered, and hence, their generation relies on a different model and algorithm (clustering instead of graph traversal). Finally, in this work we are also interested in generating travel packages for groups of users traveling together rather than just a single user.

The idea of learning travel packages was recently explored in [3]. This work proposed learning topics conditioned on both the tourists and the intrinsic features (i.e., locations and travel seasons) of landscapes. As a result, preferences on which landscapes to visit, in which season, and how to travel from one point to another (transportation modes), are extracted. This work does not propose interactive refinement of one's travel preferences and does not support group travel.

5.2 Composite Items

Composite retrieval was studied with different semantics in recent work [1, 7–10, 13–15, 23]. Most existing algorithms rely on a two-stage process that decouples the query (e.g., a CI must contain one museum and 2 restaurants) from the optimization goal (e.g., each CI is a set of close landmarks in a city). In [13], it was shown that an integrated approach produces better representative CIs than a two-stage approach. We hence build on that and extend it to build personalized CIs for groups.

TP type	uniform (11 members)	non-uniform (7 members)
individual	3.45	3.69
batch	2.91	3.8
non-personalized	3.37	3.83

Table 6: Independent evaluation of customized travel packages.

	batch vs.		individual vs.
	individual	non-personalized	non-personalized
uniform	82%	63%	54%
non-uniform	72%	57%	14%

Table 7: Comparative evaluation of customized travel packages.

5.3 Recommendation and Interactivity

Out of the multitude of itinerary recommendation approaches [24–27], only a few are interactive. In [24], a user provides feedback on the next set of POIs to visit, the system then recommends the best itineraries and further suggests new POIs, with optimal utility, to solicit feedback for. In GroupTravel, the system recommends POIs to replace those unwanted by a user or to form a CI with some selected POIs. We do not assume any prior knowledge about a city. Additionally, we focus on enabling group-based interaction with TPs.

MOBI is a collaborative itinerary planning framework [28]. Each user provides preferences and constraints in the form of "I want {at most, at least, exactly} [number] {activities, hours} of $\{cat_1, cat_2, \cdots, cat_n\}$", which resembles our query. Users interact with proposed itineraries and are told which constraints remain to be satisfied. In our work, users intervene in a second stage to refine the package. We have shown that helping bootstrap travel package construction is preferred as it induces fewer interactions.

Finally, in our previous work [4], we studied the benefit of interactivity in the generation of customized travel packages for a single user. We found that while personalization helps the selection of relevant POIs to include in a travel package, customization is necessary to allow users to customize their travel packages as they explore the alternatives the city has to offer. Customization has also been shown to help refine users' profiles based on their interactions with travel packages. In this current work, we extend the approaches and techniques we proposed for generating customized travel packages to support group travel.

6 CONCLUSION

We develop GroupTravel, a framework that generates travel package for groups. GroupTravel aggregates individual preferences into a single group preference using consensus methods developed for group recommendation. GroupTravel relies on a fuzzy clustering algorithm to generate k valid, representative, cohesive and personalized composite items that form a travel package. Travelers can interact with the generated travel package to further customize it. We run extensive synthetic and real data experiments and show that our findings are consistent with previous work in generating travel packages for single users [4] and in group recommendation [5, 6].

This work opens several research directions. One immediate challenge is to incorporate different collaboration models into the primitives used to interact with the TPs. We are examining different models such as the star model where a designated traveler moderates all requests from others in the same group, the sequential model where a TP is customized in a pipeline fashion, and a hybrid model where different primitives are requested in parallel by different travelers. This additional expressiveness raises new algorithmic questions and new ways of conducting user studies at scale.

ABSTRACT

Personal Data Management Systems are flourishing allowing an individual to integrate all her personal data in a single place and use it for her benefit and for the benefit of the community. This leads to a significant paradigm shift since personal data become massively distributed. In this context, an important issue needed to be addressed is: how can users/applications execute queries and computations over this massively distributed data in a secure and efficient way, relying exclusively on peer-to-peer (P2P) interactions? In this paper, we motivate and study the feasibility of such a pure P2P personal data management system and provide efficient and scalable mechanisms to reduce the data leakage to its minimum with covert adversaries. In particular, we show that data processing tasks can be assigned to nodes in a verifiable random way, which cannot be influenced by malicious colluding nodes. Then, we propose a generic solution which largely minimizes the verification cost. Our experimental evaluation shows that the proposed protocols lead to minimal private information leakage, while the cost of the security mechanisms remains very low even with a large number of colluding corrupted nodes. Finally, we illustrate our generic protocol proposal on three data-oriented use-cases, namely, participatory sensing, targeted data diffusion and more general distributed aggregative queries.

1 INTRODUCTION

The time of individualized management and control over one's personal data is upon us. Thanks to smart disclosure initiatives (e.g., BlueButton [9] and GreenButton in US, MesInfos [16] in France, Midata [25] in UK) and new regulations (e.g., the Europe's new General Data Protection Regulation [27]), users can access their personal data from the companies or government agencies that collected them. Concurrently, Personal Data Management System (PDMS) solutions are flourishing [4] both in the academic (e.g., Personal Data Servers [1], Personal Information Management Systems, Personal Data Stores [14], Personal Clouds [20]) and industry [12, 26, 33]. Their goal is to offer a data platform allowing users to easily store and manage into a single place data directly generated by user devices (e.g., quantified-self data, smart home data, photos, etc.) and data resulting from user interactions (e.g., user preferences, social interaction data, health, bank, telecom, etc.). Users can then leverage the power of their PDMS to benefit from their personal data for their own good and in the interest of the community. Thus, the PDMS paradigm holds the promise of unlocking new innovative usages.

Let us consider three emblematic distributed applications based on large user communities which could greatly benefit from the PDMS paradigm: (1) mobile participatory sensing apps [36], in which mobile users produce sensed geo-localized data (e.g., traffic, air quality, noise, health conditions) to compute spatially aggregated statistics benefiting the whole community; (2) subscription-based or profile-based data diffusion apps [38], in which PDMS users provide preferences or exhibit profiles in order to selectively receive pertinent information; and (3) distributed query processing over the personal data of large sets of individuals [37], in which users contribute with their personal data and issue queries over the globally contributed data (e.g., computing recommendations, participative studies).

However, these exciting perspectives should not eclipse the security issues raised by the PDMS paradigm. Indeed, each PDMS can store potentially the entire digital life of its owner, thereby proportionally increasing the impact of a leakage. Hence, centralizing all users' data into powerful servers is risky since these data servers become highly desirable targets for attackers: huge amounts of personal data belonging to millions of individuals could be leaked or lost as illustrated by the recent massive attacks (e.g., Facebook, Yahoo or Equifax). Besides, such a centralized solution makes little sense in the PDMS context in which data is naturally distributed at the users' side [19].

Alternatively, recent works [4, 14, 20, 33] propose to let the user data distributed on personal trustworthy platforms under users' control. Such platforms can be built thanks to the combination of (1) a Trusted Execution Environment (TEE) (i.e., secure hardware such as smart cards [1] or secure micro-controllers [4, 5, 20], ARM TrustZone [18], or Intel SGX [29]) and (2) specific software (e.g., minimal Trusted Computing Base and information flow control [22, 29]). In this paper, we follow this approach and consider that a PDMS is a dedicated personal device that the user possesses and is secured thanks to TEE hardware.

In addition, as in many academic and commercial approaches [33], we assume that the PDMS personal device offers a rather good connectivity and availability like, for instance, home-cloud solutions [4, 12, 26, 33] (e.g., a set-top box or a plug computer [4]). Thus, PDMSs can establish peer-to-peer (P2P) connections with other PDMSs, and can be used as data processor in order to provide part of the processing required in distributed applications. Hence, our objective is to study solutions based on a full distribution of PDMSs (called nodes interchangeably) which can act as data sources and data processors and communicate in a peer-to-peer fashion. We discard solutions requiring recentralizing the distributed personal data during its processing, since this would dynamically create a personal data concentration leading to a similar risk as with centralized servers.

Incorporating TEEs greatly increases the protection against malicious PDMS owners. However, since no security measure can be considered as unbreakable, we cannot exclude having some corrupted nodes in the system and, even worse, those corrupted nodes can collude and might very well be undistinguishable from honest nodes, acting as covert adversaries [7]. Also, since data processing relies exclusively on PDMS nodes, and given the very high scale of the distribution which disqualifies secure multi-party computation (MPC) protocols [31], sensitive data leaks are unavoidable in the presence of corrupted nodes, i.e., some data

might be disclosed whenever a corrupted node is selected as a data processor.

The goal of this paper is to assess the feasibility of building a secure and efficient data processing system over a fully distributed network of PDMS housing covert adversaries. To achieve it we provide mechanisms to reduce the data leakage to its minimum, and make the following contributions:

(1) We propose a P2P architecture of PDMSs, called SEP2P (for Secure and Efficient P2P), based on classical Distributed Hash Tables (DHT) and analyze potential data leakages of data sources and data processors. We show that (i) data tasks should be assigned to nodes in a *verifiable random* way, i.e., the assignment cannot be influenced by malicious colluding nodes; and (ii) any data-oriented task, whether it is storage or computation, should be *atomic*, i.e., reduced to a maximum such that it minimizes the quantity of sensitive data accessible by the task.

(2) We focus on the verifiable random assignment problem and propose a generic solution (i.e., independent of the distributed computation tasks) which largely minimizes the verification cost (e.g., 8 asymmetric crypto-operations with a SEP2P network of 1M nodes of which 10K are colluding corrupted nodes).

(3) We experimentally evaluate the quality and efficiency of the proposed protocols. The verifiable random assignment protocol leads to minimal private information leakage, i.e., linear with the number of corrupted nodes, while the cost of the security mechanisms remains very low even with a large number of colluding corrupted nodes.

(4) We address the task atomicity subproblem by providing sketches of solutions for the three classes of applications indicated above. We do not propose full solutions since task atomicity is dependent on the considered class of distributed computation and as such needs to be studied in detail.

Sections 2 to 5 present these four contributions respectively. We finally discuss the related work in Section 6 and conclude the paper in Section 7.

2 SEP2P ARCHITECTURAL DESIGN

2.1 Base System Architecture

SEP2P is a peer-to-peer system and only relies on the PDMS nodes to enable the aforementioned applications. Consequently, each node may play several roles for SEP2P applications:

Node role 1. Each node is a potential **data source**. For instance, producing sensed geo-localized data about the local traffic speed, or sharing grades used to compute recommendations.

Node role 2. Given the fully-decentralized nature of SEP2P, each node is a potential **data processor**, also called **actor**, providing part of the required processing.

Node role 3. The initiator of a distributed processing is called the **triggering node (*T*)**. *T* could be any node with participatory sensing applications, or the query issuer in distributed query or data diffusion applications.

2.2 Efficient P2P Data Processing

Relying on a fully-distributed system induces several problems, e.g., integrating new nodes, maintaining a coherent global state, making nodes that do not know each other interact, handling churn, maintaining some metadata. It thus requires a communication overlay allowing for efficient node discovery, data indexing and search. Fortunately, these problems have already been extensively studied in the literature and the *Distributed Hash Tables* (DHTs) appear to be the solution reaching consensus.

Background 1. A **distributed hash table (DHT)** [23, 30, 34] in a P2P network offers an optimized solution to the problem of locating the node(s) storing a specific data item. The DHT offers a basic interface allowing any node of the network to store data, i.e., $store(key, value)$, or to search for certain data, i.e., $lookup(key) \rightarrow value$. DHTs proposals [23, 30, 34] share the concepts of keyspace or **DHT virtual space** (e.g., a 224 bits string obtained by hashing the key or the node ID), space partitioning (mapping space partitions to nodes, using generally a distance function), and overlay network (set of routing tables and strategies allowing reaching a node, given its node ID). For instance, the virtual space is represented as a multi-dimensional space in CAN [30], as a ring in Chord [34] or as a binary tree in Kademlia [23] and is uniformly divided among the nodes in the network. Thus, each node is responsible for the indexing of all the $(key, value)$ pairs where the key falls in the subspace it manages. Both the data storage and the lookup operations are thus fully distributed in a DHT. DHTs have interesting properties: uniform repartition of the data, scalability, fault tolerance and do not require any central coordination.

Hence, SEP2P leverages the classical DHT techniques as a basis for communication efficiency and scalability.

2.3 Security Considerations

In this paper, we use the terminology of ARM [35] to designate the three attack levels on a PDMS node, i.e., *hack*, *shack* and *lab attacks*. A *hack attack* is a software attack in which the attacker (the PDMS owner or remote attacker) downloads code on the device to control it. A *shack attack* is a low-budget hardware attack, i.e., using basic equipment and knowledge. Finally, a *lab attack* is the most advanced, comprehensive and invasive hardware attack for which the attacker has access to laboratory equipment, can perform reverse engineering of a device and monitor analog signals. Note that shack and lab attacks require a physical access to the device and that TEEs are designed to at least resist hack and shack attacks.

Our threat model considers three security assumptions:

Assumption 1. *Each PDMS is locally secured by using TEE-like technology flourishing nowadays* (e.g., [18, 20, 29]). This assumption is reasonable considering that a PDMS is supposed to store the entire digital life of its owner. A major security feature of TEE technology is to provide isolation, i.e., strong guarantees that the local computation inside the TEE cannot be spied upon, even in the presence of an untrusted computational environment. Hence, to break to confidentiality barrier of a TEE, a lab attack is mandatory. This has an important consequence: *an attacker cannot conduct a successful attack on a remote node, i.e., not under her possession.*

Assumption 2. *Each PDMS device is supplied with a trustworthy certificate attesting that it is a genuine PDMS.* Without this assumption, an attacker can easily emulate nodes in the network, and conduct a Sybil attack [11], mastering a large proportion of nodes (e.g., playing the role of data processor nodes), thus defeating any countermeasure. Note that this does not require an online PKI (the certificate can be attached to the hardware device and not to the device owner).

Assumption 3. *Corrupted nodes by a lab attack behave like covert adversaries*, i.e., they derive from the protocol to obtain private information only if they cannot be detected [7], as detected malicious behavior leads to an exclusion from the system.

2.4 Threat Model

The above considered assumptions already offer a certain level of security at the node and system levels. Yet, no hardware security can be described as unbreakable. Therefore, our threat model considers that an attacker (e.g., one or several colluding malicious users) can possess several PDMSs and conduct lab attacks on these devices, thus mastering several corrupted nodes which can collude. For simplicity, we will call them *colluding nodes*.

It is important to notice that the worst-case attack is represented by the maximum number of colluding nodes in the system (i.e., controlled by a single entity). Corrupting few nodes can lead to some private data disclosure, but this will be very limited in a well-designed system with a large number of nodes. Therefore, an attacker needs to increase the collusion range to fully benefit from the attack (i.e., access a significant amount of private data).

Thereby, the remaining question is: how many colluding nodes could an attacker control in the system? The main difficulty for an attacker is that colluding nodes must remain indistinguishable from honest nodes (see Assumption 3). Since PDMSs are associated to "real" individuals (e.g., by delivering the device only to real users proving their identity), collusions between individuals remains possible (hidden groups) but such collusions cannot scale without being minimally advertised, hence breaking the indistinguishability mentioned above. Thus, wide collusions are extremely difficult to build since it requires significant organization between a very large number of users, which in practice requires an extremely powerful attacker as well as extreme discretion, and are thus the equivalent of a state-size attack. Finally, note that considering a large proportion of colluding nodes (e.g., 10%) is vain as it would inexorably lead to large disclosure whatever the protocol having a reasonable overhead (e.g., outside the MPC scope). Hence, in this paper we consider that a very powerful attacker could control up to a small percentage (e.g., 1%) of the nodes, which corresponds to a wide collusion requiring a lab attack on these nodes as well as a highly organized collusion between the owners of those nodes.

What does the system protect? The objective of SEP2P is to offer the maximum possible confidentiality protection of the user private data under the above considered threat model. Many other issues related to statistical databases (e.g., inferences from results, determining the authorized queries, query replay, fake data injection, etc.) or to network security (e.g., message drop/delay, routing table poisoning [39]) are complementary to this work and fall outside of the scope of this paper. Similarly, we leave aside the problems related to the attestation and integrity of the code executing distributed computations (e.g., against corrupted nodes that maliciously modify the computation results).

2.5 SEP2P Requirements

Given the considered threat model, we derive in this section the requirements that a SEP2P must address to protect the data privacy of the users. Since we cannot exclude having colluding nodes in the system and since the colluding nodes behave like covert adversaries, private information leakage is unavoidable. Under these conditions, the best countermeasures one can take are: (i) *minimize the risk* of a data leakage, i.e., reduce at most the probability of a leakage to happen; and (ii) *minimize the impact* of a data leakage, i.e., reduce at most the leakage size. Obviously, these countermeasures should not generate overheads that render the system unpractical. This leads to:

Requirement 1 (security). Random actor selection. Ensure that colluding nodes cannot influence the selection of the data processor nodes.

Requirement 2 (security). Task atomicity. Data tasks should be atomic, i.e., reduced to a maximum such that it minimizes the required sensitive data to execute the task.

Requirement 3 (efficiency). Security overheads. Minimize the number of costly operations, e.g., cryptographic signature verifications or communication overhead, and ensure system scalability with an increasing number of nodes or colluding nodes.

The task atomicity requirement is similar to the principle of compartmentalization in information security, which consists in limiting the information access to the minimum amount allowing an entity to execute a certain task. Typically, a node can execute a subtask without knowing the purpose or the scope of the global task. Dividing a given distributed computation in atomic tasks obviously depends on the precise definition of that computation. Hence, we restrict our analysis in Section 5 to sketches of solutions for the three application classes considered in this paper.

Independently of the distributed protocol chosen to implement some given application, the system must delegate the data-oriented tasks to randomly selected nodes. Therefore, the random selection protocol is generic and constitutes the security basis of any distributed protocol in our system. However, given the considered threat model, it is challenging to design an actor selection protocol that is both secure and efficient. Section 3 addresses this problem while section 4 evaluates the proposed solution.

3 SECURE ACTOR SELECTION

Let us first detail some useful classical cryptographic tools focusing on the properties used in our protocol.

Background 2. A **cryptographic hash function** [24] is a one-way function that maps a data of arbitrary size to a fixed size bit string (e.g., 224 bits) and is resistant to collision. An interesting property of hash functions is that output distribution is uniform. In the following, *hash*() refers to cryptographic hash.

Background 3. A **cryptographic signature** [24] can be used by a node n to prove that a data d was produced by n (authentication) and has not been altered (integrity). The signature is produced by encrypting $hash(d)$ using the private key of n. Any node can verify the signature by decrypting it using the public key of n and comparing the result with $hash(d)$. The signature includes the signer public key certificate, $cert_n$ (see Assumption 2).

We consider a system of N nodes, in which we want to randomly select A actors, despite wide collusion attacks from C colluding nodes. The main notations are summarized in Table 1.

3.1 Effectiveness, Cost and Optimal Bounds

Ideally, we would want to ensure that all A actors are honest, but this is impossible, since colluding nodes are indistinguishable from honest nodes. Therefore, the best achievable protection is obtained when actors are randomly selected and the selection cannot be influenced by C colluding nodes, i.e., the average number of corrupted selected actors in the ideal case is $A_{ideal_C} = A \times C/N$

N	Total number of nodes in the SEP2P system
A	Number of actor nodes (data processors)
C	Maximum number of colluding nodes ($C \geq 1$)
A_C	Average number of corrupted actors for a given protocol
A_{ideal_C}	Average number of corrupted actors for an ideal protocol
T	Triggering node (starting the execution)
k	Security degree
α	Security threshold
S	Execution Setter node, computing actor list
R_i, rs_i	DHT region R_i of size rs_i

Table 1: Main notations for Sections 3.1 and 3.2

($A_{ideal_C} > 0$). Thus, the impact of a collusion attack remains proportional with the number of colluding nodes, which is the best situation given our context. This guarantees that the attacker cannot obtain more private information than what she can passively get from observing the information randomly reaching its colluding nodes.

The following definitions quantify the security effectiveness and security cost of an actor selection protocol.

Definition 1. The **security effectiveness** of an actor selection protocol is defined as the ratio between A_{ideal_C} and the average number of corrupted selected actors for the measured protocol (A_C), i.e., security effectiveness = A_{ideal_C}/A_C. The security effectiveness has maximum value (i.e., 1) when $A_C = A_{ideal_C}$ and minimum value (i.e. C/N) when all the actors are corrupted.

Definition 2. A **verifier node** is a node who needs verifying the actor list before delivering sensitive data, e.g., a data source.

Definition 3. The **security cost** of an actor selection protocol is defined as the number of asymmetric cryptographic operations, e.g., signature verification, required by verifier nodes to check the selected actor list.

Note that the security cost considers only the verification of the actor list and not the cost of building the list. The rationale is that the verification cost has a larger impact on the overall performance since the number of verifier nodes can be high in a large distributed system: data sources need to verify the actor list before delivering their data. Other performance related issues (cost of the actor list generation, load balancing, maintenance costs) are discussed in Section 3.6 and 4.

Optimal bounds. The best possible case one could expect in terms of security effectiveness and cost in our context can be achieved using an idealized trusted server that knows all the nodes and provides a different random actor list for each system computation. This ideal solution reaches a maximal security effectiveness and a security cost of 1, since any verifier node must only check the signature of the trusted entity.

Evidently, this solution in not acceptable since it represents a highly desirable target for attackers, i.e., a central point of attack and contradicts the fully distributed nature of SEP2P. Therefore, we need distributed solutions relying only on the nodes. To underline the existing tension between security effectiveness and cost, we discuss two basic distributed protocols for the actor selection, focusing either on the security cost or on the security effectiveness. To simplify the protocols description, we initially assume a full mesh network overlay, i.e., each node knows the complete list of nodes in the system and its evolution over time.

Baseline cost-optimal protocol. The triggering node (T) selects randomly the actors. The security effectiveness is minimal: $A_C = min(A, C)$ since T may be corrupted (which is the case when any node can trigger a computation). There is thus no necessity to provide any signature: the security cost is 0.

Baseline security-optimal protocol. Proposing an optimal protocol in terms of security is challenging in a decentralized architecture (without any supporting trusted party) and considering covert adversaries. This conjunction leads to a situation where no single node in the system can claim to securely provide a list of actors (the provider itself can be corrupted). The work in [8] proposes the CSAR protocol which provides a secure way to generate a verifiable random value under the condition that there is at least one honest node participating in the distributed protocol. Applying to our context, we can ensure generating a real random value only if there are at least $C + 1$ participating nodes. Also, once we obtain a verifiable random value, we can derive up to A random values by repeatedly hashing the initial value $A - 1$ times. The final step is to map the set of A random values to the nodes. This can be easily done, e.g., by sorting the nodes on their public key and associating the random value to a rank in the sorted list. This protocol has an optimal security effectiveness, i.e., 1, since the actors are guaranteed to be selected randomly. On the other hand, checking the CSAR results requires one signature verification per participant. Thus, the security cost is $C + 1$ asymmetric cryptographic operations per verifier node. Since C can be large, such a solution cannot scale with large systems and wide collusion attackers as it would lead to an extreme verification cost.

Moreover, to achieve these security bounds, both protocols require a full mesh network overlay which is also extremely costly to maintain in practice, especially for large networks. This contradicts the efficiency and scalability requirement formulated in Section 2.5. Using a DHT overlay instead of a full mesh solves the problem of communication efficiency/scalability. However, this will impact the optimal bounds of both protocols. For the first protocol, the security cost increases from 0 to up to A since a verifier node which does not "know" any of the actors has to verify their certificates to be sure that the actors are genuine PDMSs (to avoid Sybil attacks). Similarly, for the second protocol, the security cost increases to $2(C + 1) + A$ for the same reason, i.e., checking that participant and selected actors are genuine PDMSs. Even worse, the optimal security effectiveness can no longer be guaranteed since with a DHT, there is no secure way of associating the random values to the nodes unless using secure DHT techniques [39] with a large impact on performance.

3.2 Overview of the Proposed Solution

To address all these problems, we propose a protocol that reaches maximal security effectiveness at a verification cost of $2k$. k is called the *security degree* and is very small. Also, our protocol builds directly on a classical, efficient DHT overlay without requiring any modifications. We describe some important features in SEP2P which make this possible and then sketch the protocol.

Imposed and uniform distribution of node location: the node ID, used when inserting a node in the DHT, is imposed in SEP2P, in a way that leads to a uniformly distributed node location in the DHT virtual space. Consequently, colluding nodes are also evenly distributed in the DHT, thus avoiding spatial clusters. We use extensively this property to drastically reduce the cost of security by taking localized decisions (see below), i.e., limited to the nodes situated in "small" regions in the virtual space. Achieving imposed node location is easy, based on the public key of the certificate of each node. We compute a cryptographic hash of this key, which is, by construction, uniformly distributed, and use this hash for insertion in the DHT virtual space. The advantages of using the public key are (i) its uniqueness; and (ii) the node location can be checked with a single signature verification.

Probabilistic guarantees: Given the imposed, uniform node location which applies indistinctly to honest and colluding nodes, we can have probabilistic guarantees on the maximum number of colluding nodes in a DHT subspace of a given size, called *DHT region* hereafter. We can compute the probability of having **at least** k **colluding nodes** (see Section 3.3) and choose the DHT region size such that the probability is very close to 0. In our context, we want to have a probability smaller than α, the security threshold. The main idea is to set α so that the probability of having k colluding nodes in the same region becomes so low that we can consider that it "never happens", e.g., $\alpha = 10^{-6}$ (see Section 4.1). Such a guarantee is used in the protocol sketched below and then detailed in the following subsection.

Figure 1: Sketch of verifiable selection

Sketch of verifiable selection protocol of A ***actors (see Figure 1)***

(1) Run a distributed protocol inspired from CSAR [8] to generate a **verifiable random value**, i.e., proven to have been truly randomly generated by k nodes if at least one is honest (see Section 3.4). The k nodes are selected in a DHT region R_1, centered on the triggering node (T), whose region size rs_1 is set such that we have probabilistic guarantees to "never" (probability $< \alpha$) have k or more colluding nodes, i.e., at least one of the k nodes is honest.

(2) Map the hash of that random value into coordinates to define a location p in the DHT virtual space and contact through the DHT the node, called **execution Setter** (S), managing this location.

(3) S then selects k nodes (the actor list builders) in a region R_2, centered on p, using probabilistic guarantees, such that we "never" have k or more colluding nodes. Given the uniform distribution of the node on the virtual space, we have $rs_2 = rs_1$.

(4) Each actor list builder then selects A nodes in a region R_3, centered on p, whose size rs_3 is such that R_3 includes at least A nodes with high probability (see Section 3.6 and Section 4.3 for rs_3 tuning).

(5) Run a **distributed verifiable selection protocol** in the spirit of [8] such that the k nodes selected in (3) can: (i) check the validity of the random value generated in (1); (ii) build the actor list securely; (iii) sign both the random value and the list of A actors. This step is detailed in Section 3.5.

The result is a list of A actors that is signed by k nodes, among which at least one is honest. Doing so reduces the verification cost to $2k$ asymmetric cryptographic operations: k to check the certificate of the k list builders, verifying that they belong to region R_2, centered on p; and k to check each builder signature.

3.3 Providing Probabilistic Guarantees

To generate verifiable random values or validate the query actor selection, SEP2P employs distributed computations between a small subset of the nodes thanks to the notion of node legitimacy and probabilistic guarantees defined below using the notations in Table 2.

$kpub_n$	Public key of node n
$cert_n$	Trustworthy certificate of node n
$sign_n$	Signature by node n (includes $cert_n$)
TL_i	execution Trigger Legitimate node i
RND_i	Random number generated by TL_i
$(V)\,RND_T$	(Verifiable) random generated by T
SL_j	execution Setter Legitimate node j
RND_S	Random generated by S
CL_j	Partial candidate list of legitimate nodes w.r.t. R_3
CL	Candidate List of legitimate nodes
$(V)\,AL$	(Verifiable) Actor List

Table 2: Main notations for Sections 3.3 – 3.5

Definition 4. Legitimate nodes. Given a region R in the virtual space of a DHT, for any node i we say that node i is legitimate w.r.t. R iff $hash(kpub_i) \in R$.

To be able to provide probabilistic guarantees as explained in Section 3.2, we need to estimate the number of nodes in a region:

Lemma. Let R be a DHT region of size rs in a virtual space of a DHT of total size 1 (i.e., normalized) and let N be the total number of network nodes with a uniform distribution of the node location in the virtual space. The probability, PL, of having at least m legitimate nodes in R is:

$$PL(\geq_m, N, rs) = \sum_{i=m}^{N} \binom{N}{i} \cdot rs^i \cdot (1-rs)^{N-i} \qquad (1)$$

Proof (sketch): Let us consider a partition of the N nodes into two subsets containing i and $N - i$ nodes. Since the distribution of nodes is uniform in space, the probability of having the i nodes inside R and the $N - i$ nodes outside R is $rs^i \cdot (1 - rs)^{N-i}$ and there are $\binom{N}{i}$ possible combinations of generating this node partitioning. The probability of having at least m nodes in R is equal to the probability of having exactly m nodes plus the probability of having exactly $m+1$ plus... the probability of having N, which leads to the equation in (1).

Application to colluding nodes: Let $C < N$ be the maximum number of colluding nodes. We can apply formula 1 to compute the probability, PC of having at least k colluding nodes in R:

$$PC(\geq_k, C, rs) = \sum_{i=k}^{C} \binom{C}{i} \cdot rs^i \cdot (1-rs)^{C-i} \qquad (2)$$

We can notice that this probability only depends on C. It does not depend on the region center since we have a uniform distribution of the nodes on the virtual space.

3.4 Verifiable Random Generation

Our goal is to generate a random value, using k nodes and to guarantee that none of the k nodes can choose the final computed random value (or any of its bits). Any node in the system should be able to check the validity of this random value (i.e., to have proofs that it has been correctly generated). This is possible as soon as at least one of the k nodes is honest, this guarantee being obtained thanks to equation (2) by choosing the adequate size for the DHT region R and by using k legitimate nodes w.r.t. R.

A node T wanting to generate a verifiable random, selecting a region of size rs_1 with $PC(rs_1) < \alpha$ centered on itself, executes:

Verifiable random number generation protocol

(1) T contacts any k legitimates nodes TL_i ($i \in [1, k]$) w.r.t. R_1.
(2) Each TL_i sends $hash(RND_i)$ to T, where RND_i is a random number (on the same domain as the hash function, e.g., 224 bits) TL_i generates.
(3) Once T has received the k hashes, it sends back the list L of hashes to the TL_is; $L = (hash(RND_i))_{i \in [1,k]}$.
(4) Each TL_i checks that $hash(RND_i) \in L$, and, in the positive case, returns $sign_i(L)$ and RND_i.
(5) T gathers the k messages and builds the verifiable random: $VRND_T = (cert_T, (sign_i(L), RND_i)_{i \in [1,k]})$.

VRND_T = (cert_T, (sign_i(L), RND_i)_{i∈[1,k]})

Figure 2: Verifiable random

The above random generation protocol is adapted from [8] which includes a formal proof. Note that the protocol in [8] does not include the notion of node legitimacy and thus needs $C + 1$ participating nodes instead of k. Intuitively, the nodes commit on their selected random value by sending its hash (Step 2), and all the hash values are known by each of the k nodes before providing the final signature (Step 4). Therefore, an attacker controlling $k - 1$ TL_i nodes cannot influence the final random value since these nodes cannot change their random values (committed at Step 2). Thus, the correct random value of a single honest node is enough to obtain a truly random final value RND_T.

To obtain and check the verifiable random value, any node must: (i) check $cert_T$ and compute L by hashing all RND_i; (ii) for $i \in [1, k]$, check $cert_i$, check the legitimacy of TL_i using $cert_T$ and validate $sign_i(L)$. The final random value is $RND_T = RND_1 \oplus RND_2 \oplus \cdots \oplus RND_k$.

In (i), we verify that T is a genuine PDMS, retrieve the center of the region R_1 and compute L, both being necessary for the next verification; (ii) starts by confirming that each TL_i is genuine, then it ensures that they are legitimate w.r.t the location of T and R_1, after which it confirms the hash list by checking the signatures, and finally, it computes RND_T.

3.5 Distributed Secure Selection Protocol

The main goal of the proposed protocol is to select the A actors such that this selection cannot be influenced by colluding nodes.

Definition 5. The **execution Setter** (S) is chosen randomly based on a verifiable random generated by T. Its role is to coordinate the selection of the computation actors and to setup the execution by sending the appropriate information to each actor.

In the following, we assume that each node n in SEP2P keeps a node cache, called $cache_n$, of the IP address and certificate of legitimate nodes w.r.t. a region of size rs_3 centered on node n location. The cache size and the cache maintenance cost are discussed in Section 3.6 and evaluated in Section 4.3.

SEP2P distributed secure actor selection protocol

(1) Generates the verifiable random $VRND_T$ (see Section 3.4).
(2) Maps $hash(RND_T)$ into coordinates and contact S through the DHT.
(3) S contacts any k legitimates nodes w.r.t. R_2, SL_j ($j \in [1, k]$) and sends to each $VRND_T$ (see Section 3.4).
(4) Each SL_j sends $hash(RND_j \| CL_j)$ to S, where RND_j is a random number SL_j generates, and CL_j is the set of nodes from $Cache_j$ which are legitimate w.r.t. R_3.
(5) Once S has received the k hashes, it sends back the list L_1 of hashes to all SL_j; $L_1 = (hash(RND_j \| CL_j))_{j \in [1,k]}$.
(6) Each SL_j checks that its own $hash(RND_j \| CL_j) \in L_1$ and, in the positive case, returns RND_j and CL_j.
(7) S gathers the k messages and sends to all SL_j the list $L_2 = ((RND_j, CL_j)_{j \in [1,k]})$.
(8) Each SL_j does the following:
    (a) Checks $VRND_T$ and computes RND_T (see Section 3.4).
    (b) Checks that each (RND_j, CL_j) from L_2 is consistent with the corresponding $hash(RND_j \| CL_j)$ from L_1.
    (c) Computes the union, after removing possible duplicates, of all CL_j to obtain a candidate list of legitimate nodes CL.
    (d) Computes the $RND_S = RND_1 \oplus RND_2 \oplus \cdots \oplus RND_k$.
    (e) Sorts CL on $kpub_n \oplus RND_S$ (where $kpub_n$ is the public key of a node $n \in CL$) and selects the A first candidates to build the actor list AL.
    (f) Checks the legitimacy of AL nodes w.r.t. R_3.
    (g) Signs (RND_T, AL) and sends it to S.
(9) S gathers k results and builds the verifiable actor lists: $VAL = (RND_T, AL, (sign_j(RND_T, AL)))_{j \in [1,k]}$.

The goal of **steps 1 and 2** is to displace the DHT region, where actors will be selected, from T to S with three benefits: (1) T is likely to be corrupted (as any node is allowed to trigger a computation) while S is chosen randomly using the verifiable random protocol; (2) it distributes the potential leaks in a different region for each computation; (3) it balances the load on the whole SEP2P network thus improving the overall performance.

Steps 3 to 6 are similar to steps 1 to 4 of the verifiable random protocol, except that the signature by SL_j is delayed to Step 8.g. Delaying the signature allows SL_js to check and attest the validity of $VRND_T$ (step 8.a). The protocol cost is increased (since k nodes verify $VRND_T$) but the verifying cost is reduced accordingly since having k SL_js signing RND_T (step 8.g) means that it is correct (remind that at least one of the k SL_js is honest).

Steps (8.b) to (8.e) are dedicated to the actor list building (AL) based on the candidate list (CL) and deserve a more detailed explanation: in our context, in order to securely build the actor list, the k participants first have to agree on a common basis and then execute, in parallel, a procedure that is unpredictable and gives identical results to all participants. Since it is unpredictable we are certain that the inputs cannot be manipulated beforehand so as to influence the rest of the procedure. Since it gives identical results for all actor list builders, and since at least one node is honest, we are sure that no colluding node can alter the results. By sorting the nodes in CL using a verifiable random number and the public keys of the nodes fulfills both requirements: the random number takes care of the unpredictability, while the commitment of each SL_j on their intermediary lists in step 4, coupled with the XOR operation on the public keys of CL nodes, is a simple yet effective way of producing identical results.

In **steps 8.f and 8.g**, k SL_js check the validity of the result, i.e., that any actor of AL belongs to R_3 and attest it by signing the results. Note that this check is not necessary for any actor n in AL that was found in k CL_j since this fact attests that at least one honest node possesses n in its $Cache_j$. Assuming $Cache_j$ contains only genuine nodes (we say that $Cache_j$ is valid - see Section 3.6) and since $rs_3 > rs_2$, most of the actors in AL will be found in k CL_j, thus diminishing drastically the actor list building cost. Actually the validity of $Cache_j$ is necessary to ensure that a colluding node selected as SL cannot hide honest nodes with the hope of having a larger proportion of colluding nodes in AL. Indeed, at least one of the SL is honest and will provide its full $Cache_j$ that will be thus included in CL. We can observe that $Cache_j$ can be actually seen as the relevant part (for node j) of a full mesh network, which offers its benefits without paying the whole maintenance cost.

To check the verifiable actor list (VAL), any verifier node must do: for $j \in [1, k]$, check $cert_j$, check the legitimacy of SL_j using RND_T and validate $sign_j(AL)$. Thus, the verifying cost is limited to k certificate verifications and k signature verifications, i.e., $2k$ asymmetric crypto-operations. We show in Section 4 that k is generally lower than 6.

3.6 Protocol Implementation Details

In this section we discuss a few important implementation issues of the proposed actor selection protocol.

Despite the uniform distribution of nodes on the DHT virtual space, there is no absolute guarantee of not having **sparse DHT regions**. This can have two negative impacts on the SEP2P protocol: during the selection of k TLs in R_1 (or k SLs in R_2) and A actors in R_3. Both cases exhibit interesting trade-offs:

Choosing R_1 (or R_2) region size: on the one hand, a small rs leads to a smaller k value, which in turn reduces the protocol verification cost. On the other hand, setting rs too small can lead to situations in which nodes have less than k legitimate nodes in their R region and as such cannot participate in the actor selection protocol (as triggering node or execution setter) which is problematic. For this reason, in SEP2P we provide a table of couples (k_i, rs_i), named **k-table**, which allows any node to find k_i legitimate nodes in the region of associated rs_i size. The k-table is computed thanks to PL and PC (equations (1) and (2)) to ensure that whatever the couple chosen, the probability of having k or more colluding nodes remains equal. The largest k of the k-table corresponds to the region size allowing any node to find those legitimate nodes with a very high probability, i.e., 1-α, while lower values allow to reduce the security cost in denser network regions. Thus, the k-table optimizes the overall cost of the SEP2P protocol and warrants that any node can be selected as triggering node or execution setter.

Choosing R_3 region size: Choosing a too small rs_3 has a negative impact on the system performance. If the SLs cannot find enough nodes in R_3, they can attest it (e.g., in Step 8.c in SEP2P protocol) and S can use the k signatures to displace the actor selection to another region (e.g., selected by rehashing the initial RND_T). This mechanism allows the protocol to be executed successfully even if some network regions are sparser. However, there are two drawbacks. First, the cost of the actor selection increases since (part of) SEP2P protocol must be executed twice (or more times). Second, this also introduces an unbalance in the system load since the sparse regions cannot fully take part in data processing. Finally, setting rs_3 to very large values (see Section 4.3) is not an option since the maintenance cost of the cache increases proportionally when nodes join or leave the network.

Joining the network and $Cache_j$ validity: Due to space limitation, we only sketch the joining procedure in the case of a Chord DHT (leaving the network can be easily deduced). As mentioned above, any node must maintain a consistent node cache despite the natural evolution of the network. Thus, a node joining the network must ask its successors and predecessors (Chord DHT) to provide their node cache attested by k legitimate nodes in a region of size rs_1 centered on their location. The new node can then make the union of these caches and keep only legitimate nodes w.r.t R_3 centered on its location. The resulting cache contains only genuine nodes and is thus valid since it has been attested by at least k nodes in a region of size rs_1 centered on the successors or predecessors of the new node (a recurrence proof can be established).

Reusing an actor list: If there is no mechanism that prevents an attacker from reusing an actor list, then she only has to keep generating such lists until she obtains one she deems satisfactory. To counter this behavior, we put in place two mechanisms: (i) a timestamp and (ii) a limit to the number of triggered executions a node can make. With (i) we prevent any node from reusing an actor list: TLs and SLs add a timestamp to their signatures which will respectively be checked by the SLs and the data sources. If the timestamp is too distant, the computation is cancelled. Enforcing (ii) is possible thanks to the node cache and the k-table: the TLs solicited by T first check if T chose the smallest possible number of TLs (as their node cache contains, by construction, R_1 centered on T, they are capable of judging), thus forcing T to choose the same TLs. They then only have to monitor and limit the number of queries T does in a given amount of time.

Failures and disconnections: In the most complex case of node failures (i.e., unexpected disconnection) of a TL, SL or S, either RND_T or AL cannot be computed and the protocol must be restarted (i.e., T generates a new RND_T). However, the probability of failures during the execution of the secure actor selection being low in our context, such restarts do not lead to severe execution limitations as mentioned above. The case of "graceful" disconnections is easier: we can safely force nodes involved in the actor selection process to remain online until its completion, thus avoiding the restarts. If a node, selected as actor wants to disconnect (or fails), the impact will be mainly on the result quality since part of the results will be missing.

4 EXPERIMENTAL EVALUATION

This section evaluates the effectiveness, efficiency, scalability and robustness of the SEP2P actor selection protocol.

4.1 Experimental Setting

Reference methods. To better underline our contributions and to provide a comparison basis, we implemented three strategies in addition to the SEP2P actor selection protocol. We discarded the baseline cost-optimal and security-optimal protocols from the evaluation since the former does not provide any security while the latter is much too costly and not scalable (w.r.t. N and C) to be used in practice. Hence, we used for comparison more advanced actor selection strategies based on these protocols but using our verifiable random generation protocol with k participants (see Section 3.4).

The first two strategies use the verifiable random to designate the execution Setter (S) which freely chooses the actor list (as in the cost-optimal protocol). These strategies differ only in the verification process. The first one, ES.NAV (for Execution Setter, No Actor Verification) requires verifying the legitimacy of S but not of the actors. The second one, ES.AV requires, in addition, to verify that actors are genuine PDMSs. ES.AV is expected to provide better security effectiveness than ES.NAV at a higher verification cost. The third strategy, M.Hash (for Multiple Hash) is derived from the security optimal protocol, but uses a DHT instead of a full mesh network. Verifiers must check that actors are genuine PDMSs and that they are "near" the random values determined by the initial verifiable random, hashed as many times as there are actors.

Strategy	**Description**
ES.NAV	Execution Setter with No Actor Verification
ES.AV	Execution Setter with Actor Verification
M.Hash	Multiple Hash (with Actor Verification)
SEP2P	Proposed protocol (Section 3.5)

Param.	**Description**	Values(**default**)
N	Number of nodes	10K; **100K**; 10M
$C\%$	% of colluding nodes	0.001%; 0.01%; 0.1%; **1%**; (10%)
A	Number of actors	8; 16; **32**; 64; 128; 256
α	Security threshold	10^{-4}; $\mathbf{10^{-6}}$; 10^{-10}
$\mid Cache_j \mid$	Node cache size	**48** or varying from 8 to 32K
MTBF	Mean time betw. failure	from **1h** to 5 days

Metrics	**Unit(s) & comments**
Security effectiveness	Ratio (1 = ideal, C/N = worst)
Verification cost	Number of asymmetric crypto-operations
Latency of setup cost	Number of exchanged messages and number of asymmetric crypto-operations (per minute for the maintenance overhead)
Total work setup cost	
Maintenance overhead	
Security degree (k)	Ratio (1 = ideal, C/N = worst)

Table 3: Strategies, parameters and metrics

Simulation platform. We identified all the parameters that may impact the security and efficiency of the proposed strategies and considered all the metrics (see Table 3) that are worth evaluating to analyze the strengths and weaknesses of the proposed strategies, i.e., security effectiveness and cost, setup cost, scalability, robustness w.r.t. failure or disconnections. Let us note that a real implementation of the SEP2P distributed system is not very useful if we consider the above listed objectives of the evaluation. Also, measuring the scalability for very large systems (e.g., 10M nodes) with many parameters is practically impossible. Therefore, as in most of the works on distributed systems [30, 34], we base our evaluation on a simulator and objective metrics. That is, the latency is measured as the number of asymmetric crypto-operations and exchanged messages between peers instead of absolute time values. This allows for a more precise assessment of the system performance than time latency, which can greatly vary in our context because of the node heterogeneity (e.g., TEE resources or network performance).

Our simulator is built on top of a DHT network. Currently, we implemented Chord and CAN as DHT overlays and use Chord for the results presented in this paper. The simulator allows to force choosing a given Execution Setter (by artificially fixing the RND_T value). We used this feature to obtain the exhaustive set of cases for a given network setting, each node being the Execution Setter, and then capture the average, maximum and standard deviation values for our metrics. The parameters and metrics of the simulator are described in Table 3. Values in bold are the default choices and their tuning is discussed throughout the Section. Note that (1) the verification cost is given by verifier node; (2) the latency indicates the "duration" of the protocol executed in parallel; (3) the total work indicates the cumulative number of cryptographic operations and communications during the execution of a protocol.

Security threshold value: Generating several networks and varying the security threshold α, we experimentally observed that for $\alpha = 10^{-4}$, an attacker never controls k or more nodes. However, given the importance of this parameter for the system security, we set $\alpha = 10^{-6}$ and show in Figure 6 the impact of choosing $\alpha = 10^{-10}$ on a small ($10K$) and large ($10M$) network. Indeed, if an attacker could master by chance k colluding nodes in a region of size $rs_1 = rs_2$, then she could completely circumvent the security mechanism of SEP2P since, for example, she can obtain k signatures from these regrouped colluding nodes for an actor list of her willing. Note that increasing α reduces the probability accordingly but increases the verification cost in a logarithmic way (as discussed below in Section 4.3).

4.2 Security Effectiveness versus Efficiency

Figure 3 represents the security effectiveness (Y axis) versus the verification cost (X axis) for the four measured strategies and with $C\%$ varying from 0.001% to 10%. Note that the value of 10% is not realistic: it would lead to large disclosure even with an optimal random actor selection protocol, and as mentioned in Section 2.4, is equivalent to state-size attack. We have however run the simulation with 10% to understand its impact on the security effectiveness and cost.

Security effectiveness: SEP2P achieves an ideal security effectiveness, i.e. as good as a trusted server, independently of the number of colluding nodes. Indeed, the selection of actors is truly random, thus providing the same results as the ideal case. In addition, the verification cost ($2k$) is also very low (4 to 8 asymmetric crypto-operations for $C\% \leq 1\%$). Not surprisingly ES.NAV has the same verification cost than SEP2P, but the cost of ES.AV or M.Hash is much larger ($2k + A + 1$ and $2k + A$ respectively) since both must check the certificate of each actor in the list. This check allows ES.AV to have better security effectiveness than ES.NAV when C is very small ($C < A$). With respect to security effectiveness, ES.NAV, ES.AV and M.Hash are far from offering an adequate protection. Let us explain the cause for the poor security effectiveness: while RND_T value is correctly chosen, an attacker mastering a corrupted node located "sufficiently near" from $hash(RND_T)$ can claim to be the Execution Setter and then select a list of actors including a maximum number of colluding nodes. Here, "sufficiently near" means that it satisfies the check made by the verifiers. Note that we tuned the system parameters such that we can be "sure" to have always a node sufficiently near of any random value to allow executing the actor selection protocol for any RND_T. The same problem arrives with M.Hash for each new random destination, thus explaining the poor security effectiveness. Hence, increasing the number of verifications or selecting each actor in a different network region does not solve the intrinsic limitation of these strategies. Note also that this behavior does not affect SEP2P. Indeed, even if the Execution Setter is a corrupted node, it cannot influence the actor list selection since it is done by k SLs (S only routes the messages between the SLs).

Setup costs: Figures 4 and 5 show the setup costs (Y axis in log scale) in terms of asymmetric crypto-operations and exchanged messages respectively, once more with respect to the verification cost (X axis). Curves with empty symbols represent latency while plain symbols represent total work. The results show that SEP2P is the slowest in latency and has the higher total setup cost for crypto-operations. These "bad" results are the consequence of two design choices: (1) to increase the security effectiveness, we

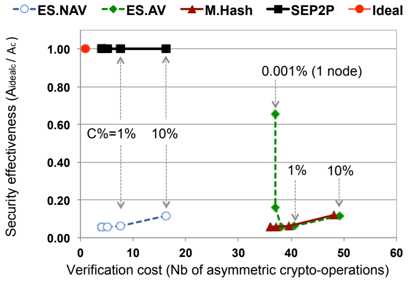

Figure 3: Sec. Effectiveness vs Verification

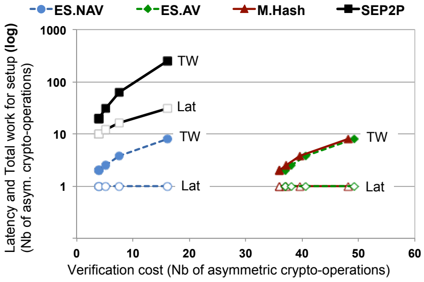

Figure 4: Setup asymmetric crypto-costs

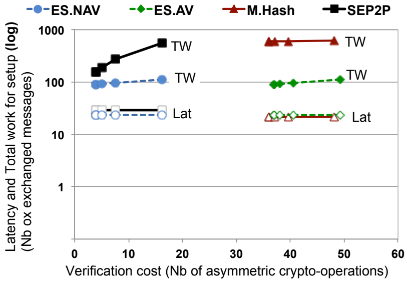

Figure 5: Setup communication costs

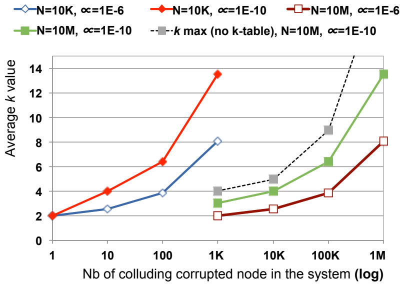

Figure 6: k versus C (N and $\propto$ vary)

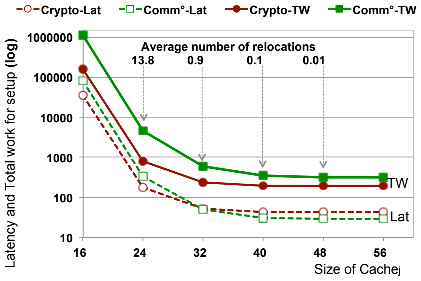

Figure 7: Setup costs varying R3 size

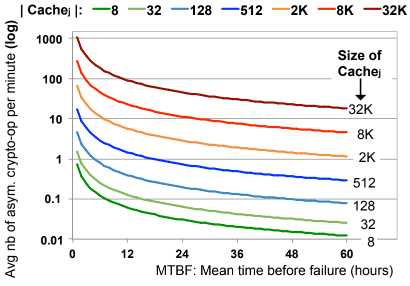

Figure 8: Maintenance overheads

run our protocol on k SL nodes thus increasing the total setup cost; and (2) we voluntarily make most of the checks during the setup (e.g., checking the actor certificates or verifying their availability) in order to reduce, as much as possible, the subsequent verification cost. Since this verification process will potentially be performed by a (very) large set of nodes (e.g., data sources), it is in our best interest to reduce it to avoid overloading the entire system. Figures 4 and 5 illustrate this aspect: our non-optimal setup cost is balanced by an optimized verification cost (and ideal disclosure in Figure 3). Note also that most operations are done in parallel (either by k TLs or SLs), thus leading to a reasonable setup latency (around 20 crypto-operations and 30 exchanged messages). We can also note in Figure 5 that M.Hash achieves the worst total work for setup (exchanged messages), because of the A routings in the DHT. Finally, we can remark the almost identical latency of ES.NAV, ES.AV and M.Hash on both metrics. Indeed, they all run the same initial protocol to compute RND_T. With respect to communication, the results are also identical because all DHT routings for M.Hash are done in parallel.

4.3 Scalability and Robustness

We now concentrate on SEP2P to study its scalability and its robustness to node failure.

Scalability: To study the scalability, we compute the averaged k value varying C and N. Indeed, k is the main factor in the verification cost, setup latency and total work (since everything is done k times). As seen in Section 3.6, depending on C and N, we can compute a k-table which gives several increasing values of k with increasing region size. We have considered small (10K) to very large (10M) networks and four values for $C\%$, leading to eight different SEP2P network configurations. For each configuration, we have computed, for each node, the minimal value for k with respect to the k-table and then averaged the results. Figure 6 shows the average k (Y axis) versus the $C\%$ (X Axis in log scale) for several network size considering two values for α: 10^{-6} and 10^{-10}. We also plot on the same figure the value of k without k-tables (the grey curve) to highlight the benefit brought by k-tables (only shown for the large network with $\alpha = 10^{-10}$). This figure offers many insights. (1) **SEP2P is highly scalable w.r.t. N:** Indeed, k values are identical for small and large networks independently of α if we consider the percentage of colluding nodes and not the absolute value (e.g., 1% colluding nodes is equivalent to absolute values of $C = 100$ and $C = 100K$ for the small and large networks). Indeed, scaling N and C in the same proportion leads to reduce $rs_1 = rs_2$ size accordingly. Note that with a single corrupted node, the k optimization is useless ($k = C + 1$ in that case) regardless of the α value. **(2) k increases slowly when $C\% < 1\%$:** k remains smaller than 6 even with $\alpha = 10^{-10}$. For $N = 10M$ and $C\% = 1\%$, the k-optimization reduces the number of participants in the verifiable random generation from $100K$ to 6. **(3) α has a small influences on k:** increasing α by four orders of magnitude increases k from 1 unit (e.g., $1K$ colluding nodes for $N = 10M$) to 5 units (e.g., $1K$ colluding nodes for $N = 10K$ or $1M$ colluding nodes for $N = 10M$). **(4) the k-table optimization is important:** k-tables allow reducing k by 1 unit up to 9 units (for 10% colluding nodes).

Number of actors: We also studied the impact of the variation of the number of actors. Overall, this results in a linear increase in the total work in terms of communications as the k SLs must check for the availability of A legitimate nodes to construct their respective CLs. For the sake of brevity, we omit here these results.

Node cache size: We now focus on adapting the node cache size to the maximum number of required actors. Our goal is to evaluate the impact of the cache size on the global performances. To do so we take a reference network with $N = 100K$, $C\% = 1\%$ and $A = 32$ and vary the average cache size on the whole network (we compute $rs3$ easily dividing the cache size by N). Figure 7 shows the results (Y axis in log-scale). For each cache size, we simulated an execution on each node of the network and computed the average values for our metrics. Our measures show that with a very small cache, the probability of relocating the actor selection process is high (the SLs do not find enough legitimate nodes in their cache w.r.t. R_3), which then leads to an increased latency and total work. Choosing a cache size greater than A, the query is almost never relocated (see Figure 7), giving better performances. This would lead to choose the largest possible cache. However, constructing such a cache also means maintaining it.

Maintenance costs: We also evaluated the impact of the cache size in the presence of node disconnections and, more generally, the impact of disconnections. To observe it, we simulated disconnections and measured their cost depending on the size of the node cache ($Cache_j$) using the default values for C, N, α and resulting k. We then considered those costs as a baseline and computed the global impact in a network where nodes disconnect (and reconnect) every x hours (mean time before failure or MTBF). We represent this cost in terms of asymmetric cryptographic operations (see Figure 8 - Y axis in log scale). The number of exchanged messages is not shown because graphs are very similar. We also computed these metrics for large node cache sizes (up to $32K$) to confirm that full mesh networks cannot be an alternative to DHT. Our results show that an overestimated cache is excessively costly even with an MTBF of 5 days: it consumes a large portion of the overall computing power of the entire system just to maintain it up to date. With small MTBFs, the network would be probably not maintainable. Since the number of actors for a computation is likely to be relatively small (e.g., few hundred, see Section 5), we can safely set the node cache size around 512 which leads to a reasonable maintenance cost (less than 1 signature per node per minute on average for MTBF = 1 day) and never trigger relocations (see Figure 7).

5 TASK ATOMICITY

5.1 Proposed Use Cases

We now focus on requirement 2, illustrating task atomicity on the use cases proposed in Section 1.

Use case 1: Mobile participatory sensing is used in many smart city applications for urban monitoring such as traffic monitoring (e.g., Waze or Navigon), evaluating the quality of road infrastructures, finding available parking spaces or noise mapping [36]. In these scenarios, the community members act as mobile probes and contribute to spatial aggregate statistics (density, averaged measures by location and time, spatial interpolation [36]) which in turn, benefit the whole community. As an alternative to the classical centralized architecture, the distributed PDMS paradigm increases the privacy guarantees for the users, thus encouraging their participation. A mobile user can generate sensing data (e.g., using her smartphone or vehicular systems) which is securely transmitted and recorded into her PDMS (e.g., a home box). This way each PDMS becomes a potential data source in the system. These data can then be aggregated by a small subset of data processor nodes to produce the required spatial aggregate statistics, which can be broadcasted to all the participating nodes.

Use case 2: Users can **subscribe to information flows based on their preference or user profile** (e.g., RSS feeds, specific product promotions or ads, etc.). A user profile can be represented by a set of concepts associating metadata terms (e.g., location, age, occupation, income, etc.) to values specific to each user. These associations are traditionally stored at a publication server to allow targeting the interested nodes. Instead, we propose to distributively store and index those profiles in SEP2P, thus greatly improving users' privacy. We call a concept index, an index associating for each concept the list of node addresses having this concept. Storing and searching this concept index is straightforward with a DHT. Each node does a $store(concept, IPaddress)$ for each concept in its profile. To find all the nodes matching a certain target profile (e.g., a logical expression of concepts), a DHT search is launched for each concept in the profile. Then, a set of randomly selected data processors are used to pick up the scattered pieces of the concept index, apply the logical expression of the target profile and compute the matching target nodes (*TN*), i.e., their IP addresses. Finally, the information is sent to the selected targets.

Use case 3: We consider **queries over the personal data contributed by a large set of individuals**, e.g., to compute recommendations, make participative studies. To achieve a high degree of pertinence and avoid flooding the system, such queries should target only a specific subset of the nodes, i.e., the nodes exposing a given user profile. Query examples are numerous, e.g., get the top-10 ranked movies by academics from Paris, or find the average number of sick leave days of pilots in their forties. The query processing is done in two steps which roughly correspond to the use case 2 combined with use case 1. First, the relevant subset of nodes, which match the query profile, must be discovered (use case 2). Then, the selected subset of target nodes become data sources which supply the required data (e.g., number of sick leave days) to compute the query result (use case 1). The main differences are that only the selected nodes provide data and that the result is transmitted only to the querier node and not to the entire system.

5.2 Detailed Node Roles

From the above description, we can define new node roles:

Node role 4. A **metadata indexer** (*MI*) stores part of the metadata shared by the nodes, allowing pertinent and efficient distributed data processing.

Node role 5. A **target finder** (*TF*), applies a logical expression on its input to produce a list of target nodes.

Node role 6. A **data aggregator** (*DA*) applies an aggregative function to its input and produces partially aggregated results.

Node role 7. A **main data aggregator** (*MDA*) aggregates its input and produces the final result.

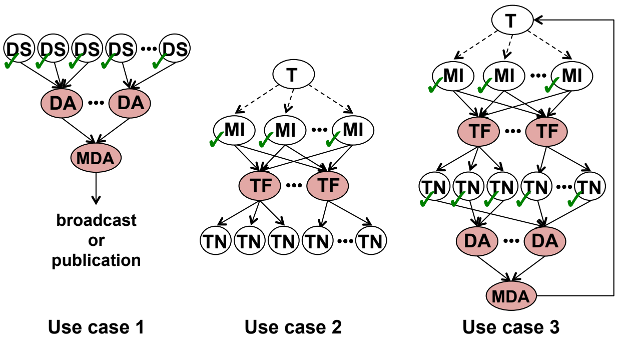

Figure 9: Distributed execution plans for the use cases

These roles allow designing distributed execution plans for the three use cases as shown in Figure 9. The nodes that must be chosen using the SEP2P protocol are shown in pink, and we used the symbol √ to denote that a node is a verifier (as specified in Section 3.6). This must be done each time a node discloses some sensitive data, thus on data sources and metadata indexers.

5.3 Towards Task Atomicity

The node roles and DEP proposed above already provide some task compartmentalization dividing the whole processing in tasks. However, much more can be done to minimize the impact of data leakage. In this section we present a few methods to achieve task atomicity. Our objective is mainly to show that task atomicity can be indeed performed and that it can significantly improve the system security when used in conjunction with the secure random actor selection. Given the space limitation, a detailed study of task atomicity is left for future work.

Metadata index protection: The concept index design already exhibits some form of task atomicity: (1) it is evenly distributed among all the nodes using the DHT mechanisms; (2) the imposed location of nodes in the DHT (see Section 3.2) leads to a randomized association between concepts and *MI* nodes. Nevertheless, a single corrupted node could disclose all the index information it owns. Further security improvements can be obtained by splitting each concept into s shares using the Shamir's secret sharing technique [32] which requires knowing at least p ($p \leq s$) shares to reconstruct the secret. Disclosing a single concept will now require p colluding nodes randomly selected.

User data protection: We consider here sensed data in use case 1 or the result of queries performed on a single PDMS in use case 2. Considering several *DA*s already reduces the impact of potential data leakage by a corrupted *DA* node. A simple way to reduce further this impact is to realize the aggregation on anonymized data (e.g., average traffic speed without user identity) or data without semantics (e.g., averaging data, a salary for instance, without knowing its meaning) or even encrypted data (with deterministic encryption). Note also that aggregation is continuous in the mobile sensing use case and that selected *DA* node will change at each iteration.

User identity protection: User's PDMS actively participate in the DEP either by receiving information (use case 2) or queries (use case 3) or by sending information (use cases 1 and 3). They thus communicate with *DA* nodes or receive messages from *TF* nodes, both being potentially corrupted. The reception / transmission task should be "isolated" to make one more step towards task atomicity. This can be achieved using the notion of proxy-forwarder that we illustrate for the *TN-DA* communication in the use case 3. The *TN* (which is actually a data source) must transmit its local result (e.g., number of sick leave days) to the *DA* node. *TN* can choose randomly any node *P* in the system and send the data, encrypted with the public key of the *DA* (known from the Verifiable Actor List). *P* will receive this data and transmit it to the *DA*. Thus, *DA* will have the data without knowing the sender, while *P* will know the sender but not the data. Note that (1) *TN* has good reasons to choose randomly *P* since it is the most interested in protecting its data; (2) the probability that both *DA* and *P* to be colluding nodes is extremely low ($\approx (C/N)^2$); and (3) we could use several proxies, thus mimicking anonymization network techniques (e.g., Tor).

6 RELATED WORK

DHT security. Several works focus on DHT security [40] considering the following attacks: (i) Sybil attack: an attacker generates numerous false DHT nodes to outnumber the honest nodes. Introducing an (offline) certificate authority, is deemed to be among the most effective defenses against the Sybil attack [11]. (ii) Routing table poisoning (eclipse attack): an attacker attempts to control most of the neighbors of honest nodes to isolate them. According to [40] the best strategy against such attacks is to constrain the DHT node identifiers. Again, using a central authority to provide verifiable identifiers is the simplest yet most effective way of achieving this goal [34]. (iii) Routing and storage attacks: Sybil and eclipse attacks do not directly impact the DHT, they are mainly necessary means for future attacks, like various denials of service (DoS). For instance, the objectives might be to prevent a lookup request from reaching its destination, denying the existence of a valid key, or impersonating another node to deliver false data. These DoS attacks are usually classified as routing and storage attacks and most of the mechanisms employed to negate them are based on redundancy at the storage and routing levels [40]. Thus, none of these works consider the secure and efficient actor selection for distributed processing as in SEP2P.

Secure Multi-party Computation and differential privacy. Cryptographic protocols have been proposed to protect the users' privacy in distributed computations with a focus on data confidentiality enforcement in personal data aggregation. Examples of computations related to this work are personal time-series clustering [2], kNN similarity queries [17], and location-based aggregate statistics [28]. However, MPC raises major scalability issues which in practice limit such protocols to specific types of computations [31].

Although it yields interesting results in privacy protection [15], differential privacy generally requires a central trusted aggregating node and ad-hoc adaptations depending on the targeted queries. As we search to provide a generic framework and exclude having a central actor to avoid a single point of failure, both requirements cannot be met by differential privacy. Even though local differential privacy [13] tries to address our first requirement, the solutions offered until now are still not generic, while the pertinence or the quality of the results may still be problematic with some applications [13]. Also, differential privacy exhibits intrinsic limitations with applications requiring continuous data flow aggregation (e.g., such as mobile participatory sensing) because of temporal correlation between consecutive data batches [10].

Distributed data aggregation using secure hardware. To overcome the limitations of MPC or differential privacy, several works propose using secure hardware at the user-side. Several secure protocols have been proposed for SQL aggregation [37], spatio-temporal aggregation [36], top-*k* full-text search [21], or privacy-preserving data publishing [3]. SEP2P also considers a secure PDMS at the user-side but our attack model considers having many colluding nodes. Moreover, the focus in SEP2P is on the secure and efficient random node selection. Differently, existing work focus on data aggregation or publishing and consider that all the nodes in the network participate in the protocol with their data being thus complementary to SEP2P.

Secure server-centric approaches. The above cited solutions are based on fully-distributed (P2P) or hybrid architectures. Alternatively, one could envision a solution based on a secured centralized server [6]. However, this raises important issues. First, users are exposed to sophisticated attacks, whose cost-benefit is high on a centralized database. Second, centralizing all users' data into one powerful server makes little sense in the PDMS context in which data is naturally distributed at the users' side. Hence, users might be reluctant to use such a massively centralized data service. Finally, new legislation such as the European GDPR [27] may hinder the development of such centralized solutions.

7 CONCLUSION

Personal Data Management Systems arrive at a rapid pace allowing users to share their personal data within large P2P communities. While the benefits are unquestionable, the important risks of private personal data leakage and misuse represent a major obstacle on the way of the massive adoption of such systems. This paper is one of the first efforts to deal with this important and challenging issue. To this end, we proposed SEP2P, a fully-distributed P2P system laying the foundation for secure, efficient and scalable execution of distributed computations. By considering a realistic threat model, we analyzed the fundamental security and efficiency requirements of such a distributed system. We showed that the secure selection of random actor nodes is the basis of security for any distributed computation. Then, we proposed secure and highly efficient protocols to address the actor selection problem. Our simulation-based experimental evaluation indicates that our protocol leads to minimal private information leakage, i.e., increasing linearly with the number of colluding nodes. At the same time, the cost of the security mechanisms depends only on the maximum number of colluding nodes and remains very low even with wide collusion attacks.

This work opens the way for several interesting research problems. In particular, to further minimize the impact of a private data leakage, the random actor selection needs complemented with task atomicity, i.e., decompose the computation process such that it minimizes the amount of sensitive data the processor nodes have access to. To underline this requirement, we discussed in this paper three types of representative applications in the PDMS context and provided sketches of solutions to achieve task atomicity. Certainly, this problem deserves a deeper look and constitutes our main objective as future work.

ABSTRACT

A key service in vehicular transportation is routing according to estimated travel times. With the availability of massive volumes of vehicle trajectory data, it has become increasingly feasible to estimate travel times, which are typically modeled as probability distributions in the form of histograms. An earlier study shows that use of a carefully selected, context-dependent subset of available trajectories when estimating a travel-time histogram along a user-specified path can significantly improve the accuracy of the estimates. This selection of trajectories cannot occur in a pre-processing step, but must occur online—it must be integrated into the routing itself. It is then a key challenge to be able to select very efficiently the "right" subset of trajectories that offer the best accuracy when the cost of a route is to be assessed. To address this challenge, we propose a solution that applies novel indexing to all available trajectories and that then is capable of selecting the most relevant trajectories and of computing a travel-time distribution based on these trajectories. Specifically, the solution utilizes an in-memory trajectory index and a greedy algorithm to identify and retrieve the relevant trajectories. The paper reports on an extensive empirical study with a large real-world GPS data set that offers insight into the accuracy and efficiency of the proposed solution. The study shows that the proposed online selection of trajectories can be performed efficiently and is able to provide highly accurate travel-time distributions.

1 INTRODUCTION

Vehicular transportation is an important global phenomenon that impacts the lives of virtually all of us. We rely on it for mobility, and we are affected by congestion, accidents, and air and noise pollution. Its influence can be expected to continue into the foreseeable future. For example, in the European Union alone, more than 75% of all freight transport and more than 80% of passenger transport rely on the road networks [8]. The availability of high-resolution GPS trajectories allows for reliable map-matching to a road network. The resulting trajectories are called *network-constrained trajectories* (NCT) and can be used to obtain travel-time estimates for paths in the network, thus making transportation more predictable, safe, and environmentally friendly.

When using such a data set, the most straightforward approach to computing a travel-time estimate for a path is to compute a real-valued estimate for each segment in the path and then sum up these to obtain an estimate for the full path. This approach can be refined by collecting travel-time histograms for each segment and then combine them by means of convolution to obtain a travel-time histogram for the full path. This improves the accuracy of estimates since travel times are better modeled as distributions than real valued. Further, the distributions often do not follow a parameterized distribution, e.g., normal or uniform, and are therefore better estimated with histograms. This segment level approach can also be extended to computing different histograms for different times of day, e.g., the 96 15-minute intervals of the day, to account for changing congestion throughout the day. These histograms can be used as edge weights by routing algorithms to compute better results. All of the above approaches, however, only consider travel-time estimates at the segment level. These approaches fail to take into account factors like the times it takes to pass through intersections, going straight or turning left or right, which are hard to model accurately. An earlier study [26] shows that travel-time estimates for a given path can be improved considerably when they are computed from trajectories that strictly follow the path, as opposed to computing them from segment-level estimates. This type of path-based estimate relies on efficiently processing *strict path queries* (SPQ) as proposed by Krogh et al. [14], which is a query on a trajectory set that only returns trajectories which traversed a given path without detours.

We propose a system that can compute time-varying and personal travel-time histograms for any path in a network based on a large trajectory set. It would be infeasible and impractical to pre-compute and store these time-varying and personal weights for any path in a network before routing occurs. For example, given even a moderately sized road network of a million segments, for all 15-minute windows, nearly a 100 million histograms would be needed to just cover every single segment, with the storage requirements increasing dramatically when considering larger path lengths. We therefore obtain the weights for a path on-the-fly by expressing them as a series of SPQs, which we can efficiently process using our in-memory NCT index. If any of these sub-queries fails to retrieve a sufficient number of matching trajectories, we apply a greedy algorithm that relaxes the SPQ's predicates until the retrieved trajectory set has a specified cardinality. Since performance is crucial in our setting, we also implement a cardinality estimator for SPQs to prevent unnecessary index traversals. We also show that carefully choosing the initial set of SPQs increases the accuracy of the path weights and increases the performance of the query. We perform extensive experiments using a real-world trajectory data set containing 1.4 million trajectories from Northern Denmark, which shows that our approach is suitable for real-time applications.

Series ISSN: 2367-2005 10.5441/002/edbt.2019.15

The main contributions of this paper are the following:

- An adapted NCT index that supports efficient computation of travel-time histograms for SPQs.
- A greedy algorithm that enables efficient processing of any SPQ in periodic time intervals.
- A cardinality estimator for SPQs.
- A detailed analysis of the accuracy and performance of the solution and its components.

The rest of the paper is structured as follows. Section 2 provides an overview of prior work, preliminaries, and a detailed problem description. Section 3 describes the query processing method, while Section 4 details the construction and use of the NCT index. Section 5 outlines the experimental setup and the evaluation metrics. Section 6 reports on the results of the experiments, and Section 7 concludes.

2 PROBLEM FORMULATION

This section provides an overview of prior work, preliminaries, and a problem definition.

2.1 Related Work

We review approaches to travel-time estimation and then, we review network-constrained trajectory indexing with a focus on indexes supporting SPQs.

2.1.1 Travel-Time Estimation. Earlier studies on travel-time estimation compute histograms for single segments [15], which still requires to model turn costs [27], or for short pre-defined paths with considerable traffic [4], which are then convolved at query time. In our approach, travel-times are computed for sub-paths instead of only for individual segments. This approach implicitly handles turn costs within sub-paths, and turn costs only need to be modeled explicitly in-between sub-paths if applicable. Other approaches based on tensor decomposition [25], support vector regression [28], variance-entropy-based clustering [29], or deep neural networks [24] have also been proposed. But they either do not provide travel-time distributions or do not provide estimates for specific paths but only for origin-destination pairs.

2.1.2 NCT Indexing. Several indexes for network-constrained trajectories based on R-trees [5, 6, 9] or B+-trees [20] have been proposed, but they are often only optimized for range queries or nearest neighbor queries.

Two indexes have been proposed to support strict path queries, NETTRA [14] and the SNT-index [12]. NETTRA is a disk-based index designed to answer SPQs with minimal I/O and also supports efficient updates of the index, but may return false positives due to hash collisions. The SNT-index uses data structures adapted from string matching to efficiently identify matching trajectories. This index was originally designed to retrieve all matching trajectory IDs in a given time interval that fulfill the SPQ requirement. We extend it to accommodate travel-time retrieval as well.

2.2 Network Graph & Trajectories

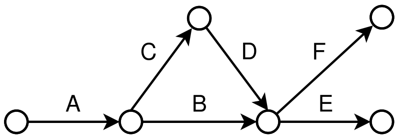

Figure 1: Example Road Network

Table 1: Example of $\mathcal{F}$ and Function *estimateTT*

e	*c*	*z*	*sl*	*l*	*estimateTT*
A	*motorway*	*rural*	110	900	29.5 s
B	*primary*	*city*	50	120	8.6 s
C	*secondary*	*city*	30	40	4.8 s
D	*secondary*	*city*	30	80	9.6 s
E	*primary*	*city*	50	100	7.2 s
F	*primary*	*rural*	80	800	36.0 s

A spatial network is modeled as a directed graph $G = (V, E, \mathcal{F})$, where V is a vertex set, $E \subseteq V \times V$ is a set of edges that represent road segments, and $\mathcal{F} : E \rightarrow Cat \times Z \times SL \times L$ is a set of functions, where Cat is the set of road categories, Z is the set of different types of zones the segments are located in, SL is the set of speed limits in kilometers per hour (or $\frac{1000}{3600}$ meters per second), and L is the set of segment lengths in meters. From this we can derive the function $estimateTT(e_i) = 3.6 \frac{\mathcal{F}(e_i).l}{\mathcal{F}(e_i).sl}$ that returns the traversal time in seconds if the segment is traversed at the speed limit. This function is used as a fallback so that we can return a result even if no data is available for a segment. Every edge $e \in E$ has a category that captures the road type of the segment it represents and a zone type describing its location. Figure 1 shows the graph representation of the road network we use in examples. Table 1 shows the mapping of each segment to categories $c \in Cat = \{motorway, primary, secondary\}$ and zones $z \in Z = \{city, rural\}$.

A traversable sequence of segments $P = \langle e_0, e_1, \ldots, e_{l-1} \rangle$ is called a path, with $|P| = l$. A sub-path $\langle e_i, \ldots, e_{j-1} \rangle$, with $0 \leq i < j \leq l$, of P is denoted as $P[i, j)$. The set of trajectories is given as $\mathcal{T} \subseteq \mathcal{D} \times \mathcal{U} \times \mathcal{S}$, where $\mathcal{D}$ is the set of all trajectory ids, $\mathcal{U}$ is the set of all drivers. Further, $\mathcal{S} : \mathbb{N}_l \rightarrow E \times \mathcal{TS} \times \mathcal{C}$ is the domain of functions from the set consisting of the first l natural numbers to the range of triples consisting of an edge $e \in E$, a timestamp $t \in \mathcal{TS}$, and a time duration $TT \in \mathcal{C}$. This domain of functions encodes finite sequences of length l.

A trajectory $tr \in \mathcal{T}$ of a user u with the id d is therefore denoted as (d, u, s), where $s \in \mathcal{S}$ is a sequence of 3-tuples:

$$s = \langle (e_0, t_0, TT_0), (e_1, t_1, TT_1), \ldots, (e_{l-1}, t_{l-1}, TT_{l-1}) \rangle,$$

where $t_0, .., t_{l-1}$ are the timestamps when a segment was entered with $\forall i \forall j (i < j \Rightarrow t_i < t_j)$, $TT_i > 0$ is the duration of the traversal of e_i, and l is the number of segments traversed.

The path of trajectory tr is called P_{tr}, and its starting time is $tr.t_0$. The duration function $Dur(tr, P) = TT_0 + TT_1 + \ldots + TT_{l-1}$ returns the sum of all segment traversal times a_{tr}^P of a path P by a trajectory. If a trajectory path P_{tr} does not contain P as a sub-path , $Dur(tr, P)$ is undefined. A trajectory set in our example road network from Figure 1 is shown below:

$$tr_0 : (0, u_1) \rightarrow \langle (A, 0, 3), (B, 3, 4), (E, 7, 4) \rangle$$
$$tr_1 : (1, u_2) \rightarrow \langle (A, 2, 4), (C, 6, 2), (D, 8, 4), (E, 12, 5) \rangle$$
$$tr_2 : (2, u_2) \rightarrow \langle (A, 4, 3), (B, 7, 3), (F, 10, 6) \rangle$$
$$tr_3 : (3, u_1) \rightarrow \langle (A, 6, 3), (B, 9, 3), (E, 12, 4) \rangle$$

2.3 Travel-Time Query

To address the shortcomings of the segment-level approach, we employ the strict path query $Q = spq(P, I, f, \beta)$ that returns a travel-time histogram H. The histogram can be derived from the traversal times of the set of trajectories $\mathcal{T}^P \subseteq \mathcal{T}$ that traverse path P without stops or detours in the time interval I, and fulfill additional filter predicates f:

$$\mathcal{T}^P = \{tr \in \mathcal{T} | \exists i, j \, (P_{tr}[i, j) = P \land tr.s.t_i \in I \land f(tr))\},$$

where $I = [t_s, t_e)$ denotes a temporal predicate with a size $\alpha = t_e - t_s$ and β is a cardinality requirement for $\mathcal{T}^P$, i.e., we only proceed if $|\mathcal{T}^P| \geq \beta$. If β is omitted all eligible trajectories are retrieved. The temporal predicate can either cover a fixed time interval, e.g., all trajectories from December 1st 2017 until May 1st 2018, or a periodic time-of-day interval denoted as $I^R = \langle \ldots, \left[t_s - 24\ hours, t_e - 24\ hours\right), \left[t_s, t_e\right), \left[t_s + 24\ hours, t_e + 24\ hours\right), \ldots, \left[t_s + n\ (24\ \ hours), t_e + n\ (24\ \ hours)\right)\rangle$, e.g., all trajectories from 8:00 until 8:30 on every day. Parameter f is an additional non-temporal filter predicate that trajectories in $\mathcal{T}^P$ have to fulfill, e.g., being from a specified driver.

Using such a query Q for a typical trip path, which can consist of dozens of segments, may not return a sufficient number of trajectories to derive accurate travel-time estimations. To address this problem, we split Q into k sub-queries $\langle Q_1, Q_2, \ldots, Q_k \rangle = \langle spq(P_1, I_1, f_1, \beta), spq(P_2, I_2, f_2, \beta), \ldots, spq(P_k, I_k, f_k, \beta) \rangle$ that return the trajectory sets $\{\mathcal{T}_1, \mathcal{T}_2, \ldots, \mathcal{T}_k\}$, where P_i are sub-paths that partition P. These can then be used to compute a set of k histograms $\{H_1, H_2, \ldots, H_k\}$ if $\forall i \, |\mathcal{T}_i| \geq \beta$. Their convolution we call $H = H_1 * H_2 * \ldots * H_k$, where $*$ is the discrete convolution operator and H is a travel-time histogram that covers the full path P. The intuition behind partitioning into k sub-queries is, that different sub-paths often provide better estimates with different predicates, e.g., user predicates mainly improve accuracy outside of cities [26]. Another advantage of partitioning the query is the increased number of eligible trajectories.

How this partitioning into sub-queries is performed and how the sub-queries are processed is discussed in Sections 3 and 4.

An example query for our example trajectory set could be $Q = spq(\langle A, B, E \rangle, [0, 15), u = u_1, 2)$. This would return $\mathcal{T}^P = \{tr_0, tr_3\}$ yielding a histogram with $H = \{[10, 11)\colon 1; [11, 12)\colon 1\}$ since $Dur(tr_0, \langle A, B, E \rangle) = 11$ and $Dur(tr_3, \langle A, B, E \rangle) = 10$. But if a larger cardinality is required, Q could be split into two queries $Q_1 = spq(\langle A, B \rangle, [0, 15), \emptyset, 3)$ and $Q_2 = spq(\langle E \rangle, [0, 15), \emptyset, 3)$ that yield the histograms $H_1 = \{[6, 7)\colon 2; [7, 8)\colon 1\}$ and $H_2 = \{[4, 5)\colon 2; [5, 6)\colon 1\}$, from which the convolution $H = \{[10, 11)\colon 4; [11, 12)\colon 4; [12, 13)\colon 1\}$ can be obtained.

3 QUERY PROCESSING

This section describes the architecture of the system, the processing of travel-time queries, and the greedy algorithm used for relaxing sub-query predicates.

3.1 Architecture

Figure 2 shows the overall system architecture, where boxes with dotted lines indicate pre-existing components, dashed lines indicate modified components, and solid lines indicate new components. At first, a GPS data set is map-matched off-line to trajectories and loaded into the modified SNT-index consisting of a collection of temporal indexes and a spatial index.

Once the trajectory set is loaded, a user is able to dispatch a strict path query Q to the `Sub-query Module` where the query is initially partitioned into k sub-queries by the `Query Partitioner` according to a simple heuristic called π, e.g., sub-paths of a fixed length, or sub-paths that have the same segment category. Each sub-query is then assigned temporal and trajectory filter predicates. Next, the `Cardinality Estimator` uses the `Histogram Store` and the `SNT-Index` to estimate the cardinality $\hat{\beta}$ of the trajectory set $\mathcal{T}_i$ returned by the sub-query $spq(P_i, I_i, f_i, \beta)$. If $\hat{\beta}$ is smaller than the desired cardinality β, the sub-query is modified by the `Sub-query Splitter` using a splitting function σ that relaxes the predicates. If the sub-query's cardinality estimate meets the requirement, it is dispatched to the index, and a trajectory set $\mathcal{T}_i$ is obtained. If $|\mathcal{T}_i| \geq \beta$, it is forwarded to the `Histogram Builder`. If the cardinality is still below the threshold, it is modified again by the `Sub-query Splitter`.

Once all trajectory sets $\{\mathcal{T}_1, \mathcal{T}_2, \ldots, \mathcal{T}_k\}$ are obtained, their travel-time sets $\{X_1, X_2, \ldots, X_k\}$ are extracted, with $X_i = \{Dur(tr, P_i) | tr \in \mathcal{T}_i\}$. From those, a set of histograms $\mathcal{H} = \{H_1, H_2, \ldots, H_k\}$ is computed, and they are convolved into a single histogram $H = H_1 * H_2 * \ldots * H_k$ that estimates the travel-time distribution for the complete path P.

3.2 Partitioning Methods

For the initial partitioning of queries, we propose five different methods. We use the query $Q = spq(P, I, f, \beta)$ with path $P = \langle A, C, D, E \rangle$ from the network in Figure 1 as example. The initial periodic time interval I_i^R is identical for all sub-queries and is always chosen so that $t_e - t_s = \alpha_{min}$, where α_{min} is the minimum time interval size, which is chosen by the system. The predicate f is also initially identical for all sub-queries but may be modified by the splitting method (cf. Section 3.3).

3.2.1 Regular (π_p). The regular partitioning creates sub-queries for paths of length p, i.e., every query is partitioned into $k = \lceil \frac{l}{p} \rceil$ sub-queries, i.e., the sub-queries $\pi_p(Q) = \langle spq(P[0, p), I_1^R, f_1, \beta), spq(P[p, 2p), I_2^R, f_2, \beta), \ldots, spq(P[p\lfloor \frac{l}{p} \rfloor, l), I_k^R, f_k, \beta) \rangle$ are created. In our experiments we chose π_1, π_2 and π_3, which for our example path yield the paths $\langle \langle A \rangle, \langle C \rangle, \langle D \rangle, \langle E \rangle \rangle$, $\langle \langle A, C \rangle, \langle D, E \rangle \rangle$, and $\langle \langle A, C, D \rangle, \langle E \rangle \rangle$, respectively.

3.2.2 Segment Category (π_C). The segment type partitioning creates partitions of sub-paths with identical segment categories, i.e., two neighboring segments e_i and e_{i+1} are split unless $\mathcal{F}(e_i).c = \mathcal{F}(e_{i+1}).c$. For our example query, this results in the sub-paths $\langle \langle A \rangle, \langle C, D \rangle, \langle E \rangle \rangle$.

3.2.3 Zone Type (π_Z). The zone type partitioning creates partitions of sub-paths within the same zone type, i.e., two neighbouring segments e_i and e_{i+1} are split unless $\mathcal{F}(e_i).z = \mathcal{F}(e_{i+1}).z$. For our example query, this results in the sub-paths $\langle \langle A \rangle, \langle C, D, E \rangle \rangle$.

3.2.4 Zone Type & Segment Category (π_{ZC}). The zone type and segment category partitioning creates partitions of sub-paths within the same zone type and segment category combination, i.e., two neighboring segments e_i and e_{i+1} are split unless $\mathcal{F}(e_i).z = \mathcal{F}(e_{i+1}).z \land \mathcal{F}(e_i).c = \mathcal{F}(e_{i+1}).c$. For our example query, this results in the sub-paths $\langle \langle A \rangle, \langle C, D \rangle, \langle E \rangle \rangle$.

3.2.5 None (π_N). No initial partitioning is attempted, and the query is processed according to one of the splitting strategies described below. For our example query, this results in the single sub-path $\langle \langle A, C, D, E \rangle \rangle$.

3.3 Splitting Methods

If a sub-query $spq(P, I, f, \beta)$ does not return the desired cardinality, it is modified by a splitting function σ described in Procedure 1 that takes a query and the list of time interval sizes $A = \langle \alpha_1, \ldots, \alpha_n \rangle$, with $\forall i \forall j \, (i < j \Rightarrow \alpha_i < \alpha_j)$, and $\alpha_1 = \alpha_{min}$ and $\alpha_n = \alpha_{max}$ as arguments.

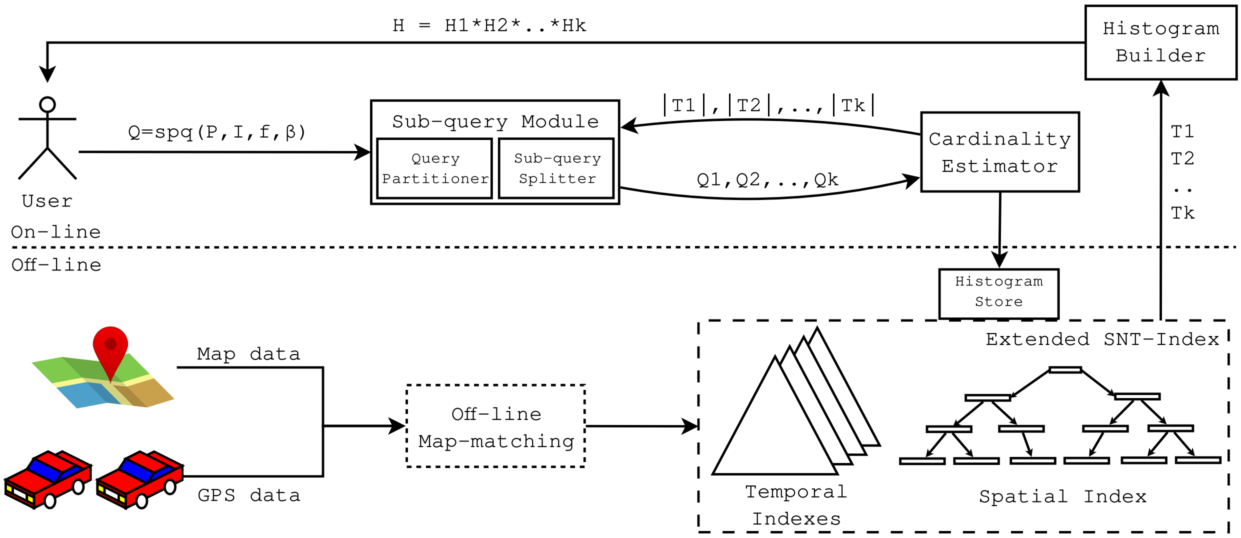

Figure 2: Overall Architecture

At first the procedure tries to increase the sample size by increasing the size of the time interval for the path by choosing the next largest size from the list A and widening the periodic interval with $widen([t_s, t_e)^R, \alpha_{i+1}) = [t_s - \frac{\alpha_{i+1}-\alpha_i}{2}, t_e + \frac{\alpha_{i+1}-\alpha_i}{2})^R$. After A has been exhausted, the path is split, and two new sub-queries with the smallest allowed time interval size α_{min} are created.

We propose two types of splitting and again use the path $P = \langle A, C, D, E\rangle$ in examples.

- σ_R Regular splitting cuts the path in half, i.e., $P_1 = P[0, \lfloor \frac{l}{2} \rfloor)$ and $P_2 = P[\lfloor \frac{l}{2} \rfloor, l)$, so splitting the example path P results in $P_1 = \langle A, C\rangle$ and $P_2 = \langle D, E\rangle$.
- σ_L Longest prefix splitting creates two sub-paths $P_1 = P[0, m)$ and $P_2 = P[m, l)$, with $1 \leq m < l$, where the maximum value for m for which $|\mathcal{T}^{P_1}| \geq \beta$ holds is chosen.

If a sub-path cannot be split further, any non-temporal filter predicates are dropped (Line 10). As a fallback, all temporal filters and the β parameter are dropped as well, i.e., for a single segment, all available trajectories are considered in the fixed time interval $[0, t_{max})$ (Line 12).

Procedure 1 Modify a sub-query *spq* to increase sample size (σ):

```
Input: Sub-query $spq(P, I, f, \beta)$, time interval sizes $A$
Output: a sequence of sub-queries $\langle Q_1, \ldots, Q_k\rangle$
1: $\alpha_i \leftarrow t_e - t_s$
2: if $\alpha_i < \alpha_{max}$ then
3:     $I'^R \leftarrow widen(I^R, \alpha_{i+1})$
4:     return $\langle spq(P, I'^R, f, \beta)\rangle$
5: else if $|P| > 1$ then
6:     $m \leftarrow split(P)$
7:     $I'^R \leftarrow shrink(I^R, \alpha_{min})$
8:     return $\langle spq(P[0, m), I'^R, f, \beta), spq(P[m, l), I'^R, f, \beta)\rangle$
9: else if $f \neq \emptyset$ then
10:    return $\langle spq(P, I^R, \emptyset, \beta)\rangle$
11: else
12:    return $\langle spq(P, [0, t_{max}), \emptyset)\rangle$
13: end if
```

4 THE INDEX

This section describes the SNT-index and how we adapt and optimize it to support travel-time queries using an example trajectory set.

4.1 SNT-Index

Koide et al. [12] proposed the SNT-index for strict path queries using the FM-index as a spatial index and a forest of B+-trees as a temporal index. The advantage of the FM-index over R-tree-based methods is that by representing the trajectory set $\mathcal{T}$ as a string T and adapting a method from substring matching, evaluating spatial queries is only dependent on the size of the spatial network ($|E|$) and not on the size of the trajectory set ($|\mathcal{T}|$). In addition, it can be established from just the FM-index whether a given path is traversed at all, often saving a costly temporal index traversal. While the original index returns a set of trajectory ids given the query $spq(P, I)$, where P is the path and I is a time interval, our index returns the traversal times of the trajectories for P, which can be stored in a histogram. Sections 4.1.1 and 4.1.2 recap the previously described SNT-index and the remaining section describes our modifications to it to facilitate the efficient retrieval of travel-times.

4.1.1 The Spatial FM-Index. For our example we are indexing the trajectory set $\mathcal{T} = \{tr_0, tr_1, tr_2, tr_3\}$ introduced earlier.

To index the trajectories, we first need to compute the trajectory string T from the alphabet $\Sigma = E \cup \{\$\}$ where the symbol \$ denotes the end of a trajectory and where $\forall e \in E\, (e > \$)$ and $T = P_{tr_0}\$P_{tr_1}\$\ldots\$P_{tr_{n-1}}\$, \forall tr \in \mathcal{T}$. With our example trajectory set, this yields the trajectory string $T = ABE\$ACDE\$ABF\$ABE\$$.

From this trajectory string, we compute an array S of all suffixes of T, where $S[i] = T[i, n)$, where $0 \leq i < n = |T|$. These suffixes are then sorted lexicographically to obtain the *suffix array SA* as shown in Figure 3, where $SA[j]$ contains the index of the j-th smallest suffix. From SA, we can then compute the *inverse suffix array ISA* where $SA[j] = i$ and $ISA[i] = j$ [17]. Every substring (or in our case, subpath) P of length l therefore has a range of ISA values $R(P) = [st, ed)$ that is defined as $R(P) = \{i \mid S[SA[i]]\,[0, l) = P\}$, e.g., the *ISA* range of the path $\langle A\rangle$ is $R(\langle A\rangle) = [4, 8)$ since four trajectories contain A and they

Figure 3: The Suffix Array and Burrows-Wheeler-Transform

Procedure 2 Calculate ISA range $[st, ed)$ for a path P of length l (*getISARange*):

```
Input: Burrows-Wheeler transform $T_{bwt}$ of the trajectory string
    $T$, symbol counts $C$, path $P = p_0 \ldots p_{l-1}$
Output: ISA range $[st, ed)$ that matches $P$
 1: $c \leftarrow p_{l-1}$
 2: $st \leftarrow C[c]$
 3: $ed \leftarrow C[c+1]$
 4: for $i \leftarrow 2$ to $l$ do
 5:     $c \leftarrow p_{l-i}$
 6:     $st \leftarrow C[c] + rank_c(T_{bwt}, st)$
 7:     $ed \leftarrow C[c] + rank_c(T_{bwt}, ed)$
 8:     if $st \geq ed$ then
 9:         return $[0, 0)$
10:     end if
11: end for
12: return $[st, ed)$
```

appear at the start of the suffixes $S[SA[st]]$ to $S[SA[ed-1]]$, and the range for $R(\langle A, B \rangle)$ is $[4, 7)$ as only three trajectories traverse this path.

The ISA range of a path can be obtained efficiently from two data structures that comprise the FM-index:

- C an array that stores the number of lexicographically smaller characters in the trajectory string for every member of the alphabet Σ, e.g., $C['B'] = 8$ since there exist 8 characters in T that are lexicographically before $'B'$.
- T_{bwt} the Burrows-Wheeler transform [3] of the trajectory string T that is defined as $T_{bwt}[i] = T[SA[i]-1]$, with $0 \leq i < |T|$. For our example, this yields the string *EFEE$$$$AAAA–CBDBB*.

We define the rank operation $rank_c(T_{bwt}, i)$ that counts the occurrences of the character c in $T_{bwt}[0, i)$. As an example of computing the ISA range, we compute the range for the path $P = \langle A, B \rangle$ as described in Procedure 2. At first, the segment $c \leftarrow B$ is set in Line 1, and $st \leftarrow 8$ and $ed \leftarrow 11$ are initialized in Lines 2 and 3. For the first (and in this case the only) iteration of the loop from Line 4 to 11, $c \leftarrow A$, $st \leftarrow 4 + rank_A(T_{bwt}, 8)$, and $ed \leftarrow 4 + rank_A(T_{bwt}, 11)$, which yields the ISA range $[4, 7)$, since the ranks are 0 and 3, respectively.

The Burrows-Wheeler transform is stored in a wavelet tree to enable rank queries in $O(log|\Sigma|)$ time [10]. Therefore, obtaining the ISA range $[st, ed)$ of any path P can be performed in $O(|P|\ log\ |\Sigma|)$ time, which does not depend on the size of T.

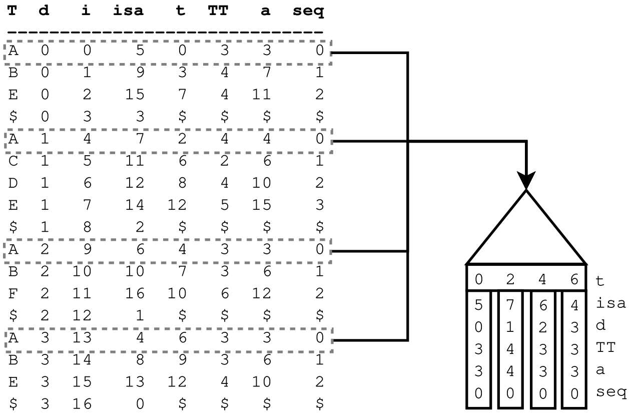
4.1.2 The Temporal Indexes. The temporal indexes $F = \{\Phi_e | e \in E\}$ contain a B+-tree for every segment in the network. Each tree indexes the records $r \in \Phi$ by the timestamp t when a trajectory entered the segment. A leaf node entry r for a timestamp t contains the ISA index (*isa*) and the trajectory identifier (d).

The original SNT-index is only capable of retrieving the trajectory ids, which would then have to be processed in turn to obtain the traversal times of the query path.

4.1.3 Extensions to the SNT-Index. To support travel-time histogram construction directly using the SNT-index, we add the following information to each leaf node in a temporal index:

- The traversal time TT of the segment in seconds.
- The sequence number *seq* of the segment in the trajectory.
- The sum of the travel-times $a_{seq} = \sum_{i=0}^{seq} TT_i$ from the start of the trajectory and up to and including the segment.

Figure 4 shows the contents of the temporal index Φ_A of segment A for our example trajectory set where each leaf is a record r, mapping a timestamp t to a tuple (isa, d, TT, a, seq). Furthermore, we add an associative container U that maps every trajectory id d to its respective user id u to check the filter predicate f. With those fields, we can build a hash table during the scan of the index of the first segment with the trajectory id and sequence number as the key (d, seq) and the aggregate of the preceding segment of the trajectory $(a_0 - TT_0)$, as value as described in Procedure 3. The sequence number is included to guard against



T	d	i	isa	t	TT	a	seq
A	0	0	5	0	3	3	0
B	0	1	9	3	4	7	1
E	0	2	15	7	4	11	2
$	0	3	3	$	$	$	$

3	4	3	3	a
0	0	0	0	seq

Figure 4: Extended Temporal Index

trajectories with circular paths. The spatial filtering is performed with the ISA range $[st, ed)$ obtained from Procedure 2 during the index scan in Line 3. The filter predicate f can be evaluated in constant time with the associative container U. The cardinality parameter β is used to reduce the processing time since not all eligible trajectories are necessary to obtain a good estimate, and the *buildMap* procedure terminates as soon as β trajectories are found (Line 6). When scanning the temporal index of the last segment in the query, we can obtain the traversal time of the query path by $a_{l-1} - (a_0 - TT_0)$ as described in Procedure 4.

4.2 Travel-Time Query

When used together, the previous three procedures make it possible to obtain the set of travel times for any path, as shown in Procedure 5, to answer the sub-query $spq(P, I, f, \beta)$. To obtain all trajectories that traversed a path P during a given time interval I, an ISA range is first obtained from the FM-index in Line 1. If a non-empty range is returned, a range scan on the index of the first (Line 6) and last segment (Line 11) of the path are performed for I and filtered by the ISA index in the leafs. If no matching trajectories exist or no periodic time interval with more than β trajectories is found (Line 7) the query returns the empty set. If the sub-query provided by Procedure 1 has a fixed time interval, the query is processed regardless of β. If that still yields no trajectories, an estimate based on the speed limit of the segment is provided (Line 13).

Procedure 6 shows how a full query is partitioned and processed. For longer trips, the periodic interval I_i^R is adapted with the shift-and-enlarge procedure (Line 4) suggested by Dai et al. [4], that shifts the beginning of the interval t_s by the sum of all previous minimums $S_i = \sum_{j=1}^{j=i-1} H_j^{min}$ and enlarges it by the sum of all previous ranges $R_i = \sum_{j=1}^{j=i-1}(H_j^{max} - H_j^{min})$.

4.3 Optimizations

4.3.1 CSS-Trees. The cache sensitive search tree (CSS-tree) proposed by Rao and Ross is a low memory overhead pointerless index that speeds up searches in sorted arrays [21]. In our system, we use it as an append-only replacement for the temporal B+-tree forest (cf. Section 4.1.2) to speed up Procedures 3 and 4 and to reduce memory consumption. Furthermore, its ability to efficiently compute the size of a key range in logarithmic time is used to improve the accuracy of the cardinality estimator (cf. Section 4.4). The CSS-tree is optimized to reduce the number of cache misses during a search by using the processor's cache line size as its node size. Since it indexes sorted arrays, only appends can be performed efficiently. We deem this an acceptable trade off because inserting additional trajectories would also require a re-computation of the entire FM-index, making the index mostly suited for batch updates.

Procedure 3 Create a mapping of trajectory identifier and sequence number (d, seq) to an antecedent travel time *diff* for the first β trajectories matching the predicates (*buildMap*):

```
Input: Temporal index $\Phi$ of the first segment of the query path,
    ISA range $[st, ed)$, time interval $I$, predicate $f$, and cardinality
    parameter $\beta$
Output: a mapping of $(d, seq)$ to $(a - TT)$
 1: $M \leftarrow \emptyset$
 2: for all $r \in \Phi$ do
 3:     if $r.t \in I \wedge st \leq r.isa < ed \wedge f(r.d)$ then
 4:         $diff \leftarrow r.a - r.TT$
 5:         $M \leftarrow M \cup \{(r.d, r.seq) \rightarrow diff\}$
 6:         if $|M| \geq \beta$ then
 7:             return $M$
 8:         end if
 9:     end if
10: end for
11: return $M$
```

Procedure 4 Compute the travel times for all eligible trajectories over the path identified in the *buildMap* function (*probeMap*):

```
Input: Temporal index $\Phi$ of the last segment of the query path,
    path length $l$, and probe table $M$
Output: a list of travel times $X$
 1: $X \leftarrow \emptyset$
 2: for all $r \in \Phi$ do
 3:     $b \leftarrow M[(r.d, r.seq + 1 - l)]$
 4:     if $b \neq \emptyset$ then
 5:         $X \leftarrow X \cup \{r.a - b.diff\}$
 6:     end if
 7: end for
 8: return $X$
```

Procedure 5 Retrieve all travel-times $X = \langle x_0, ..., x_{\beta-1} \rangle$ of trajectories in I that meet predicate f for a path P (*getTravelTimes*):

```
Input: Burrows-Wheeler transform of the trajectory string $T_{bwt}$,
    temporal indexes $F$, symbol counts $C$, path $P = p_0 ... p_{l-1}$,
    time interval $I$, predicate $f$, and cardinality parameter $\beta$
Output: a set of travel-times $X$
 1: $[st, ed) \leftarrow getISARange(T_{bwt}, C, P)$
 2: if $st \geq ed$ then
 3:     return $\emptyset$
 4: end if
 5: $\Phi_0 \leftarrow F[p_0]$
 6: $M \leftarrow buildMap(\Phi_0, [st, ed), I, f, \beta)$
 7: if $|M| < \beta$ and $isPeriodic(I)$ then
 8:     return $\emptyset$
 9: end if
10: $\Phi_{l-1} \leftarrow F[p_{l-1}]$
11: $X \leftarrow probeMap(\Phi_{l-1}, l, M)$
12: if $X = \emptyset$ and $|P| = 1$ then
13:     return $\{estimateTT(p_0)\}$
14: end if
15: return $X$
```

Procedure 6 Compute a histogram H for the query $spq(P, I, f, \beta)$ (*tripQuery*):

```
Input: Burrows-Wheeler transform of the trajectory string $T_{bwt}$,
    temporal indexes $F$, symbol counts $C$, query $spq(P, I, f, \beta)$,
    time interval sizes $A$, partitioning method $\pi$, and splitting
    method $\sigma$
Output: a histogram $H$
$\langle Q_1, \ldots, Q_k \rangle \leftarrow \pi(Q); \mathcal{H} \leftarrow \emptyset$
for all $Q_i \in \langle Q_1, \ldots, Q_k \rangle$ do
    if isPeriodic($I_i$) and $i > 1$ then
        $I_i \leftarrow [t_s + S_i, t_e + R_i)^R$
    end if
    $X_i \leftarrow$ getTravelTimes($P_i, I_i, f_i, \beta$)
    if $X_i \neq \emptyset$ then
        $\mathcal{H} \leftarrow \mathcal{H} \cup$ createHistogram($X_i$)
    else
        $\langle Q_{i+1}, \ldots, Q_k \rangle \leftarrow \langle Q_{i+1}, \ldots, Q_k \rangle \cup \sigma(Q_i)$
    end if
end for
$H \leftarrow H_1$
for all $i > 1 \wedge H_i \in \mathcal{H}$ do
    $H \leftarrow H * H_i$
end for
return $H$
```

4.3.2 Temporal Partitioning. Temporal partitioning of the SNT-index was originally proposed here [13], but not evaluated. It allows more efficient updates to the index without necessitating a complete re-computation of the FM-index which does not efficiently support updates or appends. Partitioning requires to split the trajectory set $\mathcal{T}$ into $\mathcal{T}_1, \ldots, \mathcal{T}_W$, where $\forall i < j \; (\nexists tr_i \in \mathcal{T}_i \; (\forall tr_j \in \mathcal{T}_j \; (tr_i.t_0 \geq tr_j.t_0)))$. From those trajectory sets, W trajectory strings $T^1, \ldots, T^W$ are then computed, and Procedure 2 is modified return a collection of ISA ranges from the Burrows-Wheeler transforms $T^1_{bwt}, \ldots, T^W_{bwt}$ using separate segment counters $C^1, \ldots, C^W$. Temporal partitioning also requires adding the partition identifier w to every leaf in the temporal indexes since every partition's FM-index can return a different ISA range for the same path.

4.4 Cardinality Estimator

Cardinality estimators are widely used in DBMSs to improve query plans. In our case, we want to avoid costly scans of our temporal indexes if the required sample size β cannot be met. We require a function $card(Q)$ that returns an estimate $\hat{\beta}$ for the cardinality of the return trajectory set $\mathcal{T}$ and if $\hat{\beta} < \beta$, we apply the split function σ to Q without running a costly query. The cardinality estimator relies on a time-of-day histogram for every segment and fast computation of the ISA range $[st, ed)$, which is enabled by Procedure 2. The exact count of all trajectories traversing a path $c_P = ed - st$ is efficiently retrieved. After that, the selectivity of the temporal filters needs to be estimated. The easiest way is to assume a uniform distribution throughout the day and to divide the size of a periodic interval by the length of the day, which yields the time-of-day selectivity:

$$sel_{tod} = sel(P, I^R = [t_s, t_e)^R) = \frac{t_e - t_s}{24 \; hours} \tag{1}$$

The uniformity assumption, however, usually does not hold so, the selectivity estimate can be improved by maintaining a time-of-day histogram H_e for every segment e. Then the selectivity can be estimated using the following formula:

$$sel(P, I^R = [t_s, t_e)^R) = \frac{B\big(H_{e_0}, [t_s, t_e)\big)}{B\big(H_{e_0}, [0, 24 \; hours)\big)}, \tag{2}$$

where $B\big(H, [t_s, t_e)\big)$ counts the elements of all buckets in H in the range $[t_s, t_e)$. In addition to being constrained by the time-of-day a user might wish to limit the query to a certain time frame, e.g., only considering trajectories within the past year. The selectivity can be estimated naively with the following formula:

$$sel_{tf} = sel(P, I = [t_s, t_e)) = \frac{t_e - t_s}{F[e_0]_{max} - F[e_0]_{min}}, \tag{3}$$

where $F[e_0]_{min}$ and $F[e_0]_{max}$ are the earliest and latest traversal times of segment e_0. When using the CSS-tree, the number of entries for which $t_s \leq t < t_e$ can be obtained exactly in logarithmic time and sel_{tf} can be computed exactly. To compute the selectivity of user predicates sel_u, we use the default of $\frac{1}{10}$ suggested by Selinger et al. [22]. To obtain the estimate for a query, we combine these selectivity factors to obtain our estimate $\hat{\beta} = sel_{tod} * sel_{tf} * sel_u * c_P$.

We define five different modes for the cardinality estimator:

ISA only uses the size of the ISA range c_P as estimate $\hat{\beta}$

BT-Fast uses formulas 1 and 3 to estimate the selectivity

BT-Acc uses formulas 2 and 3 to estimate the selectivity

CSS-Fast uses formula 1 and a fast lookup in the CSS-tree to estimate the selectivity

CSS-Acc uses formula 2 and a fast lookup in the CSS-tree to estimate the selectivity

5 EXPERIMENTAL SETUP

This section describes the data set and quality metrics we use to evaluate our system.

5.1 Datasets

5.1.1 OpenStreetMap. Our network graph is based on the OpenStreetMap data of the road network of Northern Denmark, which contains around 750,000 road segments. When converted to a spatial network graph, this graph has around 1.46 million directed edges [19]. Each edge represents a direction on a segment and has one of 17 different segment categories. This categorization is available for all OpenStreetMap maps and makes segment category-based partitioning possible for other map-matched trajectory datasets as well. The OpenStreetMap data also includes the speed limits for many segments, which we use as a fallback if no trajectory data is available. If the speed limit is not known, we use the median of all known speed limits of its segment category.

5.1.2 Zone Dataset. To distinguish rural and urban areas, we use the zoning map published by the Danish Business Authority [7] that consists of 4,259 zone geometries, each of which assigns one of three categories to an area:

- *city*: segments within city limits
- *rural*: segments in rural areas
- *summer house*: segments in areas zoned for summer house usage

A spatial join is used to assign a zone type to every segment in the map. A fourth category that we call *ambiguous* is assigned to segments located in more than one zone type.

5.1.3 ITSP Dataset. The "ITS Platform" dataset contains over 1.1 billion GPS points sampled at 1 Hertz collected from 458 vehicles in Aalborg and the surrounding region during the period from May 2012 to December 2014 [1].

In a preprocessing step, the GPS points are map-matched [18] to obtain in excess of 79 million segment traversals that form around 1.4 million trajectories, where a new trajectory is created if more than a 180 seconds have elapsed since the last GPS point. The map-matching algorithm also discards GPS points at the beginning and end of a trip if too few points are matched to the start and end segments of the trajectory. This is done so the durations of the segment traversals are meaningful. Each GPS record contains the trajectory ID, the vehicle ID, a segment ID, the time and date the segment was entered (minute resolution), and the time on segment (second resolution). Since the cars in our dataset are privately owned, we treat the vehicle ID as the user ID. The segment IDs are derived from the unique mapping of OpenStreetMap segment key and the driving direction. The time on a segment is also computed during the preprocessing step.

5.2 Query

We derive our query set $\mathcal{Q}$ from a random sample $\mathcal{T}_S \subset \mathcal{T}$ from our trajectory set:

$$\mathcal{Q} = \{spq(P_{tr}, I_{tr}, f, \beta) | tr \in \mathcal{T}_S\},$$

with either $f = \{u = tr.u\}$ or $f = \emptyset$ if no user filters are used and different values of β being used in the experiments. For the time interval I_{tr}, either the periodic time interval $I^R_{tr} = [tr.s.t_0 - \frac{\alpha_{min}}{2}, tr.s.t_0 + \frac{\alpha_{min}}{2})^R$ or or the fixed time interval $I_{tr} = [0, tr.s.t_0)$ is used.

For the interval size we use the values 15 *min*, 30 *min*, 45 *min*, 60 *min*, 90 *min*, and 120 *min*.

5.3 Accuracy Metric

5.3.1 sMAPE. To evaluate the accuracy of the retrieved traversal times, we use the symmetric mean absolute percentage error [2] of the sum of the means of all sub-paths.

$$\text{sMAPE} = \frac{100\%}{|\mathcal{Q}|} \sum_{i=1}^{|\mathcal{Q}|} \frac{|\sum_{j=1}^{k} \bar{X}_j - a_{tr_i}|}{\frac{1}{2}(\sum_{j=1}^{k} \bar{X}_j + a_{tr_i})},$$

where k is the respective number of sub-queries of each query $Q \in \mathcal{Q}$ and $\bar{X}_j$ is the travel-time mean retrieved with the sub-query.

5.3.2 Weighted Error. The weighted error, which we derive from sMAPE, considers the accuracy of the sub-query results and weighs them according to their fraction of the path length.

$$wE = \frac{100\%}{|\mathcal{Q}|} \sum_{i=1}^{|\mathcal{Q}|} \sum_{j=1}^{k} w_j \frac{|\bar{X}_j - a^{P_j}_{tr_i}|}{\frac{1}{2}(\bar{X}_j + a^{P_j}_{tr_i})},$$

with $w_j = \frac{\sum^{e \in P_j} \mathcal{F}(e).l}{\sum^{e \in P} \mathcal{F}(e).l}$, where P is the query path and P_j is the sub-query path.

5.3.3 Log-Likelihood. To evaluate the quality of the histograms, we compute the average log-likelihood of the travel-times a_{tr_i} with a discrete probability density function derived from the result histogram H_i.

For each trajectory with a result histogram H with a bucket width h, we compute the average log-likelihood $log\mathcal{L}$:

$$\frac{1}{|\mathcal{Q}|} \sum_{i=1}^{|\mathcal{Q}|} log\mathcal{L}(a_{tr_i}, H_i),$$

where the likelihood $\mathcal{L}(x, H)$ is defined by the discrete probability density function

$$p_H(x) = \gamma f(x, H) + (1 - \gamma)U(x),$$

where $U(x)$ is a uniform distribution defined for $[t_{min}, t_{max})$, $0 < \gamma < 1$ and

$$f(x, H) = \frac{B\big(H, [\lfloor \frac{x}{h} \rfloor, \lfloor \frac{x}{h} \rfloor + h)\big)}{B(H, [t_{min}, t_{max}))}.$$

The smoothing with the uniform distribution $U(x)$ is performed so that $p_H(x)\ \forall x \in [t_{min}, t_{max})$ never reaches zero.

5.3.4 Q-Error. To evaluate the accuracy of the cardinality estimator, we use the q-error proposed by Moerkotte et al. [16]. To estimate the quality of our cardinality estimate $\hat{\beta}$, we compare it to the actual cardinality of the retrieved trajectory set $n = |\mathcal{T}|$. For every estimate, we obtain the q-error $q = max(\hat{\beta}'/n', n'/\hat{\beta}')$ with $n' = max(n, 1)$ and $\hat{\beta}' = max(\hat{\beta}, 1)$. This is done to handle estimations for empty sets as proposed by Stefanoni et al. [23]. The q-error shows the difference in orders of magnitude between the real cardinality and the estimate.

6 EVALUATION

This section reports on the experimental results. For all experiments, a query set $\mathcal{Q}$ is generated from the trajectory set $|\mathcal{T}_S| = 6{,}942$, which is a random 1% sample of all trajectories in $\mathcal{T}$ that occur after the 8th of September 2013, the median of the timestamps in the ITSP data set. This is to ensure that every query has more than a year of trajectory data available. On average, the paths of the query set have a length of 13.7 kilometers, consist of 55 segments, and last 800 seconds.

In our study we evaluate three types of queries:

Temporal Filters that use a periodic time interval and no user filter ($spq(P_{tr}, I^R_{tr}, \emptyset, \beta)$)

User Filters that use a periodic time interval and a user filter ($spq(P_{tr}, I^R_{tr}, \{u = tr.u\}, \beta)$)

SPQ Only that use a fixed time interval and no user filter ($spq(P_{tr}, [0, t_{max}), \emptyset, \beta)$)

6.1 Qualitative Assessment

Figures 5 to 8 show the results of accuracy measured with sMAPE, the weighted error, and the log-likelihood and the average sub-query length. The figures show the results for different types of partitioning and splitting methods and filter predicates.

The regular partitioning method π_p (cf. Section 3.2.1) is used as a baseline with $p = 1, 2,$ and 3 because they are the sub-path lengths for which histograms can still be pre-computed at a reasonable overhead and because no known histogram-based methods perform better. For the user filter queries, we also evaluate the π_{MDM} method that partitions queries like π_C but only applies user filters to sub-queries with paths on main roads like motorways or other major roads connecting cities. This partitioning method is derived from the results of a previous study of travel-time estimation methods [26].

Figure 5a shows the average error for seven different partitioning methods with temporal filters. Here, π_1 performs worst, followed π_2 and π_3, and they achieve their highest accuracy at $\beta = 30$. If only the speed limits are used to estimate the travel time, sMAPE is 34.3% and if all available trajectories for each segment are used, the error is 13.8%. The partitioning methods based on the segment category and/or zone (π_C, π_Z, and π_{ZC})

together with π_N achieve very similar accuracy. Here, the accuracy peaks at $\beta = 20$. Category-based partitioning is the most stable in terms of accuracy, and zone-based partitioning provides the overall best result. The queries using user filters shown in Figure 5b perform equally well, but with the exception of π_Z do not degrade as much with higher values of β and also obtain their lowest error at $\beta = 20$ and exhibit very similar accuracy to the queries without user filters. The SPQ Only methods in Figure 5c methods did not manage to outperform the baseline because it does not use periodic intervals that can observe changing congestion, e.g., longer travel-times during rush hours. In nearly all cases with regular splitting (σ_R) achieves considerably better accuracy than longest prefix splitting (σ_L). In most cases

A similar picture to the sMAPE results can be seen for the temporal filter queries in Figure 6a, with π_N having the lowest weighted error. If only the speed limits are used to make an estimate, the weighted error is 36.9%, and if all available trajectories for each segment are used, the error is 24.0%. For the user filter queries in Figure 6b, only π_{MDM} manages to consistently outperform the baseline. The SPQ only queries shown in Figure 6c show the lowest error with the coarsest partitioning methods. The low error of the SPQ only methods is due to sub-query results being weighted according to the length of the sub-paths and not relative to the share of travel time. Estimates for paths on long segments with high speed limits, e.g., motorways, exhibit already low estimation errors and also tend to improve the most when custom predicates are used [26]. In all cases, σ_L has a higher error than σ_R. Figure 7 shows the average path lengths of the final sub-queries. We can see that there is an inverse relationship between the weighted error and the sub-query paths. We can also see that π_Z provides the coarsest partitioning with the exception of π_N, which initially provides none.

Figures 8a to 8c show the average log-likelihood with $f(x, H)$ derived form a histogram with a bucket size of $h = 10s$ and different values for β and $\gamma = 0.99$. The queries with only temporal filters and π_Z and π_{ZC} return the most accurate histograms, and the coarser the partitioning method the less accurate the histograms are with low sample sizes. Among the User Filter queries π_{MDM} consistently outperforms the other three partitioning methods. The queries run with π_N do not even outperform the baseline for $\beta < 30$. In all cases, σ_L performs worse than σ_R. We evaluated several values for γ (from 0.90 to 0.99) but the qualitative results did not change.

6.2 Efficiency

The index is implemented in C++17 and compiled with g++ 7.2.0 with the `-O3 -march=native` flags. For the performance test, the SNT-index with a CSS-forest and only a single partition is used. The FM-index is implemented using `sdsl-lite`'s integer-alphabet Huffman-shaped wavelet tree implementation, and the suffix array is computed with Yuta Mori's `sais-lite` library [17]. The performance test ran on a server with AMD Opteron 6376 processors and 512 GiB RAM. For the processing time, the average runtime in milliseconds of 6,942 queries is reported in Figure 9.

The temporal filter queries shown in Figure 9a perform very similar to the baseline, with π_C and π_{ZC} being slightly faster than regular partitioning. The combination of π_C and σ_L has been omitted in the figure for reasons of scaling since the results are in the range of 50 to 65 ms. In Figure 9b, it can be seen that the average user filter query takes around 4 to 5 times longer than the temporal filter queries; and with π_{MDM}, queries only take around twice as long since it applies non-temporal predicates only selectively. SPQ only queries have much lower processing times than do the other two query types, and all consistently outperform the baseline. The reason for their low processing times can be seen in Figure 7c and Procedure 5. Since their sub-queries tend to cover comparatively long paths, SPQ only queries need to perform considerably fewer temporal index scans than the other query types, which need to be split into more sub-queries to fulfill the cardinality requirements. The average runtime of π_N with σ_L, which is between 30 to 35 ms, has been omitted in Figure 9c. In all cases σ_L performed poorly in comparison to σ_R.

6.3 Temporal Partitioning

Figure 10 shows the effect of the temporal partitioning defined in Section 4.3.2 on memory consumption and setup time. The figures show the results for partition sizes of 7, 30, 90, and 365 days, resulting in a 138, 33, 11, and 3 partitions, respectively. We also examine the case where only one partition is used (FULL). Where applicable, the performance of the index with a B+-forest (BT) is reported as well. For the in-memory B+-trees, we use the `btree_multimap` from Google's `cpp-btree` library [11]. Figure 10a shows the memory consumption of the different index components, where *Forest* is the memory consumption of the CSS-tree or B+-tree forest, respectively. The size of the forest is not impacted by different partition sizes, but if the partition feature is removed from the index, the memory saved in the tree leafs by omitting the partition identifier w is around 300 MiB for our data set. We can also see that the in-memory B+-tree forest has slightly higher memory requirements than the CSS-forest. The associative container U used to enable user filtering (user) is also not affected by the partitioning and takes up around 65 MB for our data set. The two data structures that comprise the FM-index, the wavelet tree (WT) and the segment counter (C), are affected considerably by partitioning. The segment counter grows linearly with the number of partitions from less than 6 MB to nearly 600 MB since a separate segment count needs to be maintained for every wavelet tree. The compression rate of the wavelet tree degrades considerably with smaller trajectory strings, which for the 7 day partitioning are only a few MBs per partition as opposed to several hundred in a single partition and it grows from around 280 MB to over 4 GB. The memory requirements of the time-of-day histograms required for the cardinality estimator are affected considerably if a histogram is maintained for every non-empty partition for every segment, and the memory required for the histograms soon exceeds the amount required for the index. Figure 10b shows the memory consumption for three different bucket sizes h (1, 5, and 10 minutes).

The setup times for the index shown in Figure 10c are not significantly affected by the different partition sizes or tree types and always remain between 425 and 475 seconds. For the setup, the trajectory and map data are loaded from disk.

6.4 Cardinality Estimator

Figure 10 shows the results for the cardinality estimator. In all cases the results for partitioning method π_Z with regular splitting and $\beta = 20$ are shown. Figure 11a shows the q-error of the five different cardinality estimator modes. Here, 5,000 queries are run, after which their cardinalities n are compared with estimate $\hat{\beta}$. The simplest estimate using just the ISA range is on average off by an order of magnitude. The four other modes provide considerably more reliable estimates, with the histogram

based methods performing better than the fast ones and the CSS-tree based methods performing slightly better than their B+-tree counterparts.

Since the selectivity estimates of the estimators might underestimate cardinalities of queries, a query might be split despite covering a sufficient sample size. This may affect the quality of the overall travel-time estimate. Figure 11c, however, shows that the effects on quality are minuscule compared to the baseline (ISA) and might even yield slight improvements in accuracy.

Figure 11b shows that partitioning as well as using the cardinality estimators can impact performance significantly. For single, yearly, and quarterly partitions, the query performance changes little, and use of the cardinality estimator reduces query processing times by around 50%. For smaller partitions, however, the effects of using the cardinality estimator diminish; and with weekly partitioning, the B+-tree version of the index performs worse with the estimators. The histogram-based CSS-tree version (CSS-Acc) performs worse than the fast version (CSS-Fast), which is most likely due to the amount of time-of-day histograms that have to be scanned to obtain the selectivity sel_{tod}.

6.5 Implications

Overall our data shows that after a certain β is reached no significant gains in accuracy are obtained by increasing it further indicating smaller result sets obtained from fewer SPQs of long paths provide more accurate estimates than larger result sets obtained with short paths. One can also see that evaluating non-temporal predicates comes with a considerable overhead and for the user predicates provides no improvement in quality over the purely temporal methods. If such methods are however applied selectively (e.g. π_{MDM}) the performance overhead is mitigated and the accuracy improves. The naive regular splitting method does not only achieve better accuracy but also has a considerably shorter runtime, making it more suitable for a real-time queries. The CSS-tree version of the index is as least as fast or faster than the B+-tree-based version, but the improvements become less noticeable when using the index in conjunction with a cardinality estimator. CSS-trees reduce the memory consumption of the index as well and improve the accuracy of the cardinality estimator with their efficient range lookups. We have also shown that temporal partitioning of the index is viable in some cases, but that using time-of-day histograms to estimate the selectivity of periodic time intervals, despite slight improvements in estimator accuracy and query performance, is hardly worth the memory overhead for the evaluated data set. Additional experiments with larger data sets may offer additional insight into this trade off, but no larger trajectory data sets with user information were available to us. Our results show that modifications aimed at improving query performance often also improve the accuracy of the estimates.

7 CONCLUSIONS & OUTLOOK

Travel-time estimations in road networks can be improved considerable by utilizing large NCT data sets not only to provide estimates on a segment level, but also for full paths in the network. To our knowledge no current system supports these path-based estimations which cannot rely on pre-computations. We therefore propose a system that computes travel-time estimations based on trajectories selected at runtime and is able to improve upon the accuracy of existing histogram-based methods by expressing them as a series of strict path queries and adapting their predicates automatically to ensure accurate estimates. The SPQs are processed by our adapted SNT-index which is able to retrieve the traversal times for any path directly from the index. We have shown that the queries can be processed fast enough for real-time applications by utilizing specialized in-memory data structures and cardinality estimators tailored to SPQs. We evaluate our system with a large real-world trajectory data set and find that optimizing queries for performance is not preclusive of accuracy.

Our proposed system leaves several avenues of future work. The current greedy algorithm used for identifying a suitable partitioning and splitting of an SPQ is based on fairly simple heuristics and could be augmented by more sophisticated machine learning methods to improve accuracy of estimations. Approaches that use different values of the parameter β for each sub-query, e.g., smaller sample size requirements in rural zones, could be evaluated. While the processing time of single query might not considerably improve through parallelization the overall query throughput of the system most likely could, making it suitable for online routing applications that support a large number of users. Our approach also does not fully address the issue of data sparseness apart from providing relaxing the predicates if their selectivity is too low. Several approaches to solving the problem of data sparseness have been suggested [25, 30] and could be combined with our system to provide time-dependent travel-time estimates for paths where data is sparse.

ABSTRACT

We present the BB-Tree, a fast and space-efficient index structure for processing multidimensional read/write workloads in main memory. The BB-Tree uses a k-ary search tree for pruning and searching while keeping all data in leaf nodes. It linearizes the inner search tree and manages it in a cache-optimized array, creating the need for occasional re-organizations when data changes. To reduce the frequency of such re-organizations, the BB-Tree introduces a novel architecture for leaf nodes, called bubble buckets, which can automatically morph between different representations depending on their fill degree and are thus able to buffer a large number of insertions or deletions in-place. We compare the BB-Tree to scanning, main-memory variants of the R*-tree, the kd-tree, and the VA-file, and the recent PH-tree using different multidimensional workloads over real and synthetic data sets. The BB-Tree is the fastest access method for range queries up to a selectivity of around 20% (after which it is only beaten by scanning), the fastest method in read/write workloads, and achieves an exact-match query performance similar to that of the best point access method. In addition, it is the most space-efficient method of all considered index structures. We also describe a parallel range query operator and show that it scales with the number of physical cores.

1 INTRODUCTION

Many data sets are inherently multidimensional, with typical dimensionalities ranging from two to a few dozen. We give three examples: (1) Precision Medicine is based on the comparison of a patient's mutational landscape to that of background populations and disease cohorts. Each mutation is a multidimensional object [13], with dimensions like genomic location, type of the mutation, prevalence in a population, functional impact, etc. Oncologists query such data seeking for mutations with certain properties to discover commonalities across diseases or treatment results [21]. (2) In modern machine surveillance, a battery of sensors measure multiple properties of parts of engines, such as temperature, vibration, electric currents, humidity, accelerations in all three spatial dimensions, etc. Analyzing such data for specific events or situations often induces executing series of multidimensional range queries (MDRQ) [20]. (3) In data warehousing, commercially relevant events are described by multiple, often hierarchically organized dimensions, leading to the famous OLAP cube [11]. Slicing such a cube, i.e., selecting (aggregated) events based on values of certain dimensions, often boils down to MDRQ, for instance selecting all sales in a certain date and price range.

Searching multidimensional data can be sped up by using multidimensional index structures (MDIS). MDIS can support different types of queries; in this work we focus on range queries over all (complete-match MDRQ) or a subset of the dimensions of a data space (partial-match MDRQ). MDIS are different from one-dimensional index structures because they cannot exploit a natural sort order in the data. Especially partial-match queries require MDIS to treat all dimensions equally, which typically is achieved by building and maintaining some, often hierarchical, structure on top of the data [26]. Navigation of such a structure necessitates inefficient random access patterns, which quickly leads to the situation that MDIS are outperformed by scans when queries are less selective, irrespective of whether data are held on disk [34] or in main memory [28]. The aim of this research is thus to create an MDIS that can efficiently support exact-match and range queries, that has low memory overhead, that performs gracefully in mixed read/write workloads, that is robust against the dimensionality of the data (up to a certain point) and that is faster than scans even for less selective queries.

In this paper, we present the BB-Tree, a novel main-memory MDIS which fulfills these requirements. Conceptually, a BB-Tree is an *almost-balanced* k-ary search tree, where inner nodes recursively split the data space into k partitions according to a delimiter dimension and $k-1$ delimiter values. Data objects are stored in leaf nodes (buckets). When too many data points are inserted (or deleted) and buckets overflow (or underflow), the structure is rebuilt to achieve a balance that is beneficial regarding the depths of leaves. Within this general and well-known layout, the BB-Tree combines a number of advanced techniques that yield its superior performance.

As the main contribution, BB-Trees introduce elastic buckets, called *bubble buckets* (BB), that can efficiently handle strongly fluctuating bucket fill degrees and that significantly reduce the frequency of index rebuilds. BB automatically morph between different representations, depending on their number of stored data objects. We distinguish between *regular* and *super* BB. Regular BB can hold up to b_{max} data objects and are implemented using arrays. Super BB are composites and consist of a routing node and a set of up to k regular BB, hence, they locally add a further level to the tree. BB can dynamically grow and shrink: Overflowing regular BB let them morph into super BB, and underflowing super BB let them morph back into regular BB. Both operations leave the rest of the BB-Tree unchanged. Since overflows create k new leaf buckets, a BB can cater for a rather large number of inserts. Eventually, the tree must be rebuilt when a super BB overflows. In workloads with *hammered* inserts, i.e., series of insertions into the same small region of the space, BB help to significantly reduce the number of rebuilds and thus greatly improve the performance of writes with only minimal influence on query performance though a locally slightly deeper tree.

BB help to keep the inner search tree (IST) of the BB-Tree stable over long periods of data changes, which enables an adaptation of the inner nodes to cache lines, the basic unit of data transfers between main memory and on-die CPU caches. We always choose k depending on how many delimiter values fit into one cache line to improve cache line utilization. For instance, when implementing delimiter values with four-byte floats and running on a machine with 64-byte cache lines, k is set to 17. Furthermore, we store the inner nodes of the BB-Tree in a flat and static array to avoid pointer chasing during search, to decrease random access patterns, and thus to reduce cache misses, especially at the last cache level. Typically, such an optimization either makes the index structure completely static [15, 27] or creates the need to manage delta stores [19, 23]. In contrast, BB-Trees manage all changes in-place and also can, due to the separation between the IST and the leaves and due to the concept of BB, manage a large number of updates without index rebuilds. Additionally, eliminating pointers improves space efficiency.

We furthermore describe and evaluate a special technique for the parallelization of MDIS queries, which effectively avoids complicated data partitioning. In the parallel range query operator, search queries are evaluated by first navigating the IST to determine all buckets that may hold matching data objects. This step is performed by a single thread as the tree, due to its high fan out, is quite low even for very large data sets. In the next step, which strongly dominates the runtime of queries, all qualifying BB are scanned in parallel. As a result, the performance of the parallel range query operator scales with the number of physical cores.

In a comprehensive evaluation, we compared the BB-Tree to sequential and parallel scans and to four other MDIS, namely the recent PH-tree [35], and main-memory adapted variants of the R*-tree [12], the kd-tree [4], and the VA-file [34]. We used different real and synthetic data sets of different sizes with dimensionalities between three and 100. We evaluated complete-match and partial-match range and exact-match queries, and also considered mixed read/write workloads. The BB-Tree is the fastest method for range queries up to a selectivity of around 20% after which it is only outperformed by a scan. For exact-match queries, the BB-Tree is almost as fast as the best point access method, the PH-tree; for more than ten dimensions it even shows a superior performance. It is the fastest MDIS regarding insertions and the overall fastest method regarding deletions. Its performance is virtually unaffected by the dimensionality of the data. The BB-Tree has the best space efficiency among all MDIS, an important property for in-memory data structures.

A preliminary version of this work will appear in [29]. Here, we extend [29] by dynamic updates, parallel execution of range queries and provide extended experiments.

2 RELATED WORK

We structure our discussion of related work into two parts: (1) Main-memory indexing and (2) multidimensional indexing.

Main-Memory Indexing. The recent focus on main-memory database systems led to the development of several main-memory index structures. A popular example is the adaptive radix tree (ART) [18], designed for efficient execution of exact-match queries especially over longer keys. However, ART does not support multidimensional data and executing range queries requires a costly traversal of its radix tree. The cache-sensitive skip list [30] is a main-memory index focussing on range queries. It uses a CPU-friendly data layout aligned with the sizes of cache lines, a technique that was previously suggested by other one-dimensional index structures, such as FAST [15] or the KISS-Tree [17]. Schlegel et al. [27] showed how to linearize k-ary search trees in a read-only in-memory setting, a technique we also use for the BB-Tree. We introduced bubble buckets to handle updates efficiently. None of the aforementioned index structures is able to index multidimensional data for partial-match range queries.

Multidimensional Indexing. MDIS have been researched for decades, leading to a multitude of different methods [10].

One of the most popular MDIS is the kd-tree [4], which organizes multidimensional point objects in a binary search tree by splitting the data space at each node using one of the dimensions as delimiter. It is integrated into several mature database systems, e. g., PostgreSQL[1]. K-D-B-trees [25] combine the concepts of B-trees [2] and kd-trees to optimize I/O behaviour. Quadtrees [9] are similar to kd-trees, but split the space in all dimensions at each node, which is less efficient for high dimensionalities. The Vector Approximation-file (VA-file) [34] is a mixture between an MDIS and a sequential scan that divides the space into cells of equal size using hash functions to allow for efficient pruning. All of these approaches were originally developed for disk-based data storage but can be adapted to main-memory settings [28]. Only the K-D-B-tree keeps its structure balanced when data changes, whereas the VA-file is an essentially immutable index. A recent main-memory based MDIS is the PH-tree [35], which integrates the concepts of PATRICIA-tries and hypercubes.

The R-tree [12] is probably the most prominent access method for handling spatially extended objects, but is also frequently used for storing point objects [14]. It uses minimum bounding rectangles (MBR) to represent all objects belonging to a certain subtree. These MBR are used for pruning. The R*-tree [3] is an R-tree variant that improves partitioning by aggressively reinserting data objects leading to a more efficient search performance. It is employed by several database systems to manage spatial data, e. g., SQLite[2]. PR-trees [1] optimize I/O in disk-based systems, and X-trees [5] target data of very high dimensionality. The CR-tree [16] is an R-tree variant that compresses inner nodes to pack more entries into MBR, which increases space and cache efficiency. Recently, Qi et al. [24] proposed a novel R-tree packing technique that provides asymptotically optimal I/O search complexity. However, their technique is restricted to static data and requires a complete reconstruction of the index with every update. Accordingly, the latter three approaches are not directly relevant for our work.

There also exist a number of interesting works, which are further away from our own research. Wang et al. [32, 33] exploit the characteristics of observational data, e. g., immutability, continuous dimension values, and append-only insertions, to achieve high query efficiency. In contrast, the BB-Tree is a general-purpose MDIS that supports updates in any order. ELF [6] executes multi-column selection predicates on in-memory data, but requires delta stores to handle updates.

3 THE BB-TREE INDEX STRUCTURE

In a nutshell, a BB-Tree is a main-memory optimized MDIS for point data. It combines the pruning power of an *almost-balanced* k-ary search tree with the efficiency of scans in main memory.

Notation	Description
n	Size of the data set.
m	Dimensionality of the data set.
h	Tree height.
k	Inner nodes split the space into k subparts according to a delimiter dimension and $k-1$ delimiter values.
t	Number of available hardware threads.
B_{match}	Number of bubble buckets that need to be scanned to evaluate a certain range query.

Parameter	Description
b_{max}	Capacity of a regular bubble bucket.
$R_{samples}$	When reorganizing the inner search tree, we use $R_{samples}\%$ of all data as samples.

Table 1: Frequently used notations and input parameters.

The inner search tree (IST) is linearized and stored in a cache-optimized yet immutable array. Data objects are stored in special leaf nodes, the bubble buckets (BB), which are able to digest a large number of insertions or deletions without affecting the IST and without hurting the tree balance considerably. Nevertheless, in case of long series of hammered inserts or deletions, the BB-Tree must be rebuilt to keep its balance. In this case, the structure of the novel tree is determined using random sampling. In the following, we describe the different components and techniques of the BB-Tree in detail; Table 1 summarizes our notation.

3.1 Data Organization

A BB-Tree consists of two components: A k-ary search tree and a set of bubble buckets. Inner nodes of the search tree recursively split the data space into k disjoint subsets according to a delimiter dimension and $k-1$ delimiter values. All data are kept in BB, which initially hold up to b_{max} m-dimensional data objects, but can dynamically expand and shrink to cope with varying number of objects in the region they represent. When searching in a BB-Tree, the inner nodes are navigated to reduce the data space. Once all certainly irrelevant regions (or subtrees) have been pruned, the remaining BB are scanned to determine the true query results.

Inner search tree. The entire IST is implemented as a single, immutable array. This has several advantages: (1) Cache lines are the basic unit for transferring data between main memory and CPU caches. By choosing an appropriate value for k, the BB-Tree tailors its inner nodes to the individual cache line size of the CPU, which increases cache line utilization and reduces the amount of data transferred through the cache hierarchy. (2) Using a single dense array for representing a balanced IST makes pointers superfluous. Array indexes of child nodes are calculated in constant time based on the current tree level and the fan out k. The BB-Tree linearizes inner nodes in a breadth-first order, which reduces memory pressure and increases cache efficiency during traversals. (3) By using an array representation, searching a specific delimiter value within an inner node (as necessary during searching) can be efficiently implemented using a binary search, which requires only $log_2(k-1)$ instead of $(k-1)$ comparisons. Note that all these accesses occur within a single cache line, which means that they do not produce any cache miss.

Leaf nodes. All data objects are stored in bubble buckets. The elasticity property of BB is described in Section 3.2. For now, we assume that every BB has a maximum capacity of b_{max} objects. b_{max} is an important parameter of the BB-Tree as it determines, at query time, the balance between time spent in tree searching, resulting in pruning, and time spent in scanning, producing the query results. A high value leads to large leaf nodes storing more objects, which in turn requires less inner nodes and thus a less deep tree. Such a structure is preferable for less selective query workloads: More work is put on scans where the comparison of the data objects with the query lead to many matches, whereas less time is spent in pruning which, for less selective queries, is not effective anyway. In contrast, a lower BB capacity results in smaller leaf nodes and a deeper tree structure, which is beneficial for highly selective queries as more time is invested in successful pruning and less in scans producing almost no matches.

Delimiter values. For a good search performance, it is crucial that delimiters allow to prune subtrees and non-relevant BB as early as possible. When being rebuilt, BB-Trees choose their delimiter dimensions in the order of the number of distinct values of a dimension, moving dimensions with a high cardinality and thus a presumably higher pruning power to the top. If a dimension has more than k different values, delimiter values are determined such that each subtree features a roughly equal number of objects. If the number of inner node levels, h, is smaller than the dimensionality of the data set, m, BB-Trees thus omit the dimensions with the smallest cardinalities in the IST. Note that this scenario is quite frequent due to the high fan out of the tree which makes the BB-Tree rather flat even for very large data sets. As an example, assume a BB-Tree over one Billion objects, a fan out of $k = 17$, a b_{max} value of 1,000, and a fill degree of 50%. Adressing the resulting two million BB requires only six IST levels. Thus, low-cardinality dimensions, which are anyway problematic in terms of pruning power, do not clutter the tree. On the other hand, if h is larger than m, we employ dimensions multiple times as delimiters in a round-robin fashion. This scenario occurs especially for data sets with a dimensionality between two and four (depending on the number of objects). A special case occurs when low-cardinality dimensions are used as delimiters (see Section 3.5).

Example. Figure 1 illustrates a BB-Tree with $k = 3$, $h = 2$ (two tree levels), and nine BB managing three-dimensional data objects (buckets three to six are not displayed). Each (regular) BB can hold up to $b_{max} = 4$ data objects. Individual data objects are identified by tids. At the first level, the shown BB-Tree splits the data space into $k = 3$ partitions according to the first dimension. All data objects having a value of three or less in this dimension are held in the left subtree. All data objects having a value of seven or less, but larger than three, in this dimension are held in the middle subtree; all other data objects can be found in the right subtree. At the next level, the data space is recursively split according to the second dimension. Note that this example uses two dimensions as delimiter, although $m = 3$. Given a fan out of $k = 3$, two tree levels are sufficient for distinguishing between nine BB. Figure 2 illustrates the linearization of the IST. We link the linearized IST with the corresponding BB by maintaining an array of pointers, where entry i references the i-th BB.

SIMD. Although processing inner nodes with Single Instruction Multiple Data (SIMD) instructions sounds promising at first glance, especially because the tree is linearized and packed into a dense array, we were not able to obtain any performance benefits

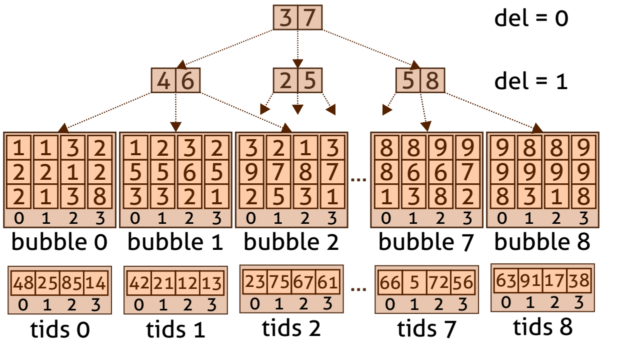

Figure 1: A BB-Tree ($k = 3$, $b_{max} = 4$) of height $h = 2$ managing $n = 36$ data objects of dimensionality $m = 3$; buckets three to six are omitted.

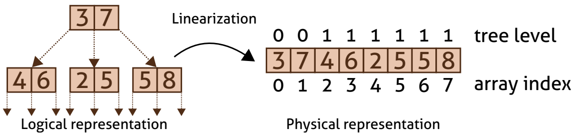

Figure 2: Linearized storage of the inner search tree.

through SIMD parallelism. Compared to a binary search, scanning inner nodes with SIMD instructions does not save many comparisons yet incurs overhead. For instance, when employing 16 delimiter values, which perfectly fit into one 64-byte cache line, a binary search requires $log_2(16) = 4$ comparisons, while a SIMD search on 256-bit registers needs two comparisons (or four comparisons if only 128-bit SIMD registers are available). These small savings are outweighed by the overhead induced by SIMD scans, especially data transfers between regular and vector registers [7], and the necessary scalar evaluation of the results of SIMD instructions.

3.2 Bubble Buckets

Until now, we described the BB-Tree as a static index structure and omitted the treatment of overflowing or underflowing leaf buckets. We lift this restriction and describe two techniques to cope with changing data, namely bubble buckets (this section) and index rebuilds (next section).

All leaf nodes are implemented as elastic bubble buckets. There exist two types of BB: A regular BB is implemented as a C++ *std::vector*, which is a dynamically growing and shrinking array, and takes inserts up to its maximum capacity b_{max}. In contrast, a super BB locally adds a further level to the tree. It consists of an inner node and a set of k regular nodes. The inner node holds a delimiter dimension and a set of delimiter values. As usual, super BB employ the dimension that has the largest number of distinct values as delimiter, and the $k - 1$ delimiter values are chosen such that the data objects are as evenly distributed as possible among the k regular child BB. Super BB morph into regular BB upon underflow, and regular BB morph into super BB upon overflow.

Inserts. The complete procedure for inserting objects is as follows: We first traverse over the inner nodes to determine the bucket that is responsible for the new object. If the chosen BB is a regular BB and has free space, we insert the object and are done. If there is no free space, we morph the BB into a super BB, and insert the data object; this also happens when the chosen BB already is a super BB. To insert into a super BB, we first check whether the super BB currently contains less than $k * b_{max}$ objects. If this is the case, we determine the appropriate child BB, which must be a regular BB, and insert the object; otherwise we reorganize the index.

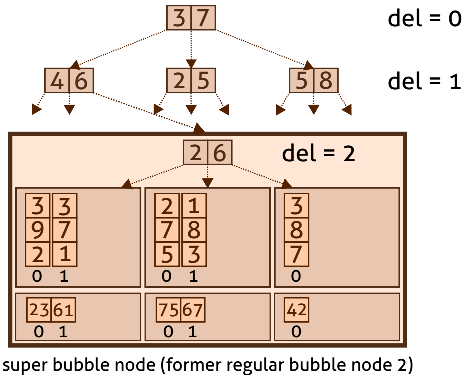

Figure 3: Assuming that a new data object (3 8 7) with tid 42 gets inserted into the BB-Tree from Figure 1, the second BB morphs into a super BB that consists of k regular nodes; dimension two is employed as delimiter.

BB can thus accommodate up to $k * b_{max}$ inserts into the same region before the index needs a rebuild. If objects are deleted during insert-heavy workloads, this period gets even longer. Within this time, the IST of the BB-Tree is stable, and the local depth is increased by at most one. However, to keep the algorithms simple we currently do not balance the size of the child nodes of a super BB, which, in theory, could lead to cases where all inserts accumulate in one child node. This would for instance happen when objects of an one-dimensional data set are inserted in a certain sort order; for such situations, other index structures are more appropriate, such as [18].

Deletes. When deleting an object, we first search the IST to determine the responsible BB and delete the object there. In the case of a regular BB, no further processing is performed. This implies that a BB-Tree may have empty leaf buckets; however, due to the dynamic size of their implementation, the memory overhead is minimal. We nevertheless rebuild the index when more than 10% of all BB are empty to get rid of superfluous inner nodes. If we delete from a child of a super BB, this bucket checks the total number of objects it contains and morphs into a regular BB in case the number is smaller than $p * b_{max}$. In the default setting, we set $p = 0.5$ to prevent pathological cases of constantly morphing BB when the b_{max}-th object is inserted and deleted iteratively.

Example. Consider again the BB-Tree from Figure 1. When we insert a new data object (3 8 7), the second bucket overflows and morphs into the super BB shown in Figure 3. Here, the super BB uses the third dimension as delimiter.

3.3 Building and Reorganizing a BB-Tree

A BB-Tree is initialized with one regular BB. After b_{max} objects have been inserted, this regular BB morphs into a super BB. With more inserts, this super BB eventually overflows, triggering a rebuild of the index. All operations, except for the very first, operate on a BB-Tree that was the result of an index rebuild.

Such a rebuild consists of four steps. First, we determine how many regular BB are needed to hold the current data, while leaving capacity for new inserts. From this number, we also derive the necessary number of levels of the IST. By default, we set the number of BB to $n/(10\% * b_{max})$ allowing each node to ingest further $90\% * b_{max}$ data objects until it overflows. This parameter may be changed if the expected workload consists of many inserts (lower value, less rebuilds, deeper tree) or few inserts (higher value, less deep tree). Second, we randomly sample $R_{samples} * n$ data objects as representatives of the whole data set. By scanning the sample data, we estimate the cardinality of each dimension. Dimensions are sorted by cardinality and assigned to the h IST levels in descending order. Third, we recursively determine the delimiter values for the inner nodes. Using the sample data, we compute an equi-depth histogram with k buckets, reflecting the distribution of the dimension values of the current level. Using that histogram, we obtain $k-1$ delimiter values such that the data are divided into k partitions of rougly equal size. In the case of a delimiter value, which occurs with a much higher frequency than the others, the derived partitions will be of unequal size. Clearly, this procedure fails for low-cardinality dimensions containing less than k distinct values. In the last step, all objects are inserted into their respective BB.

Obviously, index reorganization is an expensive operation. A random sample must be determined which is scanned multiple times, a new IST is constructed, and data objects must be moved to new locations. We chose pragmatic and fast methods for these steps, which come at certain drawbacks. First, equally splitting a subtree by one dimension is not always possible, which, in the worst case, may lead to an unbalanced BB-Tree (see Section 3.4), where subtrees at the same depth contain an unequal number of data objects. Second, we globally assign dimensions to tree levels, which again can lead to imbalances when dimensions are strongly correlated. Third, we compute the IST structure only on a sample. If the sample is small, the tree is found quickly yet might not optimally represent the data. Contrary, if the sample is large, building the tree needs more time yet probably leads to a better tree structure. We make two notes regarding these issues. First, they are shared by most other updateable MDIS. For instance, the structure of kd-trees strongly depends on the order of the insertions. The K-D-B-tree turns kd-trees into balanced search trees, but at the price of complicated and slow update operations. Second, though we cannot give formal guarantees, for the data sets we used in our evaluation, we never observed any notable imbalance. We are thus confident that unbalanced BB-Trees, which are possible in theory, remain very rare in practice.

3.4 Search Algorithms

BB-Trees focus on partial- and complete-match range queries, but also support exact-match queries.

All search queries have in common that they first exploit the linearized inner nodes to efficiently find those BB that may hold data objects relevant for the search query while pruning all others. This step is followed by sequential scans over all candidate BB to determine the data objects matching the query. Evaluation of search queries may have to follow multiple paths through the tree: Partial-match range queries must consider multiple paths whenever a node splits on a dimension which is not part of the query. Complete-match range queries have to consider multiple paths when the range covers more than one subtree. Even exact-match queries need to consider multiple paths when a low-cardinality dimension (with less than k distinct values) is used as delimiter.

Assuming the usual case, where the navigation of the IST results in only one candidate BB, exact-match queries have a complexity of $O(h * log(k) + b_{max} * m)$: They first perform h times a binary search within inner nodes and eventually scan one BB holding up to b_{max} objects, where a comparison between the query and a data object requires m value comparisons. The tree height (h) depends on the number of stored data objects, the BB capacity and the fan out: $h = log_k(n/b_{max})$. Note that the tree height is increased by one in case the search leads to a super BB. The complexity of exact-match queries is dominated by the scans of leaf nodes, calling for small values of b_{max}. On the other hand, every change of a level during IST traversal may result in a cache miss, making these operations more costly in practice.

Note that the worst-case complexity of the BB-Tree is linear in n. First, this is trivially the case when queries select all indexed objects. Second, this case occurs when less than B_{max} objects are indexed, as these are all stored in one bucket preventing pruning. Third, the worst case also applies, when BB-Trees consist of only one super BB and most data objects are inserted into the same child BB due to a inaptly-chosen delimiter dimension. However, once the super BB overflows, the data objects are distributed to multiple regular BB and the search complexity (for queries requiring only one BB) converges to the formulas given above.

For less selective range queries, scans are more attractive as more of their comparisons actually lead to matches, without any tree navigation in-between. However, determining an optimal b_{max} value would only be possible if all queries had the same, a-priori known selectivity across the entire data space, an assumption that is rather impractical. In practice, every setting of b_{max} implements an expectation on the average selectivities of queries in the future workload. In our evaluation, we will show that our default value leads to a performance that is almost on-par with MDIS specialized in exact-match queries while clearly outperforming all competitors for MDRQ.

3.5 Low-Cardinality Dimensions

We consider a dimension of a data set to have a low cardinality when its number of distinct values is smaller than k. Low-cardinality dimensions are common in real-world data sets and challenge MDIS because they make partitioning generally hard and equal partitions impossible. The problem is less severe for the BB-Tree, as it sorts delimiter dimensions by the number of distinct values, which usually keeps low-cardinality dimensions completely out of the IST. However, if a data set contains less than h dimensions and these dimensions have low cardinalities, a low-cardinality dimension will be chosen as delimiter dimension of an inner node, making it impossible to find distinct delimiter values such that the data is split into k subparts of equal size. In the worst case, where a delimiter dimension features only one distinct value, the IST loses all its pruning power and searching the BB-Tree degenerates to a sequential scan over all leaf nodes.

4 PARALLEL EVALUATION OF RANGE QUERIES

The parallel range query operator uses multiple threads to execute search queries and consists of two phases.

The first phase navigates the inner nodes with a single thread to determine the candidate BB. Traversing over the linearized inner nodes in parallel is complicated, as an optimal scheme would require solving a non-trivial load balancing problem due to different pruning effects in different subtrees. At the same

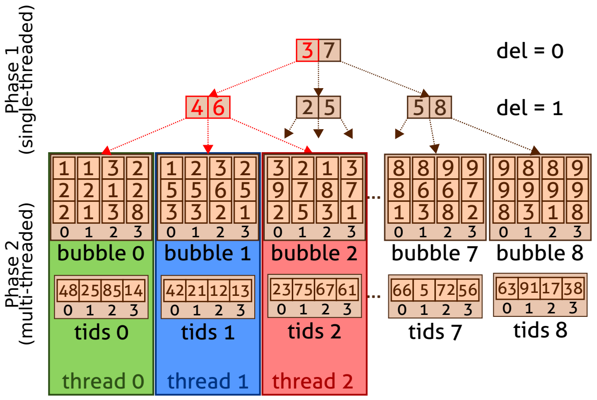

Figure 4: Parallel evaluation of an exemplary range query defined by lower boundary $[1, 0, 3]$ **and upper boundary** $[3, 7, 6]$**.**

time, there is only little to gain as the tree usually is rather flat due to its high fan out.

In the second phase, all candidate BB are scanned in parallel. Let B_{match} denote the number of candidate BB that have been determined by the first phase (super BB are considered as multiple BB). If $B_{match} \geq t$, we divide the candidate BB into t partitions of size B_{match}/t. Each partition is processed by a distinct thread using the same algorithm as in the regular, single-threaded BB-Tree. Hence, if $B_{match} = t$, we obtain the perfect degree of parallelism. If $B_{match} < t$, some threads would remain idle when sticking to the one-thread-per-bucket assignment. In this case, we assign multiple threads to single BB allowing to divide the data objects of one BB into partitions and scan these partitions in parallel.

Example. Figure 4 illustrates the parallel evaluation of a range query in a BB-Tree. The shown search query retrieves all data objects that match the lower boundary $[1, 0, 3]$ and the upper boundary $[3, 7, 6]$. The first, single-threaded phase of the query execution determines that the first three BB may hold data objects matching the range boundaries (the search path is marked in red). In the second, multi-threaded phase, these BB are searched concurrently with one CPU thread per bucket assuming that our imaginary machine features three threads ($B_{match} = t$).

5 EVALUATION

In a comprehensive evaluation, we compare the BB-Tree with state-of-the-art approaches to general-purpose indexing of multidimensional data by executing synthetic and real-world query workloads over synthetic and real-world data sets. Specifically, we aim to answer the following questions: (1) Does the performance of the BB-Tree depend on data set- or workload-specific characteristics, e. g., data dimensionality, data skew, or query selectivity (see Sections 5.4 to 5.7)? (2) How does the BB-Tree perform on mixed workloads that contain both reads and writes (see Section 5.9)? (3) What is the effect of parallelization (see Section 5.10)? (4) How efficient does the BB-Tree utilize memory space (see Section 5.11)?

5.1 Experimental Setup

Hardware. We executed all experiments on a server equipped with two Intel Xeon E5-2620 CPUs (2 GHz clock rate, 64-byte cache lines, six cores, 12 hardware threads) and 32 GB of RAM. In total, the machine features 12 cores and 24 hardware threads. Most experiments are single-threaded, some experiments investigate the parallel range query operator and therefore make use of multiple threads.

Methodology. In our evaluation, the competitors are completely kept in main memory. All data sets are inserted in random order. All experiments measure the average execution time of an operation, e. g., range query. We run experiments three times and present the arithmetic mean.

Competitors. We compare the BB-Tree with multiple approaches to general-purpose multidimensional indexing: the kd-tree [4], the PH-tree [35], the R*-tree [3], the VA-file [34] and the sequential scan [28]. Section 2 provides a brief description of the competitors; for more details we refer the interested reader to the original papers or surveys, like [10], or benchmarks, like [28]. For the R*-tree, we used an open-source, main memory implementation (https://libspatialindex.github.io/) and relied on the default configuration, but slightly adjusted the node capacities such that nodes are aligned to cache lines. For the PH-tree, which is a main-memory MDIS by design, we used a publicly available implementation shared by the authors (https://github.com/tzaeschke/phtree-1). For the kd-tree, the VA-file and the sequential scan, we used our own implementations based on the original publications, but adapted them to main-memory storage following techniques described in [28]. Most contestants, including the BB-Tree, use 32-bit floating-point values to manage dimension data. The R*-tree implementation uses 64-bit floating-point values; the PH-tree implementation uses 64-bit integer values. We evaluated the BB-Tree with $k = 17$, because $k - 1 = 16$ four-byte floating-point values fit into one cache line of the evaluation machine. Based on the observations described in Section 5.3, we empirically set $b_{max} = 2,500$. For reorganization, we use $R_{samples} = 10\%$ of all objects as samples to estimate the current data distribution.

Software. All software was implemented in C++ and was compiled with GCC using optimization flag *-O3*. We measured hardware performance counters with PAPI (http://icl.cs.utk.edu/papi/) and space consumption with valgrind (http://valgrind.org/). For the parallel range query operator, we used an open-source thread pool library (https://github.com/vit-vit/CTPL) to enable the reuse of POSIX threads. Our implementation of the BB-Tree is freely available (https://www2.informatik.hu-berlin.de/~sprengsz/bb-tree/).

5.2 Data Sets and Workloads

We evaluate the competitors on four data sets. Table 2 provides the number of data objects (n), the dimensionality (m), the number of distinct values per dimension (for UNIFORM and CLUST, we provide averages over all dimensions), and the raw size of each data set. We primarily use synthetic workloads. Unless noted otherwise, we generate synthetic range queries by randomly choosing two objects from the data set and, for each dimension, we use the smaller (larger) value of both objects as lower (upper) boundary. For GENOMIC, we execute a realistic workload, the Genomic Multidimensional Range Query Benchmark (GMRQB) [28], consisting of eight partial- and complete-match MDRQ templates of varying selectivity.

Data Set	n	m	Distinct Values per Dimension	Raw Size
UNIFORM	10k	5	10k (avg)	0.19MB
	100k	5	95k (avg)	1.91MB
	1M	5	632k (avg)	19.07MB
	10M	5-100	1M (avg)	190.74MB-3,814.7MB
	10M	5	4-64	190.74MB
CLUST	10k	5	10k (avg)	0.19MB
	100k	5	95k (avg)	1.91MB
	1M	5	632k (avg)	19.07MB
	10M	5	1M (avg)	190.74MB
POWER	10k	3	10k; 1k; 1k	0.11MB
	100k	3	100k; 2k; 2k	1.14MB
	1M	3	1M; 4k; 5k	11.44MB
	10M	3	10M; 6k; 8k	114.44MB
GENOMIC	10k-10M	19	1-63,883	0.72MB-724.79MB

Table 2: Data sets used in our experiments.

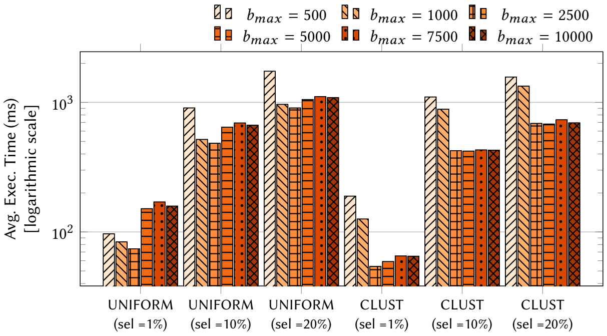

Figure 5: Performance of BB-Trees with different BB capacities (B_{max}) when executing range queries with varying selectivities (1%, 10%, and 20%) (n=10M, m=5, UNIFORM/CLUST).

Uniform Data (UNIFORM). Synthetic data facilitates experiments with arbitrary data set sizes, dimensionalities and query selectivities. We generate uniformly distributed data objects within the domain $[0, 1]$.

Clustered Data (CLUST). The five-dimensional data set CLUST features up to 20 clusters. We used a generator provided by Müller et al. [22] to generate CLUST within the domain $[0, 1]$. Within clusters, data are uniformly distributed.

Sensor Data (POWER). POWER is obtained from the DEBS 2012 challenge (http://debs.org/?p=38) and resembles real-world sensor data of hi-tech manufacturing equipment. As in previous studies [28, 33], we index three dimensions.

Genomic Data (GENOMIC). GENOMIC consists of real-world genomic variant data obtained from the 1000 Genomes Project [31]. We transformed the raw data, originally provided as text files, into 19-dimensional data objects, which can be indexed by the competitors (some attributes were provided as text and had to be converted into floating-point values). As shown in Table 2, the dimensions of GENOMIC have a highly varying cardinality, ranging from one to 63,883 distinct values. We previously defined the Genomic Multidimensional Range Query Benchmark (GMRQB) in [28], which consists of eight realistic partial- and complete-match MDRQ templates restricting between two and 19 dimensions of the data space. The templates are instantiated with concrete values obtained from the 1000 Genomes Project data and have an average selectivity between 10.76% and 0.00001%.

5.3 Impact of Bubble Bucket Capacities

The capacity of BB, as defined by b_{max}, controls the ratio between index probing (navigation of IST) and scanning (evaluation of leaf nodes) when searching in BB-Trees. While small BB put more work on index probing, large BB increase the relative time spent on scanning. As shown in previous work [28, 34], index probing is beneficial for highly selective queries and scanning is superior for less selective workloads.

We study the impact of b_{max} on the performance of range queries with varying selectivities (1%, 10%, 20%) when applied to ten million five-dimensional objects from UNIFORM and CLUST. Our goal is to find a pragmatic configuration providing a robust performance for a wide range of query selectivities and data distributions. Figure 5 shows the results.

For uniform distributions, this experiment confirms that small (large) capacities are beneficial for highly (less) selective queries. While small BB capacities are more efficient than large BB capacities for queries with an average selectivity of 1%, they become less efficient with increasing query selectivity (10% and 20%). For the selectivies considered here, BB holding up to 2,500 objects provide the best performance.

Clustered data lead to a less optimal partitioning, which lessens the pruning power of the IST and puts more work on scanning. As a result, small BB capacities become less efficient, even for small selectivities, because less BB can be pruned. Also for clustered data, BB with a maximum capacity of 2,500 objects provide either the best performance or are on a par with other configurations.

Taking the results of this experiment into account, we set $b_{max} = 2,500$ for all following experiments.

5.4 Exact-Match Queries

Figure 6 shows the average execution time of exact-match queries for the four data sets depending on the number of data objects. We execute n exact-match queries on the contestants given that n denotes the data set size. Each exact-match query retrieves a randomly-chosen, existing data object. To manage 10^4 objects, the BB-Tree does not need an IST, but employs one super BB consisting of $k = 17$ regular nodes ($b_{max} = 2,500$). In general, for exact-match queries, the performance of the BB-Tree is very similar to that of the kd-tree and the PH-tree. It clearly outperforms the R*-tree, the VA-file and the sequential scan for all data sets, often by multiple orders of magnitude. For the largest instance of GENOMIC (10^7 objects), inner nodes at the lowest tree level feature duplicate delimiter values, which require scanning multiple candidate BB and result in minor performance drops.

Typically, MDIS achieve a better exact-match query performance than sequential scans, because they can prune large parts of the data while scans need to consider all data. Although the BB-Tree needs to scan over data objects stored in BB it achieves a very competitive performance. The BB-Tree exploits the linearized inner nodes to effectively reduce the amount of data to consider for query evaluation.

5.5 Insertions and Deletions

Figure 7 presents the average time a contestant needs to ingest a data object. The shown results include the reorganizations of the BB-Tree; in a real system, we would advise to handle rebuilds in background jobs, which strongly increases insert performance. We do not insert entire data sets at once, but load object by

(d) GENOMIC (m=19)

Figure 8: Performance of delete operations on synthetic and real-world data depending on the number of data objects.

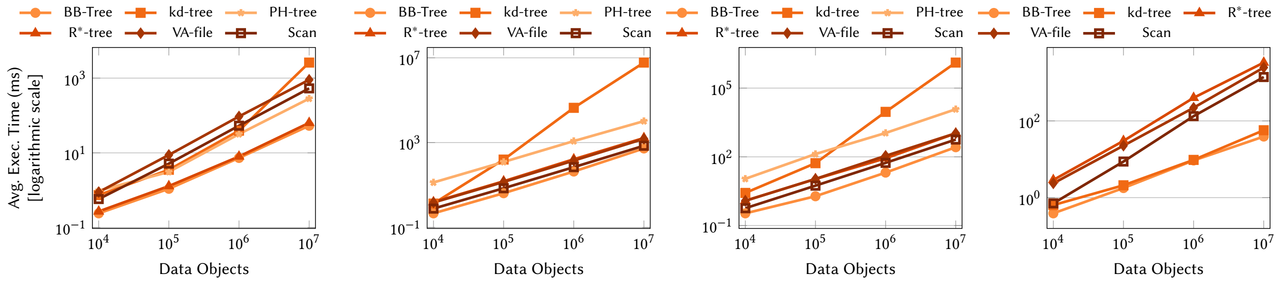
object. Thus, this experiment does not include the VA-file, which supports only bulk inserts, because it requires to know the data distribution beforehand. For instances of GENOMIC with more than 10^5 objects, the space needs of the PH-tree exceeded the available 32 GB of memory.

The scan achieves the highest insert performance, because it implements inserts by appending new data objects to a dynamic array and does not require to deal with node overflows, like the R*-tree. Notably, the BB-Tree shows a better insert performance than the kd-tree and the PH-tree and clearly outperforms the R*-tree. The concept of elastic BB effectively reduces the frequency of rebalancing operations. When dynamically inserting ten million data objects, regardless of the data set, the BB-Tree needed only three reorganizations, which took 6.55s on average (standard deviation σ = 8.75s). Smaller data sets require even less reorganizations.

Figure 8 shows the average time needed for deleting an object from the four data sets depending on data set size. The used implementation of the PH-tree did not provide a delete operator. The delete performance of the BB-Tree correlates with its exact-match query performance, because it first locates the to-be-deleted data object and then removes it from the corresponding BB. The BB-Tree outperforms all other competitors in deleting data objects, even scans, except for the largest instance of GENOMIC.

5.6 Range Queries

Figure 9 shows the average execution time of complete-match MDRQ that we generated by randomly choosing two objects from the data set. Depending on the data distribution, the obtained MDRQ objects have a varying average selectivity; UNIFORM: 0.4% (σ = 0.9%), CLUST: 19.8% (σ = 19.7%), POWER: 12.6% (σ = 13.1%), GENOMIC: 0.2% (σ = 0.2%). For CLUST, one range query may span multiple clusters, therefore average selectivities



(a) UNIFORM (m=5) **(b) CLUST (m=5)** **(c) POWER (m=3)** **(d) GENOMIC (m=19)**

Figure 9: Performance of synthetic complete-match range queries on synthetic and real-world data depending on the number of data objects. Due to the technique used to generate MDRQ (see Section 5.2), average selectivities are as follows: UNIFORM: 0.4% (σ = 0.9%), CLUST: 19.8% (σ = 19.7%), POWER: 12.6% (σ = 13.1%), GENOMIC: 0.2% (σ = 0.2%).

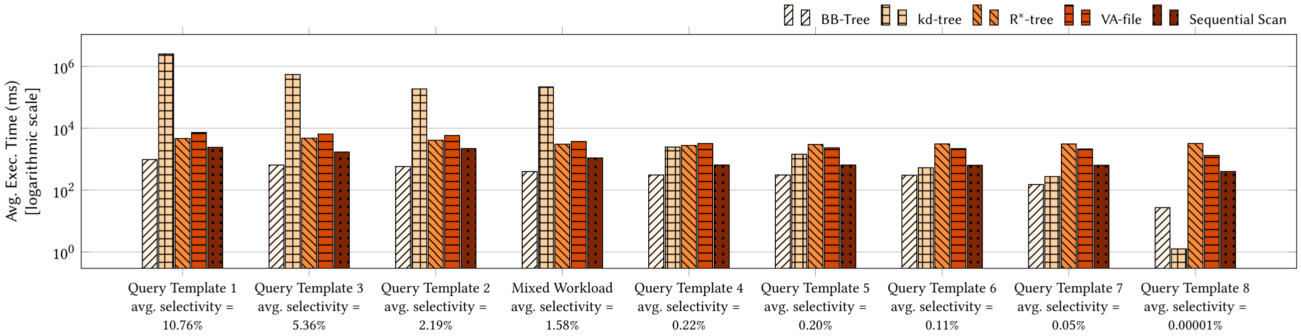


Figure 10: Performance of eight realistic MDRQ templates, including a mixed workload, from GMRQB; query templates are ordered by selectivity (n=10M, m=19, GENOMIC).

are higher than for UNIFORM although both data sets have an identical size and both are generated within $[0,1]$. The BB-Tree achieves the best overall performance and outperforms the other contestants, sometimes by up to three orders of magnitude. For UNIFORM, the R*-tree shows a performance similar to that of the BB-Tree. For GENOMIC, the kd-tree performs similar to the BB-Tree. We omit the PH-tree for all range query experiments on GENOMIC, because the implementation given by the authors crashed with failing C++ assertions.

Figure 10 presents the average execution time of the GMRQB on ten million data objects from GENOMIC. Note that most query templates, except query templates 7 and 8, have their first selection predicate in the second level of the BB-tree, which means that the GMRQB workload is rather unfavorable for our index. Nonetheless, BB-Trees consistently achieve the best performance for query templates 1-7, which are partial-match MDRQ querying 5.81 dimensions on average (σ = 4.11), and a mixed workload consisting of all query templates randomly mixed together. Only for query template 8, which resembles an exact-match query as it selects a single data object on average, they are beaten by kd-trees. For data of high(er) dimensionality, such as GENOMIC, R*-trees lose their pruning power and show a worse performance than scans.

Figure 11 shows the performance of range queries on ten million objects from UNIFORM depending on query selectivity. We omit the kd-tree because, compared to the other competitors, its execution time was orders of magnitude higher for queries selecting more than 1% of the data. The BB-Tree outperforms all other MDIS regardless of the query selectivity. It also beats the scan for queries with a selectivity of up to 20%. For less selective queries, the performance of the BB-Tree remains close to that of a scan. Furthermore, the BB-Tree achieves a very high cache efficiency, almost as good as that of a sequential scan, and follows most predicted branches leading to few pipeline flushes (see Table 3).

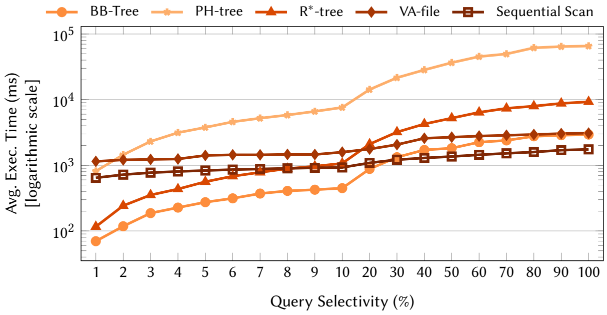

Figure 11: Performance of range queries depending on query selectivity; kd-tree is omitted as its performance decreases severely for less selective queries, strongly impairing the readability of the figure (n=10M, m=5, UNIFORM).

5.7 Impact of Dimensionality

We measure the performance of exact-match and complete-match range queries on ten million data objects from UNIFORM depending on data set dimensionality. We generate complete-match range queries with an average selectivity of 1% (σ = 0.7%). With a

	BB-Tree	kd-tree	PH-tree	R*-tree	VA-file	Scan
CPU Cycles	**164M**	8,306M	1,908M	252M	2,934M	1,582M
LLC Accesses	1.0M	824M	1.2M	2.5M	1.8M	**0.5M**
LLC Misses	0.7M	0.9M	0.8M	0.5M	1.6M	**0.3M**
TLB Misses	0.3M	1.0M	0.3M	0.3M	0.2M	**0.1M**
Branch Mispr.	**0.1M**	0.7M	3M	0.2M	10M	7M

Table 3: Performance counters per range query (1% selectivity;n=10M, m=5, UNIFORM).

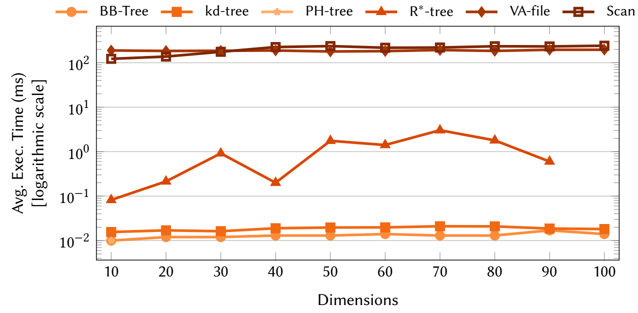

Figure 12: Performance of exact-match range queries (average selectivity = 1%, σ = 0.7%) depending on dimensionality (n=10M, UNIFORM).

growing dimensionality, this results in very low single-dimension selectivities posing serious challenges to MDIS because pruning becomes less useful. For instance, when running complete-match MDRQ with an overall selectivity of 1% on 100-dimensional uniformly distributed data, where dimensions are not correlated, single-dimension selectivities are approximately 95.50%, as $0.955^{100} \approx 0.01$.

Figure 12 shows the runtimes of exact-match queries for dimensionalities between ten and 100[3]. For such workloads, all methods except the R*-tree are mostly unaffected by the dimensionality of the data space. Similarly, Figure 13 shows the runtimes of complete-match MDRQ depending on the dimensionality. All methods show a performance degradation roughly proportional to the dimensionality of the data space, starting at a dimensionality of 20, because an increasing number of dimensions has to be compared when evaluating queries. The slow-down is more pronounced for lower dimensionalities.

We also executed workloads on instances of CLUST featuring five and ten dimensions (data not shown). All competitors behave very similar as for UNIFORM: Exact-match queries are almost unaffected by the dimensionality of the data space, whereas range queries degrade noteably.

5.8 Low-Cardinality Dimensions

Low-cardinality dimensions are challenging for BB-Trees because they make it impossible to find k different delimiter values, which limits the pruning power of the IST. We first study this effect using range queries applied to ten million five-dimensional data objects from UNIFORM with different moderately low cardinalties for all dimensions. Results are shown in Figure 14. At these cardinalities, none of the competitors is affected severely as the differences only correspond to the different query selectivities. Note that in the cases of eight and 16 distinct values per dimension, the data space includes duplicate data objects which is not supported by the PH-tree; therefore, we omit this method in this experiment.

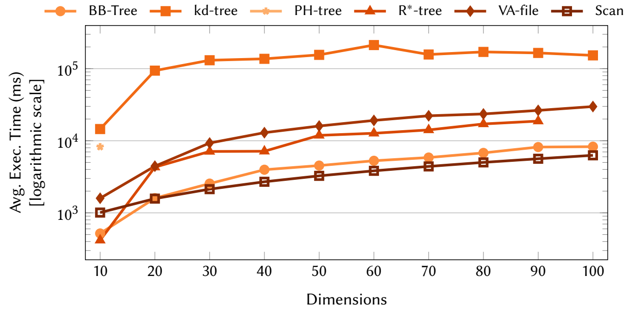

Figure 13: Performance of complete-match range queries (average selectivity = 1%, σ = 0.7%) depending on dimensionality (n=10M, UNIFORM).

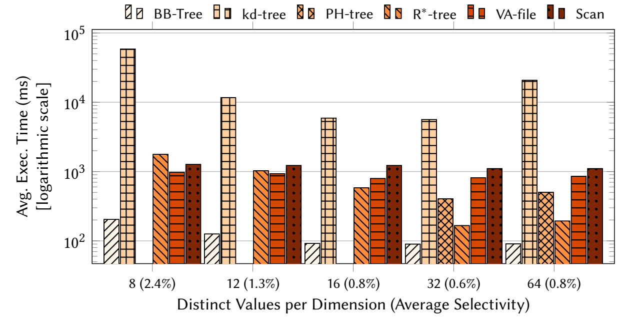

Figure 14: Performance of MDRQ with a varying selectivity depending on number of distinct values per dimension (n=10M, m=5, UNIFORM).

Next, we performed an experiment with extremely low cardinalities (between two and 12) yet used data of higher dimensionality. Figure 15 shows the performance of range queries with a selectivity of 0.00002% (σ = 0.0%), when applied to ten million 50-dimensional objects from UNIFORM. The PH-tree had to be omitted because it produced incorrect results. This experiment shows that the performance of most MDIS drops considerably with lower cardinalities, whereas scans and VA-files are much less effected. However, for such low cardinalities other index structures, like bitmaps [8], are probably a better choice anyway.

5.9 Mixed Workload

In most applications, MDIS are loaded in bulk before running large batches of search queries. Once built, inserts and deletes rarely happen. This experiment studies the contestants when running such workloads on data from GENOMIC. We use ten million data objects, of which we first insert 9,999,900[4]. Next, we run 100 inserts, 100 deletes, 2,800 exact-match queries and 7,000 range queries in random order. For inserts, we use objects, which were not bulk loaded. For exact-match queries and deletes, we randomly choose objects from the data set. This may result in queries asking for previously deleted data objects. For range queries, we

[3] Note that the space requirements of the PH-tree exceeded the available 32 GB of main memory for dimensionalities higher than ten. Similarly, the R*-tree ran out of space for 100 dimensions.

[4] For the VA-file, we insert all data objects at the beginning of the workload, because it only supports bulk inserts.

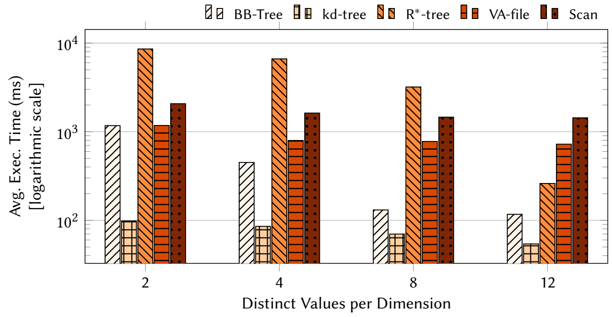

Figure 15: Performance of MDRQ with a selectivity of 0.00002% (σ = 0.0%) depending on number of distinct values per dimension; PH-tree is omitted (n=10M, m=50, UNIFORM).

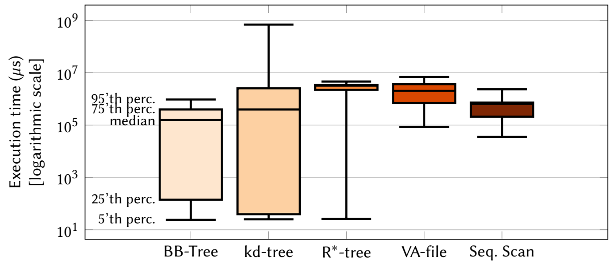

Figure 16: Execution times of single queries (inserts, deletes, exact-match and range queries) from a mixed workload in random order; bulk insert is not included; PH-tree ran out of memory (n=10M, m=19, GENOMIC).

	Bulk Insert (s)	Average/Minimum/Maximum exec. time (ms)
BB-Tree	54.7s	**262.66ms** / 0.005ms / **1,866.73ms**
kd-tree	236.7s	128,735.5ms / 0.011ms / 4,842,752ms
PH-tree		Ran out of memory.
R*-tree	2,316s	2,735.16ms / 0.008ms / 7,735.76ms
VA-file	38.7s	2,704.8ms / 0.004ms / 8,148.82ms
Seq. Scan	**7.8s**	809.83ms / **0.002ms** / 3,117.46ms

Table 4: (1) Total execution time of the bulk insert and (2) average, minimum and maximum execution time of the remaining queries of the mixed workload.

use the mixed workload from GMRQB (avg. sel.=1.58%, σ = 3.58%), which consists of all query templates randomly mixed together. Once again the PH-tree ran out of memory.

Figure 16 summarizes the runtimes. It does not include the bulk insert, because this would focus too much on inserts (ten million inserts vs. 9,900 search queries and deletions). For most contestants, insertions are the fastest operation, which would move all other operations out of the 95'th percentile. Table 4 shows the runtime of the bulk insert and summarizes the execution times of the remaining 10,000 queries. The BB-Tree achieves the highest performance in most cases. Only for the bulk insert, it is outperformed by the scan and the VA-file. The results show that the BB-Tree combines high search performance with fast inserts and deletes.

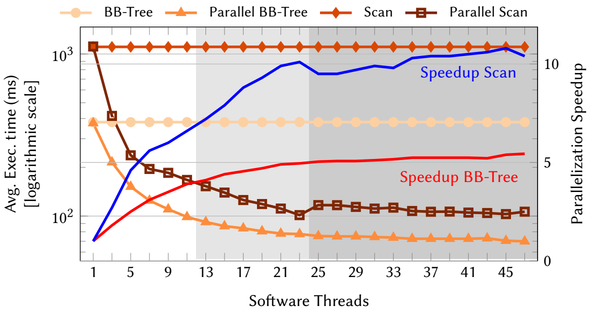

Figure 17: Performance of the mixed workload from GMRQB (avg. selectivity=1.58%) depending on the number of used software threads (n=10M, m=19, GENOMIC).

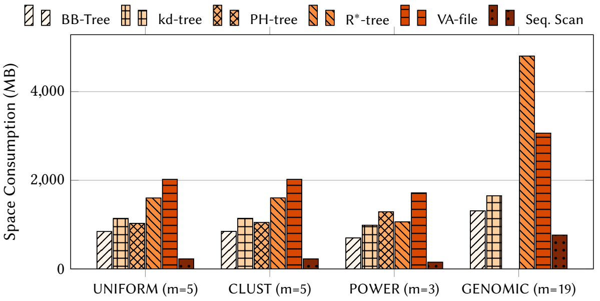

Figure 18: Space consumption of the competitors (n=10M).

5.10 Parallel Evaluation of Range Queries

Figure 17 shows the performance of the parallel range query operator when executing the mixed workload from GMRQB over ten million objects from GENOMIC depending on the number of used software threads. We compare results to a single-threaded BB-Tree, a single-threaded scan, and a parallel scan, which (1) divides the data objects into t partitions, (2) concurrently scans each partition with one thread, and (3) concatenates the results of the individual partitions. The performance of the parallel range query operator of the BB-Tree improves with the number of used threads up to a barrier established by the number of available physical cores (12 on our evaluation machine). Hyper-threading provides only few benefits for the mostly compute-bound BB-Tree, but is useful for memory-bound applications, like scans. Using moderately more threads than supported by the hardware (> 24), does neither provide benefits nor disadvantages. Scanning (up to 10.9X speed-up) benefits more from multi-threading than the BB-Tree (up to 5.5X speedup), because (a) the parallel scan leverages hyper-threading and (b) scan-based MDRQ can be completely parallelized while BB-Trees navigate the IST with a single thread. Nonetheless, BB-Trees outperform scans regardless of the number of used threads.

5.11 Space Consumption

Figure 18 shows the space consumption of the contestants when storing ten million data objects of the data sets used in the evaluation. For GENOMIC, the PH-tree required more than the available 32 GB of main memory. The BB-Tree achieves a high space efficiency, which is mainly enabled by the linearization of its inner nodes. Compared to the other MDIS, it requires the smallest index overhead over the scan.

6 CONCLUSIONS

We presented the BB-Tree as a fast and space-efficient means for storing and querying multidimensional data in main memory. It supports complete- and partial-match range queries, exact-match queries, and dynamic updates. We compared the BB-Tree with state-of-the-art MDIS using different synthetic and real-world workloads over different synthetic and real-world data sets with three to 100 dimensions. The BB-Tree beats all competitors in executing range queries up to a selectivity of 20%; for less selective queries it is only outperformed by a scan. It executes exact-match queries almost as fast as the best competitor, the PH-tree; for higher dimensionalities it even provides the best performance. The BB-Tree achieves the best insert and delete performance. We also presented a parallel variant that accelerates range queries almost linearly with the number of available CPU cores. Of course, BB-Trees are pure main-memory data structures; if data does not fit in memory, disk-based MDIS should be used like the original R*-Tree [12] or the original VA-File [34]. In future work, we intend to support nearest neighbor search and concurrent execution of search queries.

ABSTRACT

Massive volumes of data continuously generated on social platforms have become an important information source for users. A primary method to obtain fresh and valuable information from social streams is *social search*. Although there have been extensive studies on social search, existing methods only focus on the *relevance* of query results but ignore the *representativeness*. In this paper, we propose a novel Semantic and Influence aware k-Representative (k-SIR) query for social streams based on topic modeling. Specifically, we consider that both user queries and elements are represented as vectors in the topic space. A k-SIR query retrieves a set of k elements with the maximum *representativeness* over the sliding window at query time w.r.t. the query vector. The representativeness of an element set comprises both semantic and influence scores computed by the topic model. Subsequently, we design two approximation algorithms, namely Multi-Topic ThresholdStream (MTTS) and Multi-Topic ThresholdDescend (MTTD), to process k-SIR queries in real-time. Both algorithms leverage the ranked lists maintained on each topic for k-SIR processing with theoretical guarantees. Extensive experiments on real-world datasets demonstrate the effectiveness of k-SIR query compared with existing methods as well as the efficiency and scalability of our proposed algorithms for k-SIR processing.

1 INTRODUCTION

Enormous amount of data is being continuously generated by web users on social platforms at an unprecedented rate. For example, around 650 million tweets are posted by 330 million users on Twitter per day. Such user generated data can be modeled as continuous social streams, which are key sources of fresh and valuable information. Nevertheless, social streams are extremely overwhelming for their huge volumes and high velocities. It is impractical for users to consume social data in its raw form. Therefore, *social search* [7–9, 17, 19, 28, 33, 37, 39] has become the primary approach to facilitating users on finding their interested content from massive social streams.

Existing search methods for social data can be categorized into keyword-based approaches and topic-based approaches based on how they measure the relevance between queries and elements. Keyword-based approaches [7–9, 17, 28, 33, 37] adopt the *textual relevance* (e.g., TF-IDF and BM25) for evaluation. However, they merely capture the *syntactic* correlation but ignore the *semantic* correlation. Considering the tweets in Figure 1, if a query "soccer" is issued, no results will be found because none of the tweets contains the term "soccer". It is noted that the words like "as-roma" and "LFC" are semantically relevant to "soccer". Therefore, elements such as e_1, e_2 are relevant to the query but missing from the result. Thus, overlooking the semantic meanings of user queries may degrade the result quality, especially against social data where lexical variation is prevalent [14].

To overcome this issue, topic-based approaches [19, 39] project user queries and elements into the same latent space defined by a probabilistic topic model [5]. Consequently, queries and elements are both represented as vectors and their relevance is computed by similarity measures for vectors (e.g., cosine distance) in the topic space. Although topic-based approaches can better capture the *semantic* correlation between queries and elements, they focus on the *relevance* of results but neglect the *representativeness*. Typically, they retrieve top-k elements that are the most coherent with the query as the result. Such results may not be *representative* in the sense of *information coverage* and *social influence*. First, users are more satisfied with the results that achieve an extensive coverage of information on query topics than the ones that provide limited information. For example, a top-2 query on topic θ_1 in Figure 2 returns $\{e_3, e_4\}$ as the result. Nevertheless, compared with e_4, e_6 can provide richer information to complement the news reported by e_3. Therefore, in addition to *relevance*, it is essential to consider *information coverage* to improve the result quality. Second, *influence* is another key characteristic to measure the *representativeness* of social data. Existing methods for social search [7, 8, 19, 37] have taken into account the influences of elements for scoring and ranking. These methods simply use the influences of authors (e.g., PageRank [24] scores) or the retweet/share count to compute the influence scores. Such a naïve integration of influence is topic-unaware and may lead to undesired query results. For example, e_6 in Figure 1, which is mostly related to θ_1, may appear in the result for a query on θ_2 because of its high retweet count. In addition, they do not consider that the influences of elements evolve over time, when previously trending contents may become outdated and new posts continuously emerge. Hence, incorporating a topic-aware and time-critical influence metric is imperative to capture recently trending elements.

To tackle the problems of existing search methods, we define a novel Semantic and Influence aware k-Representative (k-SIR) query for social streams based on topic modeling [5]. Specifically, a k-SIR query retrieves a set of k elements from the active elements corresponding to the sliding window W_t at the query time t. The result set collectively achieves the maximum representativeness score w.r.t. the query vector $\mathbf{x}$, each dimension of which indicates the degree of interest on a topic. We advocate the representativeness score of an element set to be a weighted sum of its semantic and influence scores on each topic. We adopt a weighted word coverage model to compute the semantic score so as to achieve the best information preservation, where the weight of a word is evaluated based on its information entropy [31, 42]. The influence score is computed by a probabilistic coverage model where the influence probabilities are topic-aware. In addition, we restrict the influences within the sliding window W_t so that the recently trending elements can be selected.

The challenges of real-time k-SIR processing are two-fold. First, the k-SIR query is *NP-hard*. Second, it is highly *dynamic*, i.e., the results vary with query vectors and evolve quickly over time. Due to the submodularity of the scoring function, existing submodular maximization algorithms, e.g., CELF [16] and SieveStreaming [2], can provide approximation results for k-SIR queries with theoretical guarantees. However, existing algorithms need to evaluate all active elements at least once for a single query and often take several seconds to process one k-SIR query as shown in our experiments. To support real-time k-SIR processing over social streams, we maintain the ranked lists to sort the active elements on each topic by topic-wise representativeness score. We first devise the Multi-Topic ThresholdStream (MTTS) algorithm for k-SIR processing. Specifically, to prune unnecessary evaluations, MTTS sequentially retrieves elements from the ranked lists in decreasing order of their scores w.r.t. the query vector and can be terminated early whenever possible. Theoretically, it provides $(\frac{1}{2} - \varepsilon)$-approximation results for k-SIR queries and evaluates each active element at most once. Furthermore, we propose the Multi-Topic ThresholdDescend (MTTD) algorithm to improve upon MTTS. MTTD maintains the elements retrieved from ranked lists in a buffer and permits to evaluate an element more than once to improve the result quality. Consequently, it achieves a better $(1 - \frac{1}{e} - \varepsilon)$-approximation but has a higher worst-case time complexity than MTTS. Despite this, MTTD shows better empirical efficiency and result quality than those of MTTS.

Finally, we conduct extensive experiments on three real-world datasets to evaluate the effectiveness of k-SIR as well as the efficiency and scalability of MTTS and MTTD. The results of a user study and quantitative analysis demonstrate that k-SIR achieves significant improvements over existing methods in terms of *information coverage* and *social influence*. In addition, MTTS and MTTD achieve up to 124x and 390x speedups over the baselines for k-SIR processing with at most 5% and 1% losses in quality.

Our contributions in this work are summarized as follows.

- We define the k-SIR query to retrieve representative elements over social streams where both semantic and influence scores are considered. (Section 3)
- We propose MTTS and MTTD to process k-SIR queries in real-time with theoretical guarantees. (Section 4)
- We conduct extensive experiments to demonstrate the effectiveness of k-SIR as well as the efficiency and scalability of our proposed algorithms for k-SIR processing. (Section 5)

2 RELATED WORK

Search Methods for Social Streams. Many methods have been proposed for searching on social streams. Here, we categorize existing methods into two types: keyword-based approaches and topic-based approaches.

Keyword-based approaches [7–9, 17, 28, 33, 37, 40] typically define *top-k queries* to retrieve k elements with the highest scores as the results where the scoring functions combine the *relevance* to query keywords (measured by TF-IDF or BM25) with other contexts such as *freshness* [17, 28, 33, 37], *influence* [8, 37], and *diversity* [9]. They also design different indices to support instant updates and efficient top-k query processing. However, keyword queries are substantially different from the k-SIR query and thus keyword-based methods cannot be trivially adapted to process k-SIR queries based on topic modeling.

As the metrics for textual relevance cannot fully represent the semantic relevance between user interest and text, recent work [19, 39] introduces topic models [5] into social search, where user queries and elements are modeled as vectors in the topic space. The relevance between a query and an element is measured by cosine similarity. They define *top-k relevance query* to retrieve k most relevant elements to a query vector. However, existing methods typically consider the *relevance* of results but ignore the *representativeness*. Therefore, the algorithms in [19, 39] cannot be used to process k-SIR queries that emphasize the *representativeness* of results.

Social Stream Summarization. There have been extensive studies on social stream summarization [1, 4, 23, 25–27, 29, 36] : the problem of extracting a set of *representative* elements from social streams. Shou et al. [27, 36] propose a framework for social stream summarization based on dynamic clustering. Ren et al. [26] focus on the personalized summarization problem that takes users' interests into account. Olariu [23] devise a graph-based approach to abstractive social summarization. Bian et al. [4] study the multimedia summarization problem on social streams. Ren et al. [25] investigate the multi-view opinion summarization of social streams. Agarwal and Ramamritham [1] propose a graph-based method for contextual summarization of social event streams. Nguyen et al. [31] consider maintaining a sketch for a social stream to best preserve the latent topic distribution.

However, the above approaches cannot be applied to ad-hoc query processing because they (1) do not provide the query interface and (2) are not efficient enough. For each query, they need to filter out irrelevant elements and invoke a new instance of the summarization algorithm to acquire the result, which often takes dozens of seconds or even minutes. Therefore, it is unrealistic to deploy a summarization method on a social platform for ad-hoc queries since thousands of users could submit different queries at the same time and each query should be processed in real-time.

Submodular Maximization. Submodular maximization has attracted a lot of research interest recently for its theoretical significance and wide applications. The standard approaches to submodular maximization with a cardinality constraint are the greedy heuristic [22] and its improved version CELF [16], both of which are $(1 - \frac{1}{e})$-approximate. Badanidiyuru and Vondrak [3] propose several approximation algorithms for submodular maximization with general constraints. Kumar et al. [15] and Badanidiyuru et al. [2] study the submodular maximization problem in the distributed and streaming settings. Epasto et al. [12] and

Wang et al. [34] further investigate submodular maximization in the sliding window model. However, the above algorithms do not utilize any indices for acceleration and thus they are much less efficient for k-SIR processing than MTTS and MTTD proposed in this paper.

3 PROBLEM FORMULATION

3.1 Data Model

Social Element. A social element e is represented as a triple $\langle ts, doc, ref \rangle$, where $e.ts$ is the timestamp when e is posted, $e.doc$ is the textual content of e denoted by a bag of words drawn from a vocabulary $\mathcal{V}$ indexed by $\{1, \ldots, m\}$ ($m = |\mathcal{V}|$), and $e.ref$ is the set of elements referred to by e. Given two elements e and e' ($e'.ts < e.ts$), if e refers to e', i.e., $e' \in e.ref$, we say e' influences e, which is denoted as $e' \rightsquigarrow e$. In this way, the attribute ref captures the influence relationships between social elements [30, 35]. If e is totally original, we set $e.ref = \emptyset$. For example, tweets on Twitter shown in Table 1 are typical social elements and the propagation of hashtags can be modeled as references [18, 30]. Note that the *influence relationships* vary for different types of elements, e.g., "cite" between academic papers and "comment" on Reddit can also be modeled as references.

Social Stream. We consider social elements arrive continuously as a data stream. A social stream E comprises a sequence of elements indexed by $\{1, 2, 3, \ldots\}$. Elements are ordered by timestamps and multiple elements with the same timestamp may arrive in an arbitrary manner. Furthermore, social streams are time-sensitive: elements posted or referred to recently are more important and interesting to users than older ones. To capture the *freshness* of social streams, we adopt the well-recognized time-based sliding window [11] model. Given the window length T, a sliding window W_t at time t comprises the elements from time $t - T + 1$ to T, i.e., $W_t = \{e \in E | e.ts \in [t - T + 1, t]\}$. The set of active elements A_t at time t includes not only the elements in W_t but also the elements referred to by any element in W_t, i.e., $A_t = W_t \cup \{e' \in E | e \in W_t \wedge e' \in e.ref\}$. We use $n_t = |A_t|$ to denote the number of active elements at time t.

Topic Model. We use probabilistic topic models [5] such as LDA [6] and BTM [38] to measure the (semantic and influential) representativeness of elements and the preferences of users. A topic model $\Theta = \{\theta_1, \ldots, \theta_z\}$ consisting of z topics is trained from the corpus $\mathcal{E} = \{e.doc | e \in E\}$ and the vocabulary $\mathcal{V}$. Each topic θ_i is a multinomial distribution over the words in $\mathcal{V}$, where $p_i(w)$ is the probability of a word w distributed on θ_i and $\sum_{w \in \mathcal{V}} p_i(w) = 1$. The topic distribution of an element e is a multinomial distribution over the topics in Θ, where $p_i(e)$ is the probability that $e.doc$ is generated from θ_i and $\sum_{i=1}^{z} p_i(e) = 1$.

The selection of appropriate topic models is orthogonal to our problem. In this work, we consider any probabilistic topic model can be used as a black-box oracle to provide $p_i(w), \forall w \in \mathcal{V}$ and $p_i(e), \forall e \in E$. Note that the evolution of topic distribution is typically much slower than the speed of social stream [38, 41]. In practice, we assume that the topic distribution remains stable for a period of time. We need to retrain the topic model from recent elements when it is outdated due to concept drift.

3.2 Query Definition

Query Vector. Given a topic model Θ of z topics, we use a z-dimensional vector $\mathbf{x} = \{x_1, \ldots, x_z\}$ to denote a user's preference on topics. Formally, $\mathbf{x} \in [0, 1]^z$ and, x_i indicates the user's degree of interest on θ_i. W.l.o.g., $\mathbf{x}$ is normalized to $\sum_{i=1}^{z} x_i = 1$. Since it is impractical for users to provide the query vectors directly for their lack of knowledge about the topic model Θ, we design a scheme to transform the standard *query-by-keyword* [17] paradigm in our case: the keywords provided by a user is treated as a pseudo-document and the query vector is inferred from its distribution over the topics in Θ. Note that other query paradigms can also be supported, e.g., the *query-by-document* [39] paradigm where a document is provided as a query and the *personalized search* [19] where the query vector is inferred from a user's recent posts.

Definition of Representativeness. Given a set of elements S and a query vector $\mathbf{x}$, the *representativeness* of S w.r.t. $\mathbf{x}$ at time t is defined by a function $f(\cdot, \cdot) : 2^{|E|} \times [0, 1]^z \rightarrow \mathbb{R}_{\geq 0}$ that maps any subset of E to a nonnegative score w.r.t. a query vector. Formally, we have

$$f(S, \mathbf{x}) = \sum_{i=1}^{z} x_i \cdot f_i(S) \tag{1}$$

where $f_i(S)$ is the score of S on topic θ_i. Intuitively, the overall score of S w.r.t. $\mathbf{x}$ is the weighted sum of its scores on each topic. The score $f_i(S)$ on θ_i is defined as a linear combination of its semantic and influence scores. Formally,

$$f_i(S) = \lambda \cdot \mathcal{R}_i(S) + \frac{1 - \lambda}{\eta} \cdot \mathcal{I}_{i,t}(S) \tag{2}$$

where $\mathcal{R}_i(S)$ is the semantic score of S on θ_i, $\mathcal{I}_{i,t}(S)$ is the influence score of S on θ_i at time t, $\lambda \in [0, 1]$ specifies the trade-off between semantic and influence scores, and $\eta > 0$ adjusts the ranges of $\mathcal{R}_i(\cdot)$ and $\mathcal{I}_{i,t}(\cdot)$ to the same scale. Next, we will introduce how to compute the semantic and influence scores based on the topic model Θ respectively.

Topic-specific Semantic Score. Given a topic θ_i, we define the semantic score of a set of elements by the *weighted word coverage* model. We first define the weight of a word w in $e.doc$ on θ_i. According to the generative process of topic models [5], the probability $p_i(w, e)$ that $w \in e.doc$ is generated from θ_i is denoted as $p_i(w, e) = p_i(w) \cdot p_i(e)$. Following [31, 42], the weight $\sigma_i(w, e)$ of w in $e.doc$ on θ_i can be defined by its frequency and information entropy, i.e., $\sigma_i(w, e) = -\gamma(w, e) \cdot p_i(w, e) \cdot \log p_i(w, e)$, where $\gamma(w, e)$ is the frequency of w in $e.doc$. Then, the semantic score of e on θ_i is the sum of the weights of distinct words in $e.doc$, i.e., $\mathcal{R}_i(e) = \sum_{w \in V_e} \sigma_i(w, e)$ where V_e is the set of distinct words in $e.doc$. We extend the definition of semantic score to an element set by handling the word overlaps. Given a set S and a word w, if w appears in more than one element of S, its weight is computed only once for the element e with the maximum $\sigma_i(w, e)$. Formally, the semantic score of S on θ_i is defined by

$$\mathcal{R}_i(S) = \sum_{w \in V_S} \max_{e \in S} \sigma_i(w, e) \tag{3}$$

where $V_S = \cup_{e \in S} V_e$. Equation 3 aims to select a set of elements to maximally cover the important words on θ_i so as to best preserve the information of θ_i. Additionally, it implicitly captures the diversity issue because adding highly similar elements to S brings little increase in $\mathcal{R}_i(S)$.

Example 3.1. Table 1 gives a social stream extracted from the tweets in Figure 1 and a topic model on the vocabulary of elements in the stream. We demonstrate how to compute the semantic score $\mathcal{R}_2(S)$ where $S = \{e_2, e_7\}$ on θ_2. The frequency of each word in any element is 1. The set of words in S is $V_S = \{w_4, w_9, w_{11}\}$. The word w_9 only appears in e_2. Its weight is $\sigma_2(w_9, e_2) = 0.15$. The words w_4, w_{11} appear in both elements. As $\sigma_2(w_4, e_2) = 0.18 > \sigma_2(w_4, e_7) = 0.17$ and $\sigma_2(w_{11}, e_2) = 0.20 >$

Table 1: Example for social stream and topic model

(a) Elements extracted from tweets in Figure 1

Elem ID	Time	Words	θ_1	θ_2	References
e_1	1	$w_1, w_6, w_8, w_{14}, w_{16}$	0.2	0.8	$\varnothing$
e_2	2	w_4, w_9, w_{11}	0.26	0.74	$\varnothing$
e_3	3	w_3, w_5, w_{10}, w_{13}	0.89	0.11	$\varnothing$
e_4	4	w_7, w_{10}	1	0	e_3
e_5	5	w_6, w_8, w_{16}	0.29	0.71	e_1
e_6	6	w_2, w_7, w_{10}, w_{12}	0.7	0.3	e_3
e_7	7	w_4, w_{11}	0.33	0.67	e_2
e_8	8	w_{10}, w_{11}, w_{15}	0.51	0.49	e_2, e_3, e_6

(b) Topic-Word distribution – I

Word ID	Word	θ_1	θ_2
w_1	asroma	0	0.03
w_2	assist	0.06	0.04
w_3	cavs	0.09	0
w_4	champion	0.1	0.09
w_5	defeat	0.05	0.04
w_6	final	0.11	0.12
w_7	lebron	0.12	0
w_8	lfc	0	0.06

(c) Topic-Word distribution – II

Word ID	Word	θ_1	θ_2
w_9	manutd	0	0.07
w_{10}	nbaplayoffs	0.11	0
w_{11}	pl	0	0.11
w_{12}	point	0.15	0.14
w_{13}	raptors	0.08	0
w_{14}	realmadrid	0	0.07
w_{15}	schedule	0.13	0.12
w_{16}	ucl	0	0.11

$\sigma_2(w_{11}, e_7) = 0.19$, $\sigma_2(w_4, e_2)$ and $\sigma_2(w_{11}, e_2)$ are the weights of w_4 and w_{11} for S. Finally, we sum up the weights of each word in V_S and get $\mathcal{R}_2(S) = 0.53$. In this example, e_7 has no contribution to the semantic score because all words in e_7 are covered by e_2.

Topic-specific Time-critical Influence Score. Given a topic θ_i and two elements $e', e \in E$ ($e' \in e.ref$), the probability of influence propagation from e' to e on θ_i is defined by $p_i(e' \rightsquigarrow e) = p_i(e') \cdot p_i(e)$. Furthermore, the probability of influence propagation from a set of elements S to e on θ_i is defined by $p_i(S \rightsquigarrow e) = 1 - \prod_{e' \in S \cap e.ref} \big(1 - p_i(e' \rightsquigarrow e)\big)$. We assume the influences from different precedents to e are independent of each other and adopt the *probabilistic coverage* model to compute the influence probability from a set of elements to an element. To select recently trending elements, we define the influence score in the sliding window model where only the references observed within W_t are considered. Let $I_t(e') = \{e | e' \in e.ref \wedge e \in W_t\}$ be the set of elements influenced by e' at time t and $I_t(S) = \cup_{e' \in S} I_t(e')$ be the set of elements influenced by S at time t. The influence score of S on θ_i at time t is defined by

$$\mathcal{I}_{i,t}(S) = \sum_{e \in I_t(S)} p_i(S \rightsquigarrow e) \tag{4}$$

Equation 4 tends to select a set of influential elements on θ_i at time t. The value of $\mathcal{I}_{i,t}(S)$ will increase greatly only if an element e is added to S such that e is relevant to θ_i itself and e is referred to by many elements on θ_i within W_t.

Example 3.2. We compute the influence score $\mathcal{I}_{2,8}(S)$ of $S = \{e_2, e_3\}$ in Table 1 on θ_2 at time $t = 8$. We consider the window length $T = 4$ and $W_t = \{e_5, e_6, e_7, e_8\}$. $I_8(S)$ at time 8 is $\{e_6, e_7, e_8\}$ and e_4 expires at time 8. First, $p_2(S \rightsquigarrow e_6) = p_2(e_3 \rightsquigarrow e_6) = 0.03$. Similarly, $p_2(S \rightsquigarrow e_7) = p_2(e_2 \rightsquigarrow e_7) = 0.50$. For e_8, we have $p_2(S \rightsquigarrow e_8) = 1 - \big(1 - p_2(e_2 \rightsquigarrow e_8)\big) \cdot \big(1 - p_2(e_3 \rightsquigarrow e_8)\big) = 0.40$. Finally, we acquire $\mathcal{I}_{2,8}(S) = 0.03 + 0.5 + 0.4 = 0.93$. We can see, although e_3 is referred to by several elements, its influence score on θ_2 is low because e_3 and the elements referring to it are mostly on θ_1.

Query Definition. We formally define the *Semantic and Influence aware k-Representative* (k-SIR) query to select a set of elements S with the maximum representativeness score w.r.t. a query vector from a social stream. We have two constraints on the result of k-SIR query S: (1) its size is restricted to $k \in \mathbb{Z}^+$, i.e., S contains at most k elements, to avoid overwhelming users with too much information; (2) the elements in S must be active at time t, i.e., $S \subseteq A_t$, to satisfy the freshness requirement. Finally, we define a k-SIR query $q_t(k, \mathbf{x})$ as follows.

Definition 3.3 (k-SIR). Given the set of active elements A_t and a vector $\mathbf{x}$, a k-SIR query $q_t(k, \mathbf{x})$ returns a set of elements $S^* \subseteq A_t$ with a bounded size k such that the scoring function $f(\cdot, \mathbf{x})$ is maximized, i.e., $S^* = \operatorname{argmax}_{S \subseteq A_t : |S| \leq k} f(S, \mathbf{x})$, where S^* is the optimal result for $q_t(k, \mathbf{x})$ and $\texttt{OPT} = f(S^*, \mathbf{x})$ is the optimal representativeness score.

Example 3.4. We consider two k-SIR queries on the social stream in Table 1. We set $\lambda = 0.5$, $\eta = 2$ in Equation 2 and the window length $T = 4$. At time 8, the set of active elements A_t contains all except e_4. Given a k-SIR query $q_8(2, \mathbf{x}_1)$ where $\mathbf{x}_1 = (0.5, 0.5)$ (a user has the same interest on two topics), $S^* = \{e_1, e_3\}$ is the query result and $\texttt{OPT} = f(S^*, \mathbf{x}_1) = 0.65$. We can see e_3, e_1 obtain the highest scores on θ_1, θ_2 respectively and they collectively achieve the maximum score w.r.t. $\mathbf{x}_1$. Given an k-SIR query $q_8(2, \mathbf{x}_2)$ where $\mathbf{x}_2 = (0.1, 0.9)$ (the user prefers θ_2 to θ_1), the query result is $S^* = \{e_1, e_2\}$ and $\texttt{OPT} = 0.94$. e_3 is excluded because it is mostly distributed on θ_1.

3.3 Properties and Challenges

Properties of k-SIR Queries. We first show the *monotonicity* and *submodularity* of the scoring function $f(\cdot, \cdot)$ for k-SIR query by proving that both the semantic function $\mathcal{R}_i(\cdot)$ and the influence function $\mathcal{I}_{i,t}(\cdot)$ are monotone and submodular.

Definition 3.5 (Monotonicity & Submodularity). A function $g(\cdot) : 2^{|E|} \rightarrow \mathbb{R}_{\geq 0}$ on the power set of E is monotone iff $g(S \cup \{e\}) \geq g(S)$ for any $e \in E \setminus S$ and $S \subseteq E$. The function $g(\cdot)$ is submodular iff $g(S \cup \{e\}) - g(S) \geq g(T \cup \{e\}) - g(T)$ for any $S \subseteq T \subseteq E$ and $e \in E \setminus T$.

Lemma 3.6. *$\mathcal{R}_i(\cdot)$ is monotone and submodular for $i \in [1, z]$.*

Lemma 3.7. *$\mathcal{I}_{i,t}(\cdot)$ is monotone and submodular for $i \in [1, z]$ at any time t.*

The proofs are given in Appendices A.1 and A.2.

Given a query vector $\mathbf{x}$, the scoring function $f(\cdot, \mathbf{x})$ is a non-negative linear combination of $\mathcal{R}_i(\cdot)$ and $\mathcal{I}_{i,t}(\cdot)$. Therefore, $f(\cdot, \mathbf{x})$ is *monotone* and *submodular.*

Challenges of k-SIR Queries. In this paper, we consider that the elements arrive continuously over time. We always maintain the set of active elements A_t at any time t. It is required to provide the result for any ad-hoc k-SIR query $q_t(k, \mathbf{x})$ in real-time.

The challenges of processing k-SIR queries in such a scenario are two-fold: (1) *NP-hardness* and (2) *dynamism.* First, the following theorem shows the k-SIR query is *NP-hard.*

Theorem 3.8. *It is NP-hard to obtain the optimal result S^* for any k-SIR query $q_t(k, \mathbf{x})$.*

The *weighted maximum coverage* problem can be reduced to k-SIR query when $\lambda = 1$ in Equation 2. Meanwhile, the *probabilistic coverage* problem is a special case of k-SIR query when $\lambda = 0$ in

Table 2: Frequently Used Notations

Notation	Description
E, e, e_i	$E = \{e_1, \ldots, e_n\}$ is a social stream; e is an arbitrary element in E; e_i is the i-th element in E.
T, W_t, A_t	T is the window length; W_t is the sliding window at time t; A_t is the set of active elements at time t.
Θ, θ_i	Θ is a topic model; θ_i is the i-th topic in Θ.
$\mathbf{x}, x_i$	$\mathbf{x}$ is a z-dimensional vector; x_i is the i-th entry of $\mathbf{x}$.
$\mathcal{R}_i(\cdot), \mathcal{I}_{i,t}(\cdot)$	$\mathcal{R}_i(\cdot)$ is the semantic function on θ_i; $\mathcal{I}_{i,t}(\cdot)$ is the influence function on θ_i at time t.
$f_i(\cdot), f(\cdot,\cdot)$	$f_i(\cdot)$ is the representativeness scoring function on θ_i; $f(\cdot,\cdot)$ is the scoring function w.r.t. a query vector.
$q_t(k, \mathbf{x})$	$q_t(k, \mathbf{x})$ is a k-SIR query at time t with a bounded result size k and a query vector $\mathbf{x}$.
$S^*, \mathtt{OPT}$	S^* is the optimal result for $q_t(k, \mathbf{x})$; $\mathtt{OPT} = f(S^*, \mathbf{x})$ is the optimal representativeness score.
$\delta_i(e), \delta(e, \mathbf{x})$	$\delta_i(e) = f_i(\{e\})$ is the score of e on θ_i; $\delta(e, \mathbf{x}) = f(\{e\}, \mathbf{x})$ is the score of e w.r.t. $\mathbf{x}$.
$\Delta(e\|S)$	$\Delta(e\|S) = f(S \cup \{e\}, \mathbf{x}) - f(S, \mathbf{x})$ is the marginal score gain of adding e to S.
RL_i	RL_i is the ranked list maintained for the elements on topic θ_i.

Equation 2. Because both problems are NP-hard [13], the k-SIR query is NP-hard as well.

In spite of this, existing algorithms for submodular maximization [22] can provide results with constant approximations to the optimal ones for k-SIR queries due to the monotonicity and submodularity of the scoring function. For example, CELF [16] is $(1 - \frac{1}{e})$-approximate for k-SIR queries while SieveStreaming [2] is $(\frac{1}{2} - \varepsilon)$-approximate (for any $\varepsilon > 0$). However, both algorithms cannot fulfill the requirements for real-time k-SIR processing owing to the dynamism of k-SIR queries. The results of k-SIR queries not only vary with query vectors but also evolve over time for the same query vector due to the changes in active elements and the fluctuations in influence scores over the sliding window. To process one k-SIR query $q_t(k, \mathbf{x})$, CELF and SieveStreaming should evaluate $f(\cdot, \mathbf{x})$ for $O(k \cdot n_t)$ and $O(\frac{\log k}{\varepsilon} \cdot n_t)$ times respectively. Empirically, they often take several seconds for one k-SIR query when the window length is 24 hours. To the best of our knowledge, none of the existing algorithms can efficiently process k-SIR queries. Thus, we are motivated to devise novel real-time solutions for k-SIR processing over social streams.

Before moving on to the section for k-SIR processing, we summarize the frequently used notations in Table 2.

4 QUERY PROCESSING

In this section, we introduce the methods to process k-SIR queries over social streams. The architecture is illustrated in Figure 4. At any time t, we maintain (1) **Active Window** to buffer the set of active elements A_t, (2) **Ranked Lists** $\mathsf{RL}_1, \ldots, \mathsf{RL}_z$ to sort the lists of elements on each topic of Θ in descending order of topic-wise representativeness score, and (3) **Query Processor** to leverage the *ranked lists* to process k-SIR queries. In addition, when the topic model is given, the query and topic inferences become rather standard (e.g., Gibbs sampling [21]), and thus we do not discuss these procedures here for space limitations. We consider the query vectors and the topic vectors of elements have been given in advance.

As shown in Figure 4, we process a social stream E in a batch manner. E is partitioned into buckets with equal time length $L \in \mathbb{Z}^+$ and updated at discrete time $L, 2L, \ldots$ until the end time of the stream t_n. When the window slides at time t, a bucket B_t containing the elements between time $t - L + 1$ to t is received. After inferring the topic vector of each $e \in B_t$ with the topic model, we first update the *active window*. The elements in B_t are inserted into the *active window* and the elements referred to by them are updated. Then, the elements that are never referred to by any element after time $t - T + 1$ are discarded from the *active window*. Subsequently, the *ranked list* RL_i on each topic θ_i is maintained for B_t. The detailed procedure for ranked lists maintenance will be presented in Section 4.1.

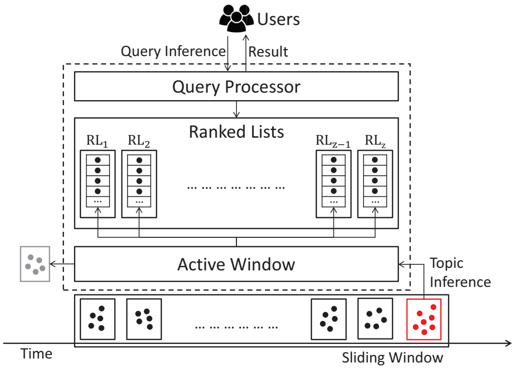

Figure 4: The architecture for k-SIR query processing

Next, let us discuss the mechanism of k-SIR processing. One major drawback of existing submodular maximization methods, e.g., CELF [16] and SieveStreaming [2], on processing k-SIR queries is that they need to evaluate every active element at least once. However, real-world datasets often have two characteristics: (1) The scores of elements are skewed, i.e., only a few elements have high scores. For example, we compute the scores of a sample of tweets w.r.t. a k-SIR query and scale the scores linearly to the range of 0 to 1. The statistics demonstrate that only 0.4% elements have scores of greater than 0.9 while 91% elements have scores of less than 0.1. (2) One element can only be high-ranked in very few topics, i.e., one element is about only one or two topics. In practice, we observe that the average number of topics per element is less than 2. Therefore, most of the elements are not relevant to a specific k-SIR query. We can greatly improve the efficiency by avoiding the evaluations for the elements with very low chances to be included into the query result. To prune these unnecessary evaluations, we leverage the ranked lists to sequentially evaluate the active elements in decreasing order of their scores w.r.t. the query vector. In this way, we can track whether unevaluated elements can still be added to the query result and terminate the evaluations as soon as possible.

Although such a method to traverse the *ranked lists* is similar to the one for top-k query [39], the procedures for maintaining the query results are totally different. A top-k query simply returns k elements with the maximum scores as the result for a k-SIR query. Although the top-k result can be retrieved efficiently from the *ranked lists* using existing methods [39], its quality for k-SIR queries is suboptimal because the word and influence overlaps are ignored. Thus, we will propose the Multi-Topic ThresholdStream (MTTS) and Multi-Topic ThresholdDescend (MTTD) algorithms for k-SIR processing in Sections 4.2 and 4.3. They can return high-quality results with constant approximation guarantees for k-SIR queries while meeting the real-time requirements.

Algorithm 1: Ranked List Maintenance

```
   Input: A social stream $E$, the window length $T$, and the
          bucket length $L$
1  $t \leftarrow 0$, initialize an empty ranked list $\mathsf{RL}_i$ for $i \in [1, z]$;
2  while $t \leq t_n$ do
3      $t \leftarrow t + L, B_t \leftarrow \{e \in E | e.ts \in [t - L + 1, t]\}$;
4      foreach $e \in B_t$ do
5          foreach $i : p_i(e) > 0$ do
6              $\delta_i(e) \leftarrow \mathcal{R}_i(e), t_e \leftarrow e.ts$;
7              create a tuple $\langle \delta_i(e), t_e \rangle$ and insert it into $\mathsf{RL}_i$;
8          foreach $e' \in e.ref$ do
9              foreach $i : p_i(e') > 0 \wedge p_i(e) > 0$ do
10                 $\delta_i(e') \leftarrow f_i(\{e'\}), t_{e'} \leftarrow e.ts$;
11                 adjust the position of $\langle \delta_i(e'), t_{e'} \rangle$ in $\mathsf{RL}_i$;
12     foreach $e$ : $e$ is never referred to after $t - T + 1$ do
13         delete the tuples of $e$ from $\mathsf{RL}_i$ with $p_i(e) > 0$;
```

4.1 Ranked List Maintenance

In this subsection, we introduce the procedure for ranked list maintenance. Generally, a ranked list RL_i keeps a tuple for each active element on topic θ_i. A tuple for element e is denoted as $\langle \delta_i(e), t_e \rangle$ where $\delta_i(e) = f_i(\{e\})$ is the topic-wise representativeness score of e on θ_i and t_e is the timestamp when e is last referred to. All tuples in RL_i are sorted in descending order of topic-wise score.

The algorithmic description of ranked list maintenance over a social stream is presented in Algorithm 1. Initially, an empty ranked list is initialized for each topic θ_i in the topic model Θ (Line 1). At discrete timestamps $t = L, 2L, \ldots$ until t_n, the *ranked lists* are updated according to a bucket of elements B_t. For each element e in B_t, a tuple $\langle \delta_i(e), t_e \rangle$ is created and inserted into RL_i for every topic θ_i with $p_i(e) > 0$ (Lines 4–7). The score $\delta_i(e)$ is $\mathcal{R}_i(e)$ because the elements influenced by e have not been observed yet. The time t_e when e is last referred to is obviously $e.ts$. Subsequently, it recomputes the influence score $\mathcal{I}_{i,t}(e')$ for each parent e' of e. After that, it updates the tuple $\langle \delta_i(e'), t_{e'} \rangle$ by setting $\delta_i(e')$ to $f_i(\{e'\})$ and $t_{e'}$ to $e.ts$. The position of $\langle \delta_i(e'), t_{e'} \rangle$ in RL_i is adjusted according to the updated $\delta_i(e')$ (Lines 8–11). Finally, we delete the tuples for expired elements from RL_i (Lines 12–13).

Complexity Analysis. The cost of evaluating $\delta_i(e)$ for any element e is $O(l)$ where $l = \max_{e \in A_t}(|V_e| + |I_t(e)|)$. Then, the complexity of inserting a tuple into RL_i is $O(\log n_t)$. For each $e' \in e.ref$, the complexity of re-evaluating $\mathcal{I}_{i,t}(e')$ is also $O(l)$. Overall, the complexity of maintaining RL_i for element e is $O\big(\mathcal{P}(l + \log n_t)\big)$ where $\mathcal{P} = \max_{e \in A_t} |e.ref|$. As the tuples for e may appear in $O(z)$ ranked lists, the time complexity of ranked list maintenance for element e is $O\big(z\mathcal{P}(l + \log n_t)\big)$.

Operations for Ranked List Traversal. We need to access the tuples in each *ranked list* RL_i in decreasing order of topic-wise score for k-SIR processing. Two basic operations are defined to traverse the ranked list RL_i: (1) RL_i.first to retrieve the element w.r.t. the first tuple with the maximum topic-wise score from RL_i; (2) RL_i.next to acquire the element w.r.t. the next unvisited tuple in RL_i from the current one. Note that once a tuple for element e has been accessed in one ranked list, the remaining tuples for e in the other lists will be marked as "visited" so as to eliminate duplicate evaluations for e.

Algorithm 2: Multi-Topic ThresholdStream

```
   Input: The ranked list $\mathsf{RL}_i$ for each $i \in [1, z]$ and a $k$-SIR
          query $q_t(k, \mathbf{x})$
   Parameter: $\varepsilon \in (0, 1)$
   Result: $S_{ts}$ for $q_t(k, \mathbf{x})$
1  $\Phi = \{(1 + \varepsilon)^j | j \in \mathbb{Z}\}$, foreach $\phi \in \Phi$ do $S_\phi \leftarrow \varnothing$;
2  foreach $i \in [1, z] : x_i > 0$ do $e^{(i)} \leftarrow \mathsf{RL}_i$.first;
3  $\delta_{max}, \mathsf{TH} \leftarrow 0$ and $\mathsf{UB}(\mathbf{x}) \leftarrow \sum_{i=1}^{z} x_i \cdot \delta_i(e^{(i)})$;
4  while $\mathsf{UB}(\mathbf{x}) \geq \mathsf{TH}$ do
5      $i^* \leftarrow \mathrm{argmax}_{i \in [1,z]} x_i \cdot \delta_i(e^{(i)}), e \leftarrow e^{(i^*)}$;
6      $\delta(e, \mathbf{x}) \leftarrow \sum_{i=1}^{z} x_i \cdot \delta_i(e)$;
7      if $\delta(e, \mathbf{x}) > \delta_{max}$ then $\delta_{max} \leftarrow \delta(e, \mathbf{x})$;
8      $\Phi = \{(1 + \varepsilon)^j | j \in \mathbb{Z} \wedge \delta_{max} \leq (1 + \varepsilon)^j \leq 2 \cdot k \cdot \delta_{max}\}$;
9      delete $S_\phi$ if $\phi \notin \Phi$;
10     foreach $\phi \in \Phi$ do
11         if $\delta(e, \mathbf{x}) \geq \frac{\phi}{2k} \wedge |S_\phi| < k$ then
12             if $\Delta(e|S_\phi) \geq \frac{\phi}{2k}$ then $S_\phi \leftarrow S_\phi \cup \{e\}$;
13     $e^{(i^*)} \leftarrow \mathsf{RL}_{i^*}$.next;
14     $\mathsf{TH} \leftarrow \min_{\phi \in \Phi : |S_\phi| < k} \frac{\phi}{2k}$, $\mathsf{UB}(\mathbf{x}) \leftarrow \sum_{i=1}^{z} x_i \cdot \delta_i(e^{(i)})$;
15 return $S_{ts} \leftarrow \mathrm{argmax}_{\phi \in \Phi} f(S_\phi, \mathbf{x})$;
```

4.2 Multi-Topic ThresholdStream Algorithm

In this subsection, we present the MTTS algorithm for k-SIR processing. MTTS is built on two key ideas: (1) a thresholding approach [15] to submodular maximization and (2) a ranked list based mechanism for early termination. First, given a k-SIR query, the thresholding approach always tracks its optimal representativeness score OPT. It establishes a sequence of candidates with different *thresholds* within the range of OPT. For any element e, each candidate determines whether to include e independently based on e's marginal gain and its threshold. Second, to prune unnecessary evaluations, MTTS utilizes *ranked lists* to sequentially feed elements to the candidates in decreasing order of score. It continuously checks the minimum threshold for an element to be added to any candidate and the upper-bound score of unevaluated elements. MTTS is terminated when the upper-bound score is lower than the minimum threshold. After termination, the candidate with the maximum score is returned as the result for the k-SIR query.

The algorithmic description of MTTS is presented in Algorithm 2. The initialization phase is shown in Lines 1–3. Given a parameter $\varepsilon \in (0, 1)$, MTTS establishes a geometric progression Φ with common ratio $(1 + \varepsilon)$ to estimate the optimal score OPT for $q_t(k, \mathbf{x})$. Then, it maintains a candidate S_ϕ initializing to $\varnothing$ for each $\phi \in \Phi$. The threshold for S_ϕ is $\frac{\phi}{2k}$. The traversal of ranked lists starts from the first tuple of each list. We use $e^{(i)}$ to denote the element corresponding to the current tuple from RL_i. MTTS keeps 3 variables: (1) δ_{max} to store the maximum score w.r.t. $\mathbf{x}$ among the evaluated elements, (2) TH to maintain the minimum threshold for an element to be added to any candidate, and 3) $\mathsf{UB}(\mathbf{x})$ to track the upper-bound score for any unevaluated element w.r.t. $\mathbf{x}$. Specifically, TH is the threshold $\frac{\phi}{2k}$ of the unfilled candidate S_ϕ (i.e., $|S_\phi| < k$) with the minimum ϕ. We set $\mathsf{TH} = 0$ before the evaluation. If $\delta(e, \mathbf{x}) < \mathsf{TH}$, e can be safely excluded from evaluation. In addition, for any unevaluated element e, it holds that $\delta_i(e) \leq \delta_i(e^{(i)})$ because the tuples in RL_i are sorted

(b) Evaluating e_6,e_2

Figure 5: Example for k-SIR processing using MTTS.

by topic-wise score. Thus, $\mathsf{UB}(\mathbf{x}) = \sum_{i=1}^{z} x_i \cdot \delta_i(e^{(i)})$ can be used as the upper-bound score of unevaluated elements w.r.t. $\mathbf{x}$.

After the initialization phase, the elements are sequentially retrieved from the ranked lists and evaluated by the candidates according to Lines 4–14. At each iteration, MTTS selects an element $e^{(i^*)}$ with the maximum $x_i \cdot \delta_i(e^{(i)})$ as the next element e for evaluation (Line 5). Subsequently, the candidate maintenance procedure is performed following Lines 6–9. It first computes the score $\delta(e, \mathbf{x})$ of e w.r.t. $\mathbf{x}$. Second, it updates the maximum score δ_{max}. Third, the range of OPT is adjusted to $[\delta_{max}, 2 \cdot k \cdot \delta_{max}]$. Fourth, it deletes the candidates out of the range for OPT. Next, each candidate S_ϕ determines whether to add e independently according to Lines 10–12. If $\delta(e, \mathbf{x}) < \frac{\phi}{2k}$ or S_ϕ has contained k elements, e will be ignored by S_ϕ. Otherwise, the marginal gain $\Delta(e|S_\phi) = f(S_\phi \cup \{e\}, \mathbf{x}) - f(S_\phi, \mathbf{x})$ of adding e to S_ϕ is evaluated. If $\Delta(e|S_\phi)$ reaches $\frac{\phi}{2k}$, e will be added to S_ϕ. Finally, it obtains the next element in RL_{i^*} as $e^{(i^*)}$ and updates TH, $\mathsf{UB}(\mathbf{x})$ accordingly (Lines 13 and 14). The evaluation procedure will be terminated when $\mathsf{UB}(\mathbf{x}) < \mathsf{TH}$ because $\delta(e', \mathbf{x}) \leq \mathsf{UB}(\mathbf{x}) < \mathsf{TH}$ is satisfied for any unevaluated element e', which can be safely pruned. Finally, MTTS returns the candidate with the maximum score as the result for $q_t(k, \mathbf{x})$ (Line 15).

Example 4.1. Following the example in Table 1, we show how MTTS processes a k-SIR query $q_8(2, \mathbf{x})$ where $\mathbf{x} = (0.5, 0.5)$ in Figure 5. We set $\varepsilon = 0.3$ in this example.

First of all, the traversals of RL_1 and RL_2 start from e_3 and e_1 respectively. Initially, we have $\mathsf{UB}(\mathbf{x}) = 0.61$ and $\mathsf{TH} = 0$. Then, the first element to evaluate is e_3 because $x_1 \cdot \delta_1(e_3) = 0.33 > x_2 \cdot \delta_2(e_1) = 0.28$. As $\delta(e_3, \mathbf{x}) = 0.34$, the range of OPT is $[0.34, 1.36]$. We have $0.34 \leq 1.3^{-4} \leq \ldots \leq 1.3^{1} \leq 1.36$ and 6 candidates with $j \in [-4, 1]$ are maintained. e_3 can be added to each of the candidates. After that, e_6 is the next element from RL_1. $\mathsf{UB}(\mathbf{x})$ and TH are updated to 0.52 and 0.09 respectively. The second element to evaluate is e_1 from RL_2. As $\delta(e_1, \mathbf{x}) = 0.31$, the candidate with $j = 1$ directly skips e_1 for $\delta(e_1, \mathbf{x}) < \frac{\phi}{2k} = 0.33$. Other candidates include e_1 as $\Delta(e_1|S_\phi) \geq \frac{\phi}{2k}$. Then, e_2 is the next element from RL_2. $\mathsf{UB}(\mathbf{x})$ decreases to 0.48 while TH increases to 0.33. Subsequently, e_6, e_2 are retrieved but skipped by all candidates. After evaluating e_2, $\mathsf{UB}(\mathbf{x})$ decreases to 0.22 and is lower than TH. Thus, no more evaluation is needed and $S_{ts} = \{e_1, e_3\}$ is returned as the result for $q_8(2, \mathbf{x})$.

The approximation ratio of MTTS is given in Theorem 4.2.

Theorem 4.2. *S_{ts} returned by MTTS is a $(\frac{1}{2} - \varepsilon)$-approximation result for any k-SIR query.*

The proof is given in Appendix A.3.

Complexity Analysis. The number of candidates in MTTS is $O(\frac{\log k}{\varepsilon})$ as the ratio between the lower and upper bounds for OPT is $O(k)$. The complexity of retrieving an element from ranked lists is $O(\log n_t)$. The complexity of evaluating one element for a candidate is $O(ld)$ where $l = \max_{e \in A_t}(|V_e| + |I_t(e)|)$ and d is the number of non-zero entries in the query vector $\mathbf{x}$. Thus, the complexity of MTTS to evaluate one element is $O(\log n_t + \frac{ld \log k}{\varepsilon})$. Overall, the time complexity of MTTS is $O\big(n'_t(\log n_t + \frac{ld \log k}{\varepsilon})\big)$ where n'_t is the number of elements evaluated by MTTS.

4.3 Multi-Topic ThresholdDescend Algorithm

Although MTTS is efficient for k-SIR processing, its approximation ratio is lower than the the best achievable approximation guarantees, i.e., $(1 - \frac{1}{e})$ [13] for submodular maximization with cardinality constraints. In addition, its result quality is also slightly inferior to that of CELF. In this subsection, we propose the Multi-Topic ThresholdDescend (MTTD) algorithm to improve upon MTTS. Different from MTTS, MTTD maintains only one candidate S from $\varnothing$ to reduce the cost for evaluation. In addition, it buffers the elements that are retrieved from ranked lists but not included into S so that these elements can be evaluated more than once. This can lead to better quality as the chances of missing significant elements are smaller. Specifically, MTTD has multiple rounds of evaluation with decreasing *thresholds*. In the round with threshold τ, each element e with $\delta(e, \mathbf{x}) \geq \tau$ is considered and will be included to S once the marginal gain $\Delta(e|S)$ reaches τ. When S contains k elements or τ is descended to the lower bound, MTTD is terminated and S is returned as the result. Theoretically, the approximation ratio of MTTD is improved to $(1 - \frac{1}{e} - \varepsilon)$ but its worst-case complexity is higher than MTTS. Despite this, the efficiency and result quality of MTTD are both better than MTTS empirically.

The algorithmic description of MTTD is presented in Algorithm 3. In the initialization phase (Lines 1–3), the candidate S and the element buffer E' are both set to $\varnothing$. The traversals of ranked lists are initialized in the same way as MTTS. The initial threshold τ for the first round of evaluation is the upper-bound score for any active element w.r.t. $\mathbf{x}$ and the termination threshold τ' is 0. After initialization, MTTD runs each round of evaluation with threshold τ following Lines 4–11. It first retrieves the set of elements E_τ whose scores potentially reach τ from the ranked lists. The method is shown in the procedure `retrieve`(τ) (Lines 13–19), which generally uses the same idea as MTTS: it traverses each ranked list sequentially in decreasing order of topic-wise scores and continuously adds the element with the maximum $x_i \cdot \delta_i(e^{(i)})$ to E_τ until the upper-bound score $\mathsf{UB}(\mathbf{x})$ is decreased to τ. After adding E_τ to the element buffer E', the evaluation procedure is started (Lines 6–10). It always considers the element $e' \in E' \setminus S$ with the maximum $\Delta_{e'}$. If the marginal gain $\Delta(e'|S)$ of adding e' to S is at least τ, e' will be included into S and deleted from E'. When S has contained k elements, MTTD is directly terminated and S is returned as the result S_{td} for $q_t(k, \mathbf{x})$. The round of evaluation is finished when no elements in E' could achieve a marginal gain of τ. Next, the termination threshold τ' is updated and the threshold τ is descended by $(1 - \varepsilon)$ times for the subsequent round of evaluation. Finally, when τ is lower than

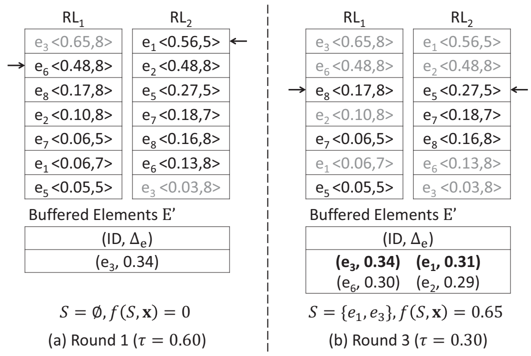
13  Procedure retrieve($\tau$)
14      $E_\tau \leftarrow \emptyset, \mathsf{UB}(\mathbf{x}) \leftarrow \sum_{i=1}^{z} x_i \cdot \delta_i(e^{(i)})$;
15      while $\mathsf{UB}(\mathbf{x}) \geq \tau$ do
16          $i^* \leftarrow \mathrm{argmax}_{i \in [1,z]}\, x_i \cdot \delta_i(e^{(i)})$;
17          $\Delta_{e^{(i^*)}} \leftarrow \sum_{i=1}^{z} x_i \cdot \delta_i(e^{(i^*)}), E_\tau \leftarrow E_\tau \cup \{e^{(i^*)}\}$;
18          $e^{(i^*)} \leftarrow \mathsf{RL}_{i^*}$.next, $\mathsf{UB}(\mathbf{x}) \leftarrow \sum_{i=1}^{z} x_i \cdot \delta_i(e^{(i)})$;
19      return $E_\tau$;
```



(a) Round 1 ($\tau = 0.60$)

(b) Round 3 ($\tau = 0.30$)

Figure 6: Example for k-SIR processing using MTTD.

τ', no more rounds of evaluations are required. In this case, S is returned as the result S_{td} for $q_t(k, \mathbf{x})$ even though it contains fewer than k elements (Line 12).

Example 4.3. In Figure 6, we illustrate the procedure for MTTD to process a k-SIR query $q_8(2, \mathbf{x})$ where $\mathbf{x} = (0.5, 0.5)$ following the example in Table 1. We also set $\varepsilon = 0.3$ in this example.

First, MTTD initializes the threshold $\tau = 0.60$ for the first round and the termination threshold $\tau' = 0$. The candidate S and the element buffer E' are initialized to $\emptyset$. In Round 1 and 2 with $\tau = 0.60$ and 0.42, MTTD retrieves 3 elements e_3, e_1, e_6 from RL_1 and RL_2 and adds them to E'. However, they are not evaluated in the first two rounds because $\Delta_{e_3} = 0.34$, $\Delta_{e_1} = 0.31$, and $\Delta_{e_6} = 0.30$, all of which are smaller than 0.42. In Round 3 with $\tau = 0.30$, e_2 is added to E'. Then, e_3 is added to S as $\Delta_{e_3} = 0.34 > \tau$. Furthermore, e_1 is also added to S as $\Delta_{e_1} = 0.31 > \tau$. At this time, $S = \{e_1, e_3\}$ has contained two elements. Therefore, MTTD is terminated and no more rounds are needed. $S_{td} = \{e_1, e_3\}$ is returned as the result for $q_8(k, \mathbf{x})$.

Table 3: Statistics of datasets

Dataset	AMiner	Reddit	Twitter
Number of Elements	1.66M	20.2M	14.8M
Vocabulary Size	580K / 71K	2.8M / 88K	3.0M / 68K
Average Length	74.5 / 49.2	24.6 / 8.6	12.6 / 5.1
Average References	3.68	0.85	0.62

The approximation ratio of MTTD is given in Theorem 4.4.

Theorem 4.4. *The result S_{td} returned by MTTD is $(1 - \frac{1}{e} - \varepsilon)$-approximate for any k-SIR query.*

The proof is given in Appendix A.4.

Complexity Analysis. Let τ_0 be the threshold τ of the first round in MTTD. The number of rounds in MTTD is at most $\lceil \log_{1-\varepsilon}(\frac{\tau'}{\tau_0}) \rceil$. Because $\tau' = f(S, \mathbf{x}) \cdot \frac{\varepsilon}{k} \geq \delta_{max} \cdot \frac{\varepsilon}{k}$ and $\tau_0 \leq d \cdot \delta_{max}$, we have $\frac{\tau_0}{\tau'} \leq \frac{kd}{\varepsilon}$ and the number of rounds is $O(\frac{\log(kd)}{\varepsilon^2})$. In each round, it evaluates $O(n''_t)$ elements where n''_t is the number of elements in the buffer E' of MTTD and the evaluation of an element is also $O(ld)$. Here, we use a max-heap for E' and thus it costs $O(\log n''_t)$ to dequeue the top element from E'. In addition, the time for retrieving an element from ranked lists is still $O(\log n_t)$. The complexity for each round is $O\big(n''_t \cdot (ld + \log n_t)\big)$. Therefore, the time complexity of MTTD is $O\big(n''_t \cdot \log(kd) \cdot \varepsilon^{-2} \cdot (ld + \log n_t)\big)$.

5 EXPERIMENTS

In this section, we conduct extensive experiments to verify the effectiveness of k-SIR query as well as the efficiency of MTTS and MTTD for k-SIR processing. We first introduce the experimental setup in Section 5.1. Then, we show the results for the effectiveness of k-SIR query in Section 5.2. Finally, the results for the efficiency and scalability of MTTS and MTTD are reported in Section 5.3.

5.1 Experimental Setup

Dataset. Three real-world datasets used in the experiments are listed as follows.

- **AMiner** [32] is a collection of academic papers published in the ACM Digital Library till 2015. We assign random timestamps to the papers published in the same year.
- **Reddit**[1] is a collection of submissions and comments on Reddit from June 01, 2014 to June 14, 2014.
- **Twitter**[2] consists of the tweets collected via the streaming API from July 14, 2017 to July 26, 2017.

The statistics of the datasets are given in Table 3. In the preprocessing, we remove stop words and noise words from the textual contents of elements. Note that we report the vocabulary size and the average length of elements both before and after the preprocessing.

Topic Model. We use LDA [6] to train topic models on the corpora of *AMiner* and *Reddit*. PLDA [21] is the implementation of LDA for training. For topic training on the corpus of *Twitter*, we use the biterm topic model [38] (BTM) because it is designed for short texts like tweets. The corpus of each dataset consists of $e.doc$ of each element e. To study how the number of topics z affects the performance of compared methods, we train 5 topic models for each dataset with z ranging from 50 to 250. Two Dirichlet priors α, β are set to $\frac{50}{z}$, 0.01 for both LDA and BTM.

[1] https://www.reddit.com/r/datasets

[2] https://developer.twitter.com/en/docs

The pre-trained topic models are loaded into memory and used as a black-box oracle for each compared method.

Compared Methods. We compare the following methods in Section 5.2 to evaluate the effectiveness of k-SIR query.

- **Top-k Keyword Query** (TF-IDF) retrieves k most relevant elements to the query keywords. We adopt the log-normalized TF-IDF weight to vectorize the elements and queries. Cosine similarity is used as the similarity measure between an element and a query.
- **Diversity-aware Top-k Keyword Query** [9] (DIV) considers both *textual relevance* and *result diversity*. Given a query q and a set of elements S, we have $score(q, S) = \lambda \sum_{e \in S} rel(q, e) + (1 - \lambda)div(S)$, where $rel(q, e)$ is the relevance of e to q and $div(S)$ is the average dissimilarity between each pair of elements in S. We set $\lambda = 0.3$ following [9]. A set of k elements S with the maximum $score(q, S)$ is returned as the result for q.
- **Sumblr** [27] is a method for social stream summarization. In our experiments, we use Sumblr for query processing as follows: given a set of keywords, we select the elements that contain at least one keyword as candidates. Then, we run Sumblr on the candidates to generate a summary of k elements as the query result. The parameters for k-means clustering and LexRank are the same as [27].
- **Top-k Relevance Query** [39] (REL) measures the relevance between an element and a query by topic modeling. It returns k elements whose topic vectors have the highest cosine similarities to the query vector as the result.
- **k-SIR Query** retrieves a set of elements S maximizing $f(S, \mathbf{x})$ w.r.t. a query vector $\mathbf{x}$. The results of MTTD are used in the effectiveness tests.

We note that TF-IDF, DIV, and Sumblr are keyword queries while REL and k-SIR use query vectors inferred from topic models. To compare them fairly, the queries are generated as follows: (1) draw the keywords from the vocabulary; (2) acquire a query vector by treating the keywords as a pseudo-document and inferring its topic vector from the topic model. To retrieve the query results, TF-IDF, DIV, and Sumblr receive the keywords while REL and k-SIR receive the query vectors.

The following methods are compared in Section 5.3 to evaluate their efficiency and scalability for k-SIR processing.

- **CELF** [16] is an improved version of the basic greedy algorithm [22]. It is the most common batch algorithm for submodular maximization and acquires $(1 - \frac{1}{e})$-approximation results for k-SIR queries. Note that $(1 - \frac{1}{e})$ is the best approximation ratio for this problem unless P=NP [13].
- **SieveStreaming** [2] is the state-of-the-art streaming algorithm for submodular maximization. It returns $(\frac{1}{2} - \varepsilon)$-approximation results for k-SIR queries.
- **Top-k Representative** retrieves k elements with the highest representativeness scores $\delta(e, \mathbf{x})$ w.r.t. a query vector $\mathbf{x}$ from ranked lists as the result, which is only $\frac{1}{k}$-approximate for k-SIR queries. We compare with it to show that traditional methods for top-k queries cannot work well for k-SIR queries.
- **MTTS** and **MTTD** are our proposed algorithms for k-SIR processing based on ranked lists.

Query and Workload Generation. We generate a k-SIR query as follows: (1) draw 1–5 words randomly from the vocabulary; (2) acquire the query vector by inferring the topic distribution of selected words from the topic model.

Table 4: Parameters in the experiments

Parameter	Setting	Default
the parameter ε in MTTS/MTTD	0.1 to 0.5	0.1
the result size k	5 to 25	10
the number of topics z	50 to 250	50
the window length T	6 hours to 30 hours	24 hours

In an experiment, we feed all elements in a dataset to compared methods in ascending order of timestamp. The active window and ranked lists perform batch-updates for each bucket of elements. Then, the query workload is generated as follows: we generate 10K k-SIR queries for each dataset and assign a random timestamp in range $[1, t_n]$ (t_n is the end time of the stream) to each query. The query results are retrieved at the assigned timestamps.

Parameter Setting. The parameters we examine in the experiments are listed in Table 4. In addition, the factors λ, η in Equation 2 are set to $0.5, 20$ for the *AMiner* and *Reddit* datasets, and $0.5, 200$ for the *Twitter* dataset. The bucket length L is fixed to 15 minutes.

Experimental Environment. All experiments are conducted on a server running Ubuntu 16.04.3 LTS. It has an Intel Xeon E7-4820 1.9GHz processor and 128 GB memory. All compared methods are implemented in Java 8.

5.2 Effectiveness

To evaluate the effectiveness of our k-SIR query, we first conduct a study on users' satisfaction for the results returned by each query method. We follow the methodology and procedure of user study in previous work on social search [9]. The detailed procedure is as follows.

First, we generate 20 queries by selecting 20 trending topics on three datasets (e.g., "*social media analysis*" on *AMiner*, "*NBA*" on *Reddit*, and "*pop music*" on *Twitter*) and use the topical words of each topic as keywords. Second, we process these queries with each method in the default setting and return a set of five elements as the results. Third, we recruit 30 volunteers who are not related to this work and familiar with the query topics to evaluate the result quality of compared methods. For each query, we ask 3 different evaluators to rank the quality of result sets and record the average score on each aspect. Specifically, each evaluator is requested to rank his/her satisfaction for the result sets on two aspects: (1) *representativeness*: the relevance to query topic and the information coverage on the query topic of its entirety (ranking from "the least representative" to "the most representative", mapped to values 1 to 5); (2) *impact*: the number of citations, comments, and retweets of selected elements (ranking from "the lowest impact" to "the highest impact", mapped to values 1 to 5).

The results of the user study are shown in Table 5. Following [9], we measure the agreement between different users by computing the Cohen's linearly weighted kappa [10] for each query on each aspect. The kappa values for *representativeness* are between 0.5 and 0.89 (0.72 on average). The kappa values for *impact* are in the range of 0.56–1.0 (0.79 on average). We observe that k-SIR achieves the highest scores among compared methods on both *representativeness* and *impact* in all datasets. We also collect feedback from users for the reason of dissatisfaction. "Low coverage" is the primary problem for TF-IDF and REL, while "containing irrelevant elements" is the main reason why the results of DIV and Sumblr are unsatisfactory.

Table 5: Results for user study

Method		TF-IDF	DIV	Sumblr	REL	k-SIR
AMiner	Represent.	2.28	1.56	3.72	2.78	**4.67**
	Impact	2.39	1.44	4.01	2.39	**4.78**
Reddit	Represent.	2.05	3.00	3.67	1.95	**4.33**

Then, we use two quantitative metrics to evaluate the effectiveness of k-SIR query: (1) *coverage*: do the result sets achieve high information coverage on query topics? Following the metric used in previous studies [2, 20], the coverage score of a result set S w.r.t. a query vector $\mathbf{x}$ is computed by $\sum_{e \in A_t \setminus S} \max_{e' \in S} rel(e, \mathbf{x}) \cdot sim(e, e')$ where $rel(e, \mathbf{x})$ is the relevance of e to $\mathbf{x}$ and $sim(e, e')$ is the similarity of e and e'; (2) *influence*: are the result sets referred by a large number of elements (e.g., citations, comments, retweets, and so on)? We use the total number of elements referring to at least one element in the result set as the influence score. For ease of presentation, the influence scores are linearly scaled to $[0, 1]$ by dividing by the influence score of top-k influential elements. To acquire the results shown in Table 6, we sample the result sets of 1K queries returned by each method and compute the average scores.

We present the quantitative results for the effectiveness of compared methods in Table 6. First, k-SIR outperforms other query methods on *information coverage*, which verifies that our semantic model is able to preserve information on query topics. Second, as only k-SIR and Sumblr account for the influences of elements, they naturally achieve much higher influence scores than other methods. k-SIR further outperforms Sumblr in terms of *influence* because k-SIR directly adopt the number of references for influence computation while Sumblr only considers the PageRank scores of authors.

Overall, the above results have confirmed that k-SIR shows better result quality than existing methods for social search and summarization in terms of *information coverage* and *influence*.

5.3 Efficiency and Scalability

Effect of ε. The average CPU time of MTTS and MTTD to process one k-SIR query (i.e., *query time*) with varying ε is illustrated in Figure 7. MTTS and MTTD show different trends w.r.t. ε. On the one hand, the query time of MTTS drops drastically when ε increases as the number of candidates in MTTS is inversely proportional to ε. On the other hand, MTTD is not sensitive to ε and typically takes slightly more time for a larger ε. This is because a greater ε often leads to a smaller threshold for termination. In this case, more elements are retrieved from ranked lists and evaluated by MTTD, which degrades the query efficiency.

The average scores of the results returned by MTTS and MTTD with varying ε are shown in Figure 8. The scores of both methods decrease when ε increases, which is consistent with the theoretical results of Theorem 4.2 and 4.4. However, both methods show good robustness against ε: compared with CELF, their quality losses are at most 5% even when $\varepsilon = 0.5$.

Effect of result size k. The average query time of compared methods with varying k is presented in Figure 9. In addition, the average ratios between the number of elements evaluated by MTTS/MTTD and the number of active elements are shown in Figure 10. First of all, MTTS and MTTD run at least one order of magnitude faster than CELF and SieveStreaming for k-SIR processing in all datasets. MTTS and MTTD can achieve up to 124x and 390x speedups over the two baselines respectively. Compared with them, MTTS and MTTD can prune most of the unnecessary evaluations (at least 98% as shown in Figure 10) by utilizing the ranked lists. Then, the query time of MTTS and MTTD significantly grows with increasing k. The result can be explained by the ratios of evaluated elements. From Figure 10, we can see the ratio increases near linearly with k. As more elements are evaluated when k increases, the query time naturally rises. Finally, we can see MTTD outperforms MTTS in most cases but the ratio of elements evaluated by MTTD is always higher than MTTS. This is because MTTD only keeps one candidate but MTTS maintains multiple candidates independently. As a result, MTTD reduces the number of evaluations though it retrieves more elements from ranked lists than MTTS.

The average scores of the results returned by MTTS and MTTD with varying k are shown in Figure 11. We can see the result quality of MTTD is always nearly equal (>99%) to CELF for different k. Meanwhile, MTTS can also return results with over 95% representativeness scores compared with CELF. The results of SieveStreaming are inferior to those of CELF, MTTS, and MTTD. Although Top-k Representative shows the best performance among compared methods, its results are of the lowest quality among compared methods. In addition, its result quality degrades dramatically when k increases because the word and influence overlaps are ignored.

Scalability. We evaluate the scalability of MTTS and MTTD with varying the number of topics z and the window length T. The results for query time are illustrated in Figure 12 and 13. The query time of MTTS and MTTD drops when z increases. Because the average number of elements on each topic deceases with increasing z, the number of evaluated elements naturally decreases. However, when $z = 250$ in the *AMiner* dataset, the query time of MTTS and MTTD grows because there are more

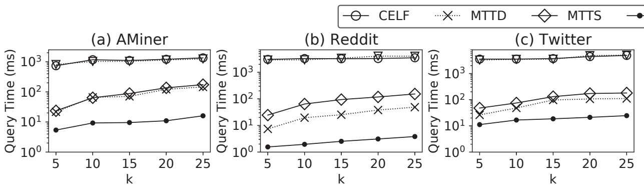

Figure 9: Query time with varying k

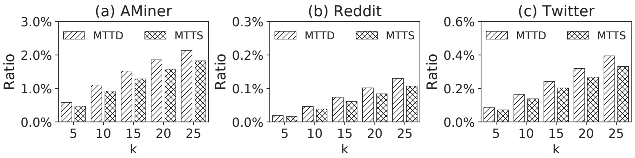

Figure 10: Ratios of evaluated elements with varying k

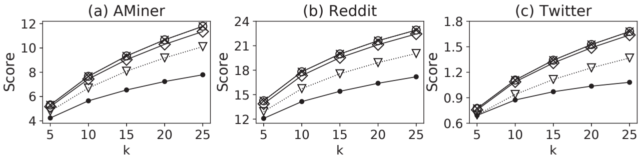

Figure 11: Scores with varying k

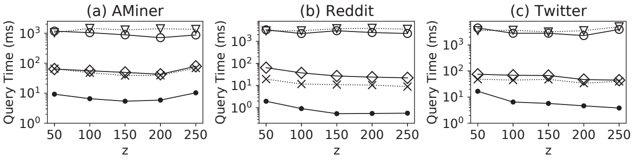

Figure 12: Query time with varying z

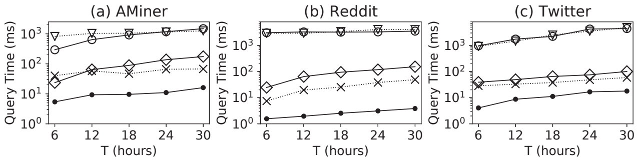

Figure 13: Query time with varying T

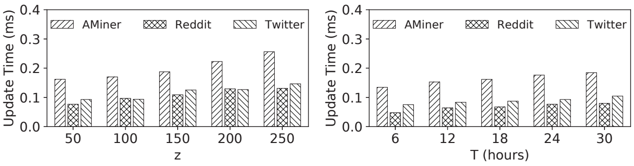

Figure 14: Update time with varying z and T

non-zero entries in the query vectors. The query time of all methods increases with T since there are more active elements. Nevertheless, MTTS and MTTD significantly outperform the baselines in all cases.

The average CPU time elapsed to update the ranked lists per arrival element is shown in Figure 14. We can see it takes more update time when z or T increases. As the number of maintained ranked lists is equal to z and the number of active elements grows with T, the cost for ranked list maintenance inevitably rises with increasing z or T. Nevertheless, the update time is always lower than 0.3ms in all datasets.

Overall, the experimental results show that our proposed methods demonstrate high efficiency and scalability for both ranked list maintenance and k-SIR processing, which can meet the requirements for real-world social streams.

6 CONCLUSION

In this paper, we defined a novel k-SIR query to retrieve a set of k representative elements from a social stream w.r.t. a query vector. We then proposed two algorithms, namely MTTS and MTTD, that leveraged the ranked lists for k-SIR processing over sliding windows. Theoretically, MTTS and MTTD provided $(\frac{1}{2} - \varepsilon)$ and $(1 - \frac{1}{e} - \varepsilon)$ approximation results for k-SIR queries respectively. Finally, we conducted extensive experiments on real-world datasets to demonstrate that (1) the k-SIR query achieved better performance in terms of *information coverage* and *social influence* than existing query methods on social data; (2) MTTS and MTTD had much higher efficiency and scalability than the baselines for k-SIR processing with near-equivalent result quality. In future work, we plan to extend our approach for supporting the incremental updates of topic models over streams.

A PROOFS OF LEMMAS AND THEOREMS

A.1 Proof of Lemma 3.6

Proof. First, for $e \in E \setminus S$ and $S \subseteq E$, we have $\mathcal{R}_i(S \cup \{e\}) - \mathcal{R}_i(S) \geq \sum_{w \in V_e \setminus V_S} \sigma_i(w, e) \geq 0$ because $-p \cdot \log p \geq 0$ for $p \in [0, 1]$. Thus, $\mathcal{R}_i(\cdot)$ is monotone.

Given any $e \in E \setminus T$ and $S \subseteq T \subseteq E$, we use $\Delta(e|S) = \mathcal{R}_i(S \cup \{e\}) - \mathcal{R}_i(S)$ and $\Delta(e|T) = \mathcal{R}_i(T \cup \{e\}) - \mathcal{R}_i(T)$ to denote the marginal score gains of adding e to S and T.

First, as $S \subseteq T$, $V_S \subseteq V_T$. We divide V_e into three disjoint subsets $V_1 = V_e \setminus V_T$, $V_2 = V_e \cap (V_T \setminus V_S)$ and $V_3 = V_e \cap V_S$. Then, it is obvious that $\Delta(e|\cdot) = \Delta(V_1|\cdot) + \Delta(V_2|\cdot) + \Delta(V_3|\cdot)$ for S and T. For V_1, we have $\Delta(V_1|S) = \Delta(V_1|T) = \sum_{w \in V_1} \sigma_i(w, e)$ because $V_1 \cap V_S = \varnothing$ and $V_1 \cap V_T = \varnothing$. For V_2, we have $\Delta(V_2|S) = \sum_{w \in V_2} \sigma_i(w, e)$ and $\Delta(V_2|T) = \sum_{w \in V_2} \max\big(0, \sigma_i(w, e) - \max_{e' \in T} \sigma_i(w, e')\big)$ as $V_2 \cap V_S = \varnothing$ and $V_2 \subseteq V_T$. Obviously, we can acquire $\Delta(V_2|S) \geq \Delta(V_2|T)$ as well. For V_3, we have $\Delta(V_3|S) = \sum_{w \in V_3} \max\big(0, \sigma_i(w, e) - \max_{e' \in S} \sigma_i(w, e')\big)$ and $\Delta(V_3|T) = \sum_{w \in V_3} \max\big(0, \sigma_i(w, e) - \max_{e' \in T} \sigma_i(w, e')\big)$ because of $V_3 \subseteq V_S \subseteq V_T$. Because $\max_{e' \in S} \sigma_i(w, e') \leq \max_{e' \in T} \sigma_i(w, e')$ for $S \subseteq T$, $\Delta(V_3|S) \geq \Delta(V_3|T)$. According to the above results, we prove $\Delta(e|S) \geq \Delta(e|T)$ and thus $\mathcal{R}_i(\cdot)$ is submodular. □

A.2 Proof of Lemma 3.7

Proof. First, given any $e' \in E \setminus S$ and $S \subseteq E$, for each $e \in I_t(S)$, we have $p_i(S \cup \{e'\} \rightsquigarrow e) - p_i(S \rightsquigarrow e) = 1 - \big(1 - p_i(S \rightsquigarrow e)\big) \cdot \big(1 - p_i(e' \rightsquigarrow e)\big) - p_i(S \rightsquigarrow e) = p_i(e' \rightsquigarrow e) \cdot \big(1 - p_i(S \rightsquigarrow e)\big) \geq 0$ for $p_i(S \rightsquigarrow e) \in [0, 1]$.

Second, given any $S \subseteq T \subseteq E$, for each $e \in I_t(T)$, we have $p_i(S \rightsquigarrow e) \leq p_i(T \rightsquigarrow e)$ for $e.ref \cap I_t(S) \subseteq e.ref \cap I_t(T)$. Therefore, for any $e' \in E \setminus T$, we have $p_i(S \cup \{e'\} \rightsquigarrow e) - p_i(S \rightsquigarrow e) = 1 - \big(1 - p_i(S \rightsquigarrow e)\big) \cdot \big(1 - p_i(e' \rightsquigarrow e)\big) - p_i(S \rightsquigarrow e) = p_i(e' \rightsquigarrow e) \cdot \big(1 - p_i(S \rightsquigarrow e)\big) \geq p_i(e' \rightsquigarrow e) \cdot \big(1 - p_i(T \rightsquigarrow e)\big) = p_i(T \cup \{e'\} \rightsquigarrow e) - p_i(T \rightsquigarrow e)$. Finally, because $\mathcal{I}_{i,t}(S) = \sum_{e \in I_t(S)} p_i(S \rightsquigarrow e)$ and $p_i(\cdot \rightsquigarrow e)$ is monotone and submodular, $\mathcal{I}_{i,t}(\cdot)$ is monotone and submodular as well. □

A.3 Proof of Theorem 4.2

Proof. The sequence of estimations Φ for OPT is in range $[\delta_{max}, 2 \cdot k \cdot \delta_{max}]$. Due to the monotonicity and submodularity of $f(\cdot, \mathbf{x})$, we have $\mathsf{OPT} \in [\delta_{max}, k \cdot \delta_{max}]$. Therefore, there must exist some $\phi \in \Phi$ such that $(1-\varepsilon)\mathsf{OPT} \leq \phi \leq \mathsf{OPT}$.

Next, we discuss two cases for such ϕ and S_ϕ.

Case 1 ($|S_\phi| = k$). For each $e \in S_\phi$, we have $\Delta(e|S') \geq \frac{\phi}{2k}$ where S' is the subset of S_ϕ when e is added. Therefore, $f(S_\phi, \mathbf{x}) \geq k \cdot \frac{\phi}{2k} \geq (\frac{1}{2} - \varepsilon)\mathsf{OPT}$.

Case 2 ($|S_\phi| < k$). For each $e \in S^* \setminus S_\phi$, if e has been evaluated by MTTS, it is excluded from S_ϕ because $\Delta(e|S') < \frac{\phi}{2k}$ where S' is the subset of S_ϕ when e is evaluated; if e has not been evaluated by MTTS, it holds that $\Delta(e|S) \leq \delta(e, \mathbf{x}) < \mathsf{UB}(\mathbf{x}) < \mathsf{TH} \leq \frac{\phi}{2k}$. Thus, $\mathsf{OPT} - f(S_\phi, \mathbf{x}) \leq f(S^* \cup S_\phi, \mathbf{x}) - f(S_\phi, \mathbf{x}) \leq \sum_{e \in S^* \setminus S_\phi} \Delta(e|S_\phi) \leq k \cdot \frac{\phi}{2k} \leq \frac{1}{2} \cdot \mathsf{OPT}$. Equivalently, $f(S_\phi, \mathbf{x}) \geq \frac{1}{2} \cdot \mathsf{OPT}$.

In both cases, we have $f(S_{ts}, \mathbf{x}) \geq f(S_\phi, \mathbf{x}) \geq (\frac{1}{2} - \varepsilon)\mathsf{OPT}$. □

A.4 Proof of Theorem 4.4

Proof. There are two cases when MTTD is terminated. Here, we discuss them separately.

Case 1 **($|S_{td}| = k$).** Let $S_j = \{e_1, \ldots, e_j\}$ ($j \in [1, k]$) be the subset of S_{td} after the first j elements are added and $S_0 = \varnothing$. Assume that e_{j+1} is added to S_j in the round with threshold τ. It holds that $\Delta(e_{j+1}|S_j) \geq \tau$ and $\Delta(e|S_j) < \frac{\tau}{1-\varepsilon}, \forall e \notin S_j \cup \{e_{j+1}\}$. Then, we have $\Delta(e_{j+1}|S_j) \geq (1-\varepsilon)\Delta(e|S_j), \forall e \in S^* \setminus S_j$. By summing up the above inequality for $e \in S^* \setminus S_j$, we have $|S^* \setminus S_j| \cdot \Delta(e_{j+1}|S_j) \geq (1-\varepsilon)\sum_{e \in S^* \setminus S_j} \Delta(e|S_j)$. Thus, we get $\Delta(e_{j+1}|S_j) \geq \frac{1-\varepsilon}{|S^* \setminus S_j|} \cdot \sum_{e \in S^* \setminus S_j} \Delta(e|S_j) \geq \frac{1-\varepsilon}{k} \cdot \sum_{e \in S^* \setminus S_j} \Delta(e|S_j)$. Due to the submodularity of $f(\cdot, \mathbf{x})$, we have $\sum_{e \in S^* \setminus S_j} \Delta(e|S_j) \geq \mathsf{OPT} - f(S_j, \mathbf{x})$. Thus,$\Delta(e_{j+1}|S_j) = f(S_{j+1}, \mathbf{x}) - f(S_j, \mathbf{x}) \geq \frac{1-\varepsilon}{k}(\mathsf{OPT} - f(S_j, \mathbf{x}))$. Equivalently, we acquire $f(S_{j+1}, \mathbf{x}) - \mathsf{OPT} \geq (1 - \frac{1-\varepsilon}{k})(f(S_j, \mathbf{x}) - \mathsf{OPT})$. Substituting S_{j+1} by $S_k, \ldots, S_1$ for k times, we prove $f(S_{td}, \mathbf{x}) = f(S_k, \mathbf{x}) \geq \big(1 - (1 - \frac{1-\varepsilon}{k})^k\big) \cdot \mathsf{OPT} \geq (1 - e^{-(1-\varepsilon)})\mathsf{OPT} \geq (1 - \frac{1}{e} - \varepsilon)\mathsf{OPT}$.

Case 2 **($|S_{td}| < k$).** We have $\Delta(e|S_{td}) < \tau' = f(S_{td}, \mathbf{x}) \cdot \frac{\varepsilon}{k}, \forall e \in S^* \setminus S_{td}$. Therefore, $\mathsf{OPT} - f(S_{td}, \mathbf{x}) \leq \sum_{e \in S^* \setminus S_{td}} \Delta(e|S_{td}) \leq \sum_{e \in S^* \setminus S_{td}} f(S_{td}, \mathbf{x}) \cdot \frac{\varepsilon}{k} \leq \varepsilon \cdot f(S_{td}, \mathbf{x})$. Therefore, we acquire $f(S_{td}, \mathbf{x}) \geq \frac{\mathsf{OPT}}{1+\varepsilon} \geq (1-\varepsilon)\mathsf{OPT}$.

In both cases, $f(S_{td}, \mathbf{x}) \geq (1 - \frac{1}{e} - \varepsilon)\mathsf{OPT}$. □

ABSTRACT

Microblogging platforms constitute a popular means of real-time communication and information sharing. They involve such a large volume of user-generated content that their users suffer from an information deluge. To address it, numerous recommendation methods have been proposed to organize the posts a user receives according to her interests. The content-based methods typically build a text-based model for every individual user to capture her tastes and then rank the posts in her timeline according to their similarity with that model. Even though content-based methods have attracted lots of interest in the data management community, there is no comprehensive evaluation of the main factors that affect their performance. These are: *(i)* the representation model that converts an unstructured text into a structured representation that elucidates its characteristics, *(ii)* the source of the microblog posts that compose the user models, and *(iii)* the type of user's posting activity. To cover this gap, we systematically examine the performance of 9 state-of-the-art representation models in combination with 13 representation sources and 3 user types over a large, real dataset from Twitter comprising 60 users. We also consider a wide range of 223 plausible configurations for the representation models in order to assess their robustness with respect to their internal parameters. To facilitate the interpretation of our experimental results, we introduce a novel taxonomy of representation models. Our analysis provides novel insights into the main factors determining the performance of content-based recommendation in microblogs.

1 INTRODUCTION

Microblogging platforms enable the instant communication and interaction between people all over the world. They allow their users to post messages in real-time, often carelessly and ungrammatically, through any electronic device, be it a mobile phone or a personal computer. They also allow for explicit connections between users so as to facilitate the dissemination and consumption of information. These characteristics led to the explosive growth of platforms like Twitter (www.twitter.com), Plurk (www.plurk.com), Sina Weibo (www.weibo.com) and Tencent Weibo (http://t.qq.com).

Their popularity has led to an information deluge: the number of messages that are transmitted on a daily basis on Twitter alone has jumped from 35 million tweets in 2010 to over 500 million in 2017 [29]. Inevitably, their users are constantly overwhelmed with information. As we also show in our experiments, this situation cannot be ameliorated by presenting the new messages in chronological order; the relatedness with users' interests is typically more important than the recency of a post. Equally ineffective is the list of trending topics, where the same messages are presented to all users, irrespective of their personal interests.

A more principled solution to information deluge is offered by *Personalized Microblog Recommendation* (PMR). Its goal is to capture users' preferences so as to direct their attention to the messages that better match their personal interests. A plethora of works actually focuses on *Content-based PMR* [6, 13, 15, 31, 40, 41, 45], which typically operates as follows: first, it builds a document model for every individual post in the training set by extracting features from its textual content. Then, it constructs a user model by assembling the document models that capture the user's preferences. Subsequently, it compares the user model to the models of recommendation candidates (documents) with a similarity measure. The resulting similarity scores are used to rank all candidates in descending order, from the highest to the lowest score, thus placing the most relevant ones at the top positions. Finally, the ranked list is presented to the user.

Content-based PMR is a popular problem that has attracted a lot of attention in the data management community [1, 15, 29–31, 55]. However, the experimental results presented in the plethora of relevant works are not directly comparable, due to the different configurations that are used for several important, yet overlooked parameters.

The core parameter is the *representation model* that is used for converting a set of unstructured texts into a structured representation that reveals their characteristics. The available options range from traditional vector space models [41, 65] to topic models [39, 50]. Also crucial is the *representation source*, i.e., the source of the microblog posts that compose user models. Common choices include the user's tweets [36] together with their retweets [17, 23, 41, 56] as well as the posts of followers [31, 50, 65] and followees [15, 31, 39]. Another decisive factor is the posting activity of a user, i.e., whether she is an information producer or seeker [5, 35]. Other parameters include the novel challenges posed by the short, noisy, multilingual content of microblogs as well as the external information that enriches their textual content, e.g., concepts extracted from Wikipedia [41] or the content of a Web page, whose URL is mentioned in a post [1].

Despite their significance, little effort has been allocated on assessing the impact of these parameters on Content-based PMR. To cover this gap, we perform a thorough experimental analysis that investigates the following questions: *Which representation model is the most effective for recommending short, noisy, multilingual microblog posts? Which is the most efficient one? How robust is the performance of each model with respect to its configuration?*

Which representation source yields the best performance? How does the behavior of individual users affect the performance of Content-based MPR? We leave the investigation of external information as a future work, due to the high diversity of proposed approaches, which range from language-specific word embeddings like Glove [49] to self-reported profile information [21].

To investigate the above questions, we focus on Twitter, the most popular microblogging service worldwide, with over 335 million active users per month.[1] We begin with a categorization of the representation sources and the users it involves, based on its special social graph: every user u_1 is allowed to unilaterally follow another user u_2, with u_1 being a *follower* of u_2, and u_2 a *followee* for u_1; if u_2 follows back u_1, the two users are *reciprocally connected.* Then, we list the novel challenges posed by the short, noisy, user-generated tweets in comparison with the long and curated content of traditional documents. We also introduce a taxonomy of representation models that provides insights into their endogenous characteristics. Based on it, we briefly present nine state-of-the-art representation models and apply them to a dataset of 60 real Twitter users (partitioned into three different categories) in combination with 223 parameter configurations, three user types and 13 representation sources. Finally, we discuss the experimental outcomes in detail, interpreting the impact of every parameter on the performance of Content-based PMR.

In short, we make the following contributions:

• We perform the first systematic study for content-based recommendation in microblogging platforms, covering nine representation models, 13 representation sources and three user types. We have publicly released our code along with guidelines for our datasets[2].

• We organize the main representation models according to their functionality in a novel taxonomy with three main categories and two subcategories. In this way, we facilitate the understanding of our experimental results, given that every (sub-)category exhibits different behavior.

• We examine numerous configurations for every representation model, assessing their relative effectiveness, robustness and time efficiency. Our conclusions facilitate their fine-tuning and use in real recommender systems.

The rest of the paper is structured as follows: Section 2 provides background knowledge on Twitter and formally defines the recommendation task we are tackling in this work. In Section 3, we present our taxonomy of representation models and describe the state-of-the-art models we consider. We present the setup of our experiments in Section 4 and their results in Section 5. Section 6 discusses relevant works, while Section 7 concludes the paper along with directions for future work.

2 PRELIMINARIES

Representation Sources. We consider five sources of tweets for modeling the preferences of a Twitter user, u:

(i) The past *retweets* of u, $R(u)$, which are the tweets she has received from her followees and has reposted herself. Apparently, their subjects have captured u's attention so intensely that she decided to share them with her followers.

(ii) All past *tweets* of u except her retweets, $T(u)$. They enclose themes u is interested in chatting or in informing her followers.

(iii) All (re)tweets of u's followees, $E(u) = \bigcup_{u_i \in e(u)}(R(u_i) \cup T(u_i))$, where $e(u) = \{u_1, \ldots, u_k\}$ is the set of her followees. $E(u)$ models a user as an *information seeker*, who actively and explicitly follows accounts providing interesting information [15, 31, 39].

(iv) All (re)tweets of u's followers, $F(u) = \bigcup_{u_i \in f(u)}(R(u_i) \cup T(u_i))$, where $f(u) = \{u_1, \ldots, u_m\}$ stands for the set of her followers. Given that they have actively decided to follow u, due to the interest they find in her posts, $F(u)$ models u as an *information producer* [31, 50, 65].

(v) All (re)tweets of u's reciprocal connections, $C(u)$=$E(u)$∩$F(u)$. Unlike the unilateral following relationship in Twitter, reciprocal connections may indicate users with very high affinity, thus providing valuable information for user modeling.

Note that all these *atomic* representation sources are complementary, as they cover different aspects of the activity of a particular user and her network. For this reason, $T(u)$ is typically combined with $R(u)$ [17, 23, 41, 56], with only rare exceptions like [36], which considers $T(u)$ in isolation. In this work, we consider not only $T(u) \cup R(u)$ (TR for short), but also the seven remaining pairwise combinations, which give rise to the following *composite* representation sources: $T(u) \cup E(u)$, $R(u) \cup E(u)$, $E(u) \cup F(u)$, $T(u) \cup F(u)$, $R(u) \cup F(u)$, $T(u) \cup C(u)$, and $R(u) \cup C(u)$. For simplicity, we denote them by TE, RE, EF, TF, RF, TC and RC, respectively.

Twitter Challenges. Tweets have some special characteristics that distinguish them from other conventional domains and pose major challenges to representation models [17, 44, 48].

(C1) Sparsity. Tweets are short, comprising up to 280 characters for most languages, except for Chinese, Korean and Japanese, where the length limit is 140 characters. As a result, they lack sufficient content for user and document modeling.

(C2) Noise. The real-time nature of Twitter forces users to tweet quickly, without taking into account the frequent grammar errors and misspellings; these are corrected in subsequent tweets.

(C3) Multilingualism. The global popularity of Twitter has led to a high diversity in tweet languages. This renders inapplicable most language-specific pre-processing techniques, such as stemming and lemmatization. Even tokenization becomes difficult: unlike the European ones, many Asian languages, such as Chinese, Japanese, and Korean, do not use spaces or other punctuation in order to distinguish consecutive words.

(C4) Non-standard language. Tweets offer an everyday informal communication, which is unstructured, ungrammatical or simply written in slang; words are abbreviated (e.g., "gn" instead of "goodnight"), or contain emoticons, such as :), hashtags like #edbt and emphatic lengthening (e.g., "yeeees" instead of "yes").

We consider the above challenges when discussing the outcomes of our experimental analysis in Section 5.

User Categories. Twitter users are typically classified into three categories [5, 35]: *(i) Information Producers* (IP) are those users who tweet and retweet more frequently than they receive updates from their followees, (ii) *Information Seekers* (IS) are those users who are less active compared to their followees, and (iii) *Balanced Users* (BU) are those exhibiting a symmetry between the received and the posted messages.

To quantify these categories, we use the ratio of *outgoing* to *incoming tweets.* For a particular user u, the former involve the tweets and retweets she posts, $R(u) \cup T(u)$, while the latter comprise the tweets and retweets of her followees, $E(u)$. Dividing the outgoing with the incoming tweets, we get the *posting ratio.* Apparently, BU is the set of users with a posting ratio close to 1, i.e., $|R(u) \cup T(u)| \simeq |E(u)|$. To ensure significantly different behavior for the other two categories, we define IP as the set of users with a posting ratio higher than 2, thus indicating that they

[2] See https://github.com/efikarra/text-models-twitter for more details.

post at least twice as many tweets as they receive. Symmetrically, we define IS as the set of users with a posting ratio lower than 0.5, receiving at least twice as many tweets as those they publish.

Problem Definition. The task of Content-based PMR aims to distinguish a user's incoming messages, R∪T, into *irrelevant* and *relevant* ones. A common assumption in the literature [17, 33, 41, 56], which allows for large-scale evaluations, is that the relevant messages are those that are retweeted by the user that receives them, an action that implicitly indicates her interests – intuitively, a user forwards a tweet to her followers after carefully reading it and appreciating its content.

In this context, Content-based PMR is usually addressed via a *ranking-based recommendation algorithm* [11, 17, 20], which aims to rank relevant posts higher than the irrelevant ones. More formally, let D denote a set of documents, U a set of users and M the representation space, which is common for both users and microblog posts (e.g., M could be the real vector space). Given a user model $UM : U \rightarrow M$ and a document model $DM : D \rightarrow M$, we define this type of recommendation algorithms as follows:

Definition 2.1. **Content-based Personalized Microblog Recommendation** learns a ranking model $RM : M \times M \rightarrow \mathbb{R}$, which, given a user u and a set of testing posts $D_{test}(u) = \{d_1, \ldots, d_k\} \subseteq E(u)$, calculates the ranking scores $RM(UM(u), DM(d_i)), \forall i \in \{1 \ldots k\}$, and returns a list with $D_{test}(u)$ ranked in decreasing score.

We consider a user u as the set of documents that stem from a particular representation source s, i.e., $s(u)$, and we build a different $UM_s(u)$ for each s. Given a set of users U along with a representation source $s = \{s(u) : u \in U\}$ and a set of labeled data $D^s_{tr} = \{D^s_{tr}(u) : u \in U\}$, where $D^s_{tr}(u) = \{(d_i, l_i), d_i \in s(u), l_i \in L\}$ and $D^s_{tr}(u) \cap D_{test}(u) = \emptyset$, the recommendation algorithm is trained as follows for each individual source s: (i) for each $u \in U$, we learn $UM_s(u)$ and $DM(d_i)$ for each $d_i \in D^s_{tr}(u)$, and (ii) we train RM on $\bigcup_{u \in U}\{(UM_s(u), DM(d_i)) : i \in \{1, \ldots |D^s_{tr}(u)|\}$.

As a recommendation algorithm, we employ the one commonly used in the literature for ranking-based PMR [15, 31, 40]: in essence, RM is a similarity function and $RM(UM(u), DM(d_i))$ measures the similarity of document model d_i and user model u.

3 REPRESENTATION MODELS

3.1 Taxonomy

We first present a taxonomy of the state-of-the-art representation models based on their internal functionality, i.e., the way they handle the order of n-grams. Figure 1 presents an overview of their relations, with every edge **A** $\rightarrow$ **B** indicating that model B shares the same n-grams with A, but uses them in a different way when representing users and documents. Based on these relations, we identify three main categories of models:

(i) **Context-agnostic models** disregard the order of n-grams that appear in a document, when building its representation. E.g., the token-based models of this category yield the same representation for the phrases "Bob sues Jim" and "Jim sues Bob".

(ii) **Local context-aware models** take into account the relative order of characters or tokens in the n-grams that lie at the core of their document representations. Yet, they lose contextual information, as they ignore the ordering of n-grams themselves. Continuing our example, the token-based models of this category are able to distinguish the bigram "Bob sues" from "sues Bob", but cannot capture the bigrams that precede or follow it.

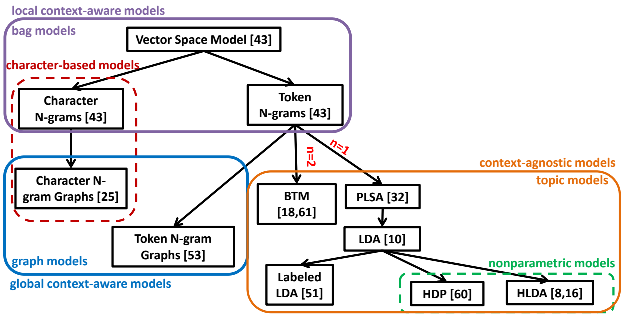

Figure 1: Taxonomy of representation models.

(iii) **Global context-aware models** incorporate into their representations both the relative ordering of tokens or characters in an n-gram and the overall ordering between n-grams in a document. Continuing our example, models of this category distinguish "Bob sues" from "sues Bob" and know that the former is followed by "sues Jim", while the latter is preceded by "Jim sues".

The first category comprises the *topic models* [9]. These are representation models that uncover the latent semantic structure of texts by determining the topics they talk about. The topics and their proportions in a document are considered as the hidden structure of a topic model, which can be discovered by exclusively analyzing the observed data, i.e., the individual tokens (words) in the original text. In general, they regard each document as a mixture of multiple topics, where each topic constitutes a set of co-occurring words. As a result, topic models are typically described in terms of probabilistic modeling, i.e., as generative processes that produce documents, words and users from distributions over the inferred topics [7].

A subcategory of context-agnostic (topic) models pertains to *nonparametric models* [16, 60], which adapt their representations to the structure of the training data. They allow for an unbounded number of parameters that grows with the size of the training data, whereas the parametric models are restricted to a parameter space of fixed size. For example, the nonparametric topic models assume that the number of topics is a-priori unknown, but can be inferred from the documents themselves, while the parametric ones typically receive a fixed number of topics as an input parameter before training.

The category of local context-aware models encompasses the bag models [43], which impose a strict order within n-grams: every n-gram is formed by a specific sequence of characters or tokens and, thus, two n-grams with different sequences are different, even if they involve the same characters or tokens; for example, the bigrams "ab" and "ba" are treated as different. The only exception is the token-based vector model with n=1, which essentially considers individual words; its context-agnostic functionality actually lies at the core of most topic models.

Finally, the category of global context-aware models includes the n-gram graph models, which represent every document as a graph in a language-agnostic way [25]: every node corresponds to an n-gram and edges connect pairs of n-grams co-located within a window of size n, with their weights indicating the co-occurrence frequency. These weighted edges allow graph models to capture global context, going beyond the local context of the bag models that use the same n-grams. Recent works suggest that the graph models outperform their bag counterparts in various tasks [42], which range from Information Retrieval [53] to Document Classification [48].

It should be stressed at this point that the bag and graph models share the second subcategory of our taxonomy: the *character-based models*. These operate at a finer granularity than their token-based counterparts, thus being more robust to noise [48]. For example, consider the words “tweet” and “twete”, where the second one is misspelled; they are considered different in all types of token-based models, but for character bi-gram models, they match in three out of four bigrams. In this way, the character-based models capture more precisely the actual similarity between noisy documents.

In the following, we collectively refer to local and global context-aware models as *context-based models*.

3.2 State-of-the-art Models

We now elaborate on the main representation models that are widely used in the literature. To describe topic models, we use the common notation that is outlined in Table 1, while their generative processes are illustrated in Figures 2(i)-(vi) using *plate diagrams*: shaded nodes correspond to the observed variables, the unshaded ones to the hidden variables, the arrows connect conditionally dependent variables, and finally, the plates denote repeated sampling for the enclosed variables for as many times as the number in the right bottom corner.

Bag Models [43]. There are two types of n-grams, the character and the token ones. These give rise to two types of bag models: the *character n-grams model* (**CN**) and the *token n-grams model* (**TN**). Collectively, they are called *bag* or *vector space models*, because they model a document d_i as a vector with one dimension for every distinct n-gram in a corpus of documents D: $DM(d_i) = (w_{i1}, \dots, w_{im})$, where m stands for the *dimensionality* of D (i.e., the number of distinct n-grams in it), while w_{ij} is the weight of the j^{th} dimension that quantifies the importance of the corresponding n-gram for d_i.

The most common weighting schemes are:

(i) Boolean Frequency (**BF**) assigns binary weights that indicate the absence or presence of the corresponding n-gram in d_i. More formally, $BF(t_j, d_i)$=1 if the n-gram t_j of the j^{th} dimension appears in document d_i, and 0 otherwise.

(ii) Term Frequency (**TF**) sets weights in proportion to the number of times the corresponding n-grams appear in document d_i. More formally, $TF(t_j, d_i)$=f_j/N_{d_i}, where f_j stands for the occurrence frequency of t_j in d_i, while N_{d_i} is the number of n-grams in d_i, normalizing TF so as to mitigate the effect of different document lengths on the weights.

(iii)Term Frequency-Inverse Document Frequency (**TF-IDF**) discounts the TF weight for the most common tokens in the entire corpus D, as they typically correspond to noise (i.e., stop words). Formally, $TF\text{-}IDF(t_j, d_i) = TF(t_j, d_i) \cdot IDF(t_j)$, where $IDF(t_j)$ is the inverse document frequency of the n-gram t_j, i.e., $IDF(t_j) = \log |D|/(|\{d_k \in D : t_j \in d_k\}| + 1)$. In this way, high weights are given to n-grams with high frequency in d_i, but low frequency in D.

To construct the bag model for a specific user u, we aggregate the vectors corresponding to the documents that capture u's interests. The end result is a weighted vector $(a(w_1), ..., a(w_m))$, where $a(w_j)$ is the *aggregation function* that calculates the importance of the j^{th} dimension for u.

The main aggregation functions are: *(i)* the sum of weights, i.e., $a(w_j) = \sum_{d_i \in D} w_{ij}$. *(ii)* the centroid of unit (normalized) document vectors, i.e., $a(w_j) = \frac{1}{|D|} \cdot \sum_{d_i \in D} \frac{w_{ij}}{||DM(d_i)||}$, where $||DM(d_i)||$ is the magnitude of $DM(d_i)$. *(iii)* the Rocchio algorithm, i.e., $a(w_j) = \alpha/|D^p| \cdot \sum_{d_i \in D^p} w_{ij}/||DM(d_i)|| - \beta/|D^n| \cdot \sum_{d_i \in D^n} w_{ij}/||DM(d_i)||$, where D^p and D^n are the sets of positive (relevant) and negative (irrelevant) documents in D, respectively, while $\alpha, \beta \in [0, 1]$ control the relative importance of positive and negative examples, respectively, such that $\alpha + \beta = 1.0$ [43].

Table 1: The notation describing topic models.

Symbol	Meaning
D	the corpus of the input documents
$\|D\|$	the number of input documents
d	an individual document in D
N_d	the number of words in d, i.e., the *document length*
U	the set of users
u	an individual user in U
$N_{d,u}$	the number of words in document d of user u
D_u	the documents posted by a user u
$\|D_u\|$	the number of documents posted by user u
V	the *vocabulary* of D (i.e., the set of words it includes)
$\|V\|$	the number of distinct words in D
w	an individual word in V
$w_{d,n}$	the word at position n in d
Z	the set of latent topics
$\|Z\|$	the number of latent topics
z	an individual topic in Z
$z_{d,n}$	the topic assigned to the word at position n in document d
θ_d	the multinomial distribution of document d over Z, $\{P(z\|d)\}_{z \in Z}$
$\theta_{d,z}$	the probability that topic z appears in document d, $P(z\|d)$
ϕ_z	the multinomial distribution of topic z over V, $\{P(w\|z)\}_{w \in V}$
$\phi_{z,w}$	the probability that word w appears in topic z, $P(w\|z)$
$Dir(\alpha)$	a symmetric Dirichlet distribution parameterized by α

To compare two bag models, $DM(d_i)$ and $DM(d_j)$, one of the following similarity measures is typically used:

(i) Cosine Similarity (**CS**) measures the cosine of the angle of the weighted vectors. Formally, it is equal to their dot product similarity, normalized by the product of their magnitudes: $CS(DM(d_i), DM(d_j)) = \sum_{k=1}^{m} w_{ik} w_{jk}/||DM(d_i)||/||DM(d_j)||$.

(ii) Jaccard Similarity (**JS**) treats the document vectors as sets, with weights higher than (equal to) 0 indicating the presence (absence) of the corresponding n-gram. On this basis, it defines as similarity the ratio between the sizes of set intersection and union: $JS(DM(d_i), DM(d_j))$=$|DM(d_i) \cap DM(d_j)|/|DM(d_i) \cup DM(d_j)|$.

(iii) Generalized Jaccard Similarity (**GJS**) extends JS so that it takes into account the weights associated with every n-gram: $GJS(DM(d_i), DM(d_j))$= $\sum_{k=1}^{m} min(w_{ik}, w_{jk})/\sum_{k=1}^{m} max(w_{ik}, w_{jk})$. Note that for BF weights, GJS is identical with JS.

Graph Models [25, 53]. There are two graph models, one for each type of n-grams, i.e., *token n-gram graphs* (**TNG**) [53] and *character n-gram graphs* (**CNG**) [25]. Both models represent each document d as an undirected graph G_d that contains one vertex for each n-gram in d. An edge connects every pair of vertices/n-grams that co-occur within a window of size n in d. Every edge is weighted according to the co-occurrence frequency of the corresponding n-grams. Thus, the graphs incorporate *contextual information* in the form of n-grams' closeness.

To construct the model for a user u, we merge the graphs of the documents representing u's interests using the update operator, which is described in [26]. To compare graph models, we can use the following graph similarity measures [25]: *(i) Containment Similarity* (**CoS**) estimates the number of edges shared by two graph models, G_i and G_j, regardless of the corresponding weights (i.e., it merely estimates the portion of common n-grams in the original texts). Formally: $CoS(G_i, G_j) = \sum_{e \in G_i} \mu(e, G_j)/min(|G_i|, |G_j|)$, where $|G|$ is the size of graph G, and $\mu(e, G) = 1$ if $e \in G$, or 0 otherwise. *(ii) Value Similarity* (**VS**) extends CoS by considering the weights of common edges. Formally, using w_e^k for the weight of edge e in G_k:

$VS(G_i, G_j) = \sum_{e \in (G_i \cap G_j)} \frac{min(w_e^i, w_e^j)}{max(w_e^i, w_e^j) \cdot max(|G_i|, |G_j|)}$. *(iii) Normalized Value Similarity* (**NS**) extends VS by mitigating the impact of imbalanced graphs, i.e., the cases where the comparison between a large graph with a much smaller one yields similarities close to 0: $NS(G_i, G_j) = \sum_{e \in (G_i \cap G_j)} min(w_e^i, w_e^j)/max(w_e^i, w_e^j)/min(|G_i|, |G_j|)$.

Probabilistic Latent Semantic Analysis (PLSA) [32]. This model assigns a topic z to every observed word w in a document d. Thus, every document is modeled as a distribution over multiple topics, assuming that the observed variables w and d are conditionally independent given the unobserved topic z: $P(w|d, z) = P(w|z)$. For an observed pair (w, d), the joint probability distribution is: $P(w, d) = P(d) \cdot \sum_z P(w, z|d) = P(d) \cdot \sum_z P(z|d) \cdot P(w|z) = P(d) \cdot \sum_z \theta_{d,z} \cdot \phi_{z,w}$, where $\theta_{d,z}$ stands for the probability that a topic z appears in document d, while $\phi_{z,w}$ denotes the probability that a word w appears in topic z (see Table 1).

Figure 2(i) depicts the generative process of PLSA: *(1)* Select a document d with probability $P(d)$. *(2)* For each word position $n \in \{1, \dots, N_d\}$: *(a)* Select a topic $z_{d,n}$ from distribution θ_d. *(b)* Select the word $w_{d,n}$ from distribution $\phi_{z_{d,n}}$. Note that $P(d)$ is the frequency of d in the corpus, thus being uniform in practice.

In total, PLSA should estimate $|D| \cdot |Z| + |Z| \cdot |V|$ parameters: $\theta_d = \{P(z|d)\}_{z \in Z}$ for each $d \in D$ and $\phi_z = \{P(w|z)\}_{w \in V}$ for each $z \in Z$. Consequently, the number of parameters grows linearly with the number of documents, leading to overfitting [10].

Latent Dirichlet Allocation (LDA) [10]. Unlike PLSA, which regards each document d as a list of probabilities θ_d, LDA assigns a random variable of $|Z|$ parameters with a Dirichlet prior to distribution θ_d. In a latter variant, a $|V|$-parameter variable with a Dirichlet prior was also assigned to ϕ_z [28]. The number of topics $|Z|$ is given as a parameter to the model and raises the following issue: the smaller the number of topics is, the broader and more inaccurate is their content, failing to capture the diverse themes discussed in the corpus; in contrast, for large values of $|Z|$, the model is likely to overfit, learning spurious word co-occurrence patterns [58].

Figure 2(ii) shows the generative process of LDA: *(1)* For each topic $z \in Z$, draw a distribution ϕ_z from $Dir(\beta)$. *(2)* For each document $d \in D$: *(a)* Select a distribution θ_d from $Dir(\alpha)$. *(b)* For each word position $n \in \{1, \dots, N_d\}$: *(i)* Draw a topic $z_{d,n}$ from distribution θ_d. *(ii)* Draw the word $w_{d,n}$ from distribution $\phi_{z_{d,n}}$.

Note that the hyperparameters α and β of the Dirichlet priors on θ and ϕ, respectively, distinguish LDA from PLSA. The former denotes the frequency with which a topic is sampled for a document, while the latter shows the frequency of a word in a topic, before actually observing any words in D.

Labeled LDA (LLDA) [51]. This is a supervised variant of LDA that characterizes a corpus D with a set of observed labels Λ. Each document d is modeled as a multinomial distribution of labels from $\Lambda_d \subseteq \Lambda$. Subsequently, each word $w \in d$ is picked from a distribution ϕ_z of some label z contained in Λ_d. Besides the observed labels, LLDA can also use $|Z|$ latent topics for all documents, assigning the labels "Topic 1",..., "Topic $|Z|$" to each document $d \in D$ [50].

Figure 2(iii) presents the generative process of LLDA: *(1)* For each topic $z \in Z$, draw a distribution ϕ_z from $Dir(\beta)$. *(2)* For each document $d \in D$: *(a)* Construct distribution Λ_d by selecting each topic $z \in Z$ as a label based on a Bernoulli distribution with parameter Φ_z. *(b)* Select a multinomial distribution θ_d over Λ_d from $Dir(\alpha)$. *(c)* For each word position $n \in \{1, \dots, N_d\}$: *(i)* Draw a label $z_{d,n}$ from distribution θ_d. *(ii)* Draw the word $w_{d,n}$ from distribution $\phi_{z_{d,n}}$. Note that the prior probability of adding a topic z to $\Lambda_d(\Phi_z)$ is practically superfluous, as Λ_d is observed for each document d.

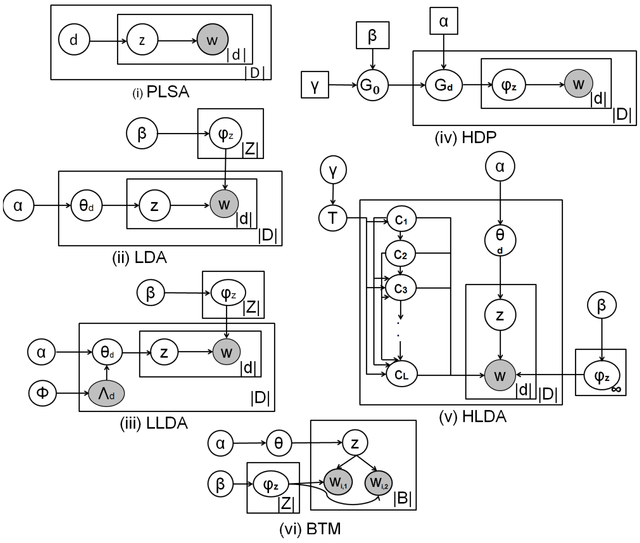

Figure 2: Plate diagrams for: (i) Probabilistic Latent Semantic Analysis (PLSA), (ii) Latent Dirichlet Allocation (LDA), (iii) Labeled LDA (LLDA), (iv) Hierarchical Dirichlet Process (HDP), (v) Hierarchical LDA (HLDA), and (vi) Biterm Topic Model (BTM).

Hierarchical Dirichlet Process (HDP) [60]. This Bayesian nonparametric model is crafted for clustering the observations of a group into mixing components. In PMR, each document corresponds to a group, the words of the document constitute the observations within the group, and the topics comprise the mixing components in the form of distributions over words.

Two are the main properties of HDP: *(i)* The number of mixing components is countably infinite and unknown beforehand. This is achieved by assigning a random variable G_j to the j^{th} group distributed according to $DP(\alpha, G_0)$, where DP stands for a Dirichlet Process, which is a probability distribution over distributions (i.e., samples from a DP are probability distributions themselves). G_0 is the base probability distribution, playing the role of the mean around which distributions are sampled by DP, while α is called concentration parameter and can be thought as an inverse variance. G_0 also follows a $DP(\gamma, H)$. *(ii)* The groups share the same components. This is achieved by linking the DPs of all groups, under the same G_0. More formally, HDP is defined as: $G_0|\gamma, H \sim DP(\gamma, H)$ and $G_j|\alpha, G_0 \sim DP(\alpha, G_0)\ \forall j$.

Figure 2(iv) shows the generative process for 1 hierarchical level: *(1)* Draw G_0 from $DP(\gamma, H)$, where H is a $Dir(\beta)$. G_0 provides an unbounded number of ϕ_z distributions, i.e., topics that can be assigned to any document $d \in D$ [60]. *(2)* For each document $d \in D$: *(a)* Associate a subset of distributions ϕ_z with d, by drawing G_d from $DP(\alpha, G_0)$. *(b)* For each word position $n \in \{1, \dots, N_d\}$: *(i)* Pick a distribution $\phi_{z_{d,n}}$ from G_d. *(ii)* Draw the word $w_{d,n}$ from $\phi_{z_{d,n}}$.

Note that it is straightforward to add more hierarchical levels to HDP, by exploiting its recursive nature. For example, in multiple corpora, where documents are grouped into broader categories, topics shared between categories are revealed and can be compared with topics shared between individual documents [60].

Hierarchical LDA (HLDA) [8, 16]. This model extends LDA by organizing the topics in Z into a hierarchical tree such that every tree node represents a single topic. The broader a topic is, the higher is its level in the tree, with the most specific topics

Table 2: Statistics for each user group in our dataset.

	IS	BU	IP	All Users
Users	20	20	9	60
Outgoing tweets (TR)	47,659	48,836	42,566	192,328
Minimum per user	1,100	766	1,602	766
Mean per user	2,383	2,442	4,730	3,205
Maximum per user	6,406	8,025	17,761	17,761
Retweets (R)	27,344	32,951	38,013	140,649
Minimum per user	840	445	1,198	445
Mean per user	1,367	1,648	4,224	2,344
Maximum per user	2,486	6,814	17,761	17,761
Incoming tweets (E)	390,638	49,566	10,285	484,698
Minimum per user	8,936	696	525	525
Mean per user	19,532	2,478	1,143	8,078
Maximum per user	53,003	7,726	1,985	53,003
Follower's tweets (F)	665,778	166,233	50,330	1,391,579
Minimum per user	1,074	110	348	110
Mean per user	33,289	8,312	5,592	23,193
Maximum per user	144,398	52,318	33,639	447,639

assigned to the leaves. Although the tree levels are fixed, the branching factor is inferred from the data, leading to a nonparametric functionality. Each document is modeled as a path from the root to a leaf and its words are generated by the topics across this path. Hence, every document representation is derived from the topics of a single path, rather than all topics in Z (as in LDA).

Specifically, HLDA is based on the *Chinese Restaurant Process* (CRP), which is a distribution over partitions of integers. CRP assumes the existence of a Chinese restaurant with an infinite number of tables. The first customer selects the first table, while the n^{th} customer selects a table based on the following probabilities [8]: $\mathbf{P_1}$=P(occupied $table_i$|previous customers)=$n_i/(n\text{-}1{+}\gamma)$, $\mathbf{P_2}$=P(next unoccupied $table_i$|previous customers)=$\gamma/(n\text{-}1{+}\gamma)$, where γ is a parameter controlling the possibility for a new customer to sit to an occupied or an empty table, and n_i are the customers already seated on table i. The placement of M customers produces a partition of M integers.

In fact, HLDA relies on the *nested Chinese Restaurant Process* (nCRP), which extends CRP by building a infinite hierarchy of Chinese restaurants. It assumes that there exists an infinite number of Chinese restaurants, each with an infinite number of tables. One of the restaurants is the root and every restaurant's table has a label, pointing to another restaurant – a restaurant cannot be referred by more than one label in the hierarchy. To illustrate the functionality of this process, assume a customer that visits the restaurants for L days. Starting from the root, she forms a path of L restaurants, one per day, following the labels of the tables she has chosen to sit based on P_1 and P_2. The repetition of this process for M customers yields an L-level hierarchy of restaurants.

Figure 2(v) presents the generative process of HLDA, with T denoting an infinite tree drawn from nCRP(γ) (i.e., the infinite set of possible L-level paths): *(1)* For each restaurant z in T, draw a distribution ϕ_z from $Dir(\beta)$. *(2)* For each document $d \in D$: *(a)* Draw an L-level path from T as follows: Let $c_{d,1}$ be the root restaurant. For each level $l \in \{2, \ldots, L\}$ pick a table from restaurant $c_{d,l-1}$ using P_1 and P_2 and set $c_{d,l-1}$ to refer to the restaurant $c_{d,l}$, which is indicated by that table. *(b)* Select a distribution θ_d over $\{1, \ldots, L\}$ from $Dir(\alpha)$. *(c)* For each word position $n \in \{1, \ldots, N_d\}$: *(i)* Draw a level $l_{d,n} \in \{1, \ldots, L\}$ from θ_d. *(ii)* Draw the word $w_{d,n}$ from distribution $\phi_{z_{d,n}}$, where $z_{d,n}$ is the topic corresponding to the restaurant $c_{d,l_{d,n}}$.

Biterm Topic Model (BTM) [18, 61]. At the core of this model lies the notion of *biterm*, which is an unordered pair of words that are located in close distance within a given text. In short documents, close distance means that both words belong to the same document, whereas in longer texts, it means that they co-occur within a window of tokens that is given as a parameter to BTM. Based on this notion, BTM addresses the sparsity in short texts like tweets (Challenge C1) in two ways: *(i)* It models the word co-occurrence for topic learning *explicitly* by considering biterms (rather than *implicitly* as in LDA, where word co-occurrence is captured by drawing a document's words from topics of the same topic distribution θ_d). *(ii)* It considers the entire corpus D as a set of biterms B, extracting word patterns from the entire training set (rather than an individual document). Overall, BTM assumes that the corpus consists of a mixture of topics and directly models the biterm generation from these topics.

Figure 2(vi) shows the generative process of BTM: *(1)* For each topic $z \in Z$, draw a distribution ϕ_z from $Dir(\beta)$. *(2)* For the entire corpus D, select a multinomial distribution θ over Z from $Dir(\alpha)$. *(3)* For each biterm position n in the entire corpus $\{1, \ldots, |B|\}$: *(a)* Draw a topic z_n from θ. *(b)* Draw two words $w_{n,1}$, $w_{n,2}$ from ϕ_{z_n}.

Note that BTM does not contain a generation process for documents. The distribution θ_d for an individual document $d \in D$ is inferred from the formula $P(z/d) = \sum_{b \in d} P(z/b) \cdot P(b/d)$, which presumes that the document-level topic proportions can be derived from the document-level generated biterms [18, 61].

Other models. There is a plethora of topic models in the literature. Most of them lie out of the scope of our experimental analysis, because they encapsulate external or non-textual information. For example, [54] and [12] incorporate temporal information from users' activity, while [21] proposes a representation model called *badges*, which combines the posting activity of Twitter users with self-reported profile information. Other topic models are incompatible with the ranking-based recommendation algorithm for Content-based PMR. For example, Twitter-LDA [64] and Dirichlet Multinomial Mixture Model [47] assign a single topic to every tweet, thus yielding too many ties when ranking document models in decreasing similarity score - all tweets with the same inferred topic are equally similar with the user model.

Using Topic Models. To build a topic model for a particular user u, we average the distributions corresponding to the documents that capture her preferences. To compare user models with document models, we use the cosine similarity. To address the four Twitter challenges, which hamper the functionality of topic models due to the scarcity of word co-occurrence patterns, we apply two different pooling schemes to the training data: *(i)* the aggregation on users, called *User Pooling* (UP), where all tweets posted by the same user are considered as a single document, and *(ii)* the aggregation on hashtags, called *Hashtag Pooling* (HP), where all tweets annotated with the same hashtag form a single document (the tweets without any hashtag are treated as individual documents). We also consider *No Pooling* (NP), where each tweet is considered as an individual document. Finally, we estimate the parameters of all topic models using *Gibbs Sampling* [24], except for PLSA, which uses *Expectation Maximization* [19].

4 EXPERIMENTAL SETUP

All methods were implemented in Java 8 and performed in a server with Intel Xeon E5-4603@2.20 GHz (32 cores) and 120GB RAM, running Ubuntu 14.04.

Table 3: The 10 most frequent languages in our dataset, which collectively cover 1,879,470 tweets (91% of all tweets).

	English	Japanese	Chinese	Portuguese	Thai	French	Korean	German	Indonesian	Spanish
Total Tweets	1,710,919	71,242	35,356	14,416	13,964	12,895	10,220	5,038	4,339	1,081
Relative Frequency	82.71%	3.44%	1.71%	0.70%	0.68%	0.62%	0.49%	0.24%	0.21%	0.05%

Our dataset was derived from a large Twitter corpus that captures almost 30% of all public messages published on Twitter worldwide between June 1, 2009 and December 31, 2009 [62]. Although slightly dated, recent studies have verified that core aspects of the users activity in Twitter remain unchanged over the years (e.g., retweet patterns for individual messages and users) [29]. Most importantly, this dataset can be combined with a publicly available snapshot of the entire social graph of Twitter as of August, 2009 (https://an.kaist.ac.kr/traces/WWW2010.html). Given that every record includes the raw tweet along with the corresponding usernames and timestamps, we can simulate the tweet feed of every user during the second half of 2009 with very high accuracy. To ensure that there is a critical mass of tweets for all representation sources and a representative set of testing documents for every user, we removed from our dataset those users that had less than three followers and less than three followees. We also discarded all users with less than 400 retweets.

From the remaining users, we populated each of the three user types we defined in Section 2 with 20 users. For IS, we selected the 20 users with the lowest posting ratios, for BU the 20 users with the closest to 1 ratios, and for IP, the 20 users with the highest ratios. The difference between the maximum ratio for IS (0.13) and the minimum one for BU (0.76) is large enough to guarantee significantly different behavior. However, the maximum ratio among BU users is 1.16, whereas the minimum one among IP users is 1.20, due to the scarcity of information providers in our dataset. This means that the two categories are too close, a situation that could introduce noise to the experimental results. To ensure distinctive behavior, we placed in the IP group the nine users that have a posting ratio higher than 2. The remaining 11 users with the highest ratios are included in the group All Users, which additionally unites IS, BU and IP to build a large dataset with 2.07 million tweets and 60 users, in total. The technical characteristics of the four resulting user groups appear in Table 2.

Each user has a different train set, which is determined by the representation source; for example, the train set for T contains all tweets of a user, except for her retweets. In contrast, the test set of every user is independent of the representation source and contains her incoming tweets; the retweeted ones constitute the *positive examples* and the rest are the *negative examples* [17, 33, 41, 56]. However, the former are sparse and imbalanced across time in our dataset. Following [17], we retain a reasonable proportion between the two classes for each user by placing the 20% most recent of her retweets in the test set. The earliest tweet in this sample splits each user's timeline in two phases: the *training* and the *testing phase.* Based on this division, we sampled the negative data as follows: for each positive tweet in the test set, we randomly added four negative ones from the testing phase [17]. Accordingly, the train set of every representation source is restricted to all the tweets that fall in the training phase.

Based on this setup, we build the user models as follows: for the bag and graph models, we learn a separate model $UM_s(u)$ for every combination of a user u and a representation source s, using the corresponding train set. For the topic models, we first learn a single model $M(s)$ for each representation source, using the train set of all 60 users. Then, we use $M(s)$ to infer the distributions over topics for the training tweets of u that stem from s. Finally, the user model $UM_s(u)$ is constructed by computing the centroid of u's training vectors/tweets [50].

Note that for all models, we converted the raw text of all training and testing tweets into lowercase. For all token-based models, we tokenized all tweets on white spaces and punctuation, we squeezed repeated letters and we kept together URLs, hashtags, mentions and emoticons. We also removed the 100 most frequent tokens across all training tweets, as they practically correspond to stop words. We did not apply any language-specific pre-processing technique, as our dataset is multilingual.

In more detail, Table 3 presents the 10 most frequent languages in our dataset along with the number of tweets that correspond to them. To identify them, we first cleaned all tweets from hashtags, mentions, URLs and emoticons in order to reduce the noise of non-English tweets. Then, we aggregated the tweets per user (UP) to facilitate language detection. Finally, we automatically detected the prevalent language in every pseudo-document (i.e., user) [46] and assigned all relevant tweets to it. As expected, English is the dominant language, but our corpus is highly multilingual, with 3 Asian languages ranked within the top 5 positions. This multilingual content (Challenge C3) prevents us from boosting the performance of representation models with language-specific pre-processing like stemming, lemmatization and part-of-speech tagging, as is typically done in the literature [4, 17, 65]. Instead, our experimental methodology is language-agnostic.

Performance Measures. We assess the effectiveness of representation models using the *Average Precision* (**AP**) of a user model $UM_s(u)$, which is the average of the Precision-at-n ($P@n$) values for all retweets. Formally [17, 41]: $AP(UM_s(u)) = 1/|R(u)| \cdot \sum_{n=1}^{N} P@n \cdot RT(n)$, where $P@n$ is the proportion of the top-n ranked tweets that have been retweeted, $RT(n)$=1 if n is a retweet and 0 otherwise, N is the size of the test set, and $|R(u)|$ is the total number of retweets in the test set. Thus, AP expresses the performance of a representation model over an individual user. To calculate the performance of a user group U, we define *Mean Average Precision* (**MAP**) as the average AP over all users in U.

To assess the robustness of a representation model with respect to its internal configuration, we consider its *MAP deviation*, i.e., the difference between the maximum and the minimum MAP of the considered parameter configurations over a specific group of users. The lower the MAP deviation, the higher the robustness.

To estimate the time efficiency of representation models, we employ two measures: *(i)* The *training time* (**TTime**) captures the aggregated modeling time that is required for modeling all 60 users. For topic models, this also includes the time that is required for training once the model $M(s)$ from the entire train set. *(ii)* The *testing time* (**ETime**) expresses the total time that is required for processing the test set of all 60 users, i.e., to compare all user models with their testing tweets and to rank the latter in descending order of similarity. For a fair comparison, we do not consider works that parallelize representation models (e.g., [16, 57, 63]), as most models are not adapted to distributed processing.

Parameter Tuning. For each representation model, we tried a wide range of meaningful parameter configurations. They are reported in Tables 4 and 5. In total, we employed 223 different

Table 4: Configurations of the 5 context-agnostic (topic) models. CS, NP, UP and HP stand for cosine similarity, no pooling, user pooling and hashtag pooling, respectively.

	LDA	LLDA	BTM	HDP	HLDA
#Topics	{50,100,150,200}			-	-
#Iterations	{1,000, 2,000}		1,000		
Pooling	{NP, UP, HP}				UP
α	50/#Topics			1.0	{10, 20}

Similarity measure	CS				
Fixed parameters	-	-	r=30	-	levels=3
#Configurations	48	48	24	12	16

configurations – excluding those violating the *memory constraint* (the memory consumption should be less than 32GB RAM), or the *time constraint* ($TTime$ should be less than 5 days). As a result, we excluded PLSA from our analysis, since it violated the memory constraint for all configurations we considered.

In total, 9 representation models were tested in our experiments. For LDA, LLDA and BTM, α and β were tuned according to [58]. For LLDA, the number of topics refers to the latent topics assigned to every tweet in addition to the tweet-specific labels. For the latter, we followed [50], using: *(i)* one label for every hashtag that occurs more than 30 times in the training tweets, *(ii)* the question mark, *(iii)* 9 categories of emoticons (i.e., "smile", "frown", "wink", "big grin", "heart", "surprise", "awkward" and "confused"), and *(iv)* the @user label for the training tweets that mention a user as the first word. Most of these labels were quite frequent in our corpus and, thus, we considered 10 variations for them, based on [50]. For example, "frown" produced the labels: :(-0 to :(-9. The only labels with no variations are the hashtag ones and the emoticons "big grin", "heart", "surprise" and "confused".

For HLDA, we did not employ the pooling strategies NP and HP and more than three hierarchical levels, as these configurations violated the time constraint. Hence, we only varied α and γ.

For BTM, we selected 1,000 iterations following [61]. For individual tweets, we set the context window (r), i.e., the maximum distance between two words in a biterm, equal to the size of the tweet itself. For the large pseudo-documents in user and hashtag pooling, we set r=30 based on [61]; for greater values, BTM conveys no significant improvement over LDA, since the larger the distance between the words in a biterm is, the more irrelevant are their topics. Larger window sizes yield higher $TTime$, too.

For bag models, some configuration combinations are invalid: JS is applied only with BF weights, GJS only with TF and TF-IDF, and the character-based n-grams, CN, are not combined with TF-IDF. Also, BF is exclusively coupled with the sum aggregation function, which in this case is equivalent to applying the boolean operator OR among the individual document models. For the Rocchio algorithm, we set α=0.8 and β=0.2, and we used only the CS similarity measure in combination with the TF and TF-IDF weights for those representation sources that contain both positive and negative examples, namely C, E, TE, RE, TC, RC and EF.

Table 5: Configurations of the 4 context-based models. Remember that BF and TF stand for boolean and term frequency weights, respectively, while (G)JS, CoS, VS, and NS denote the (generalized) Jaccard, the containment, the value and the normalized value graph similarities, resp.

	TN	CN	TNG	CNG
n	{1,2,3}	{2,3,4}	{1,2,3}	{2,3,4}

5 EXPERIMENTAL ANALYSIS

Effectiveness & Robustness. To assess the performance of the 9 representation models, we measure their *Mean MAP*, *Min MAP* and *Max MAP*, i.e., their average, minimum and maximum MAP, respectively, over all relevant configurations for a particular combination of a user type and a representation source. The outcomes for All Users are presented in Figure 3, which considers the 5 individual representation sources along with the 3 combinations that achieve the best average performance. Due to space limitations, the remaining 5 combinations along with the figures for IP, BU and IS are only presented in the extended version of the paper [59]. Nevertheless, we consider them in the discussion of our experimental results.

Every diagram also reports the MAP for two baseline methods: (i) the *Chronological Ordering* (CHR), which ranks the test set from the latest tweet (first position) to the earliest one (last position), and (ii) the *Random Ordering* (RAN), which sorts the test set in an arbitrary order. For RAN, we performed 1,000 iterations per user and considered the overall average per user type.

Starting with All Users in Figure 3, we observe that TNG consistently outperforms all other models across all representation sources. Its Mean MAP fluctuates between 0.625 (EF) and 0.784 (T). The second most effective model is TN, whose Mean MAP ranges from 0.541 (EF) to 0.673 (T). The dominance of TNG over TN is statistically significant (p<0.05) and should be attributed to its ability to capture the relations between neighboring token n-grams through the weighted edges that connect them. In this way, TNG incorporates global contextual information into its model and inherently alleviates sparsity (Challenge C1). Instead, TN exclusively captures local contextual information in the form of token sequences. The same holds for Challenges C2 and C4: both models fail to identify misspelled or non-standard token n-grams, but TNG is better suited to capture their patterns by encapsulating their neighborhood.

Regarding *robustness*, TN is more sensitive to its configuration. Its MAP deviation ranges from 0.359 (TF, RF) to 0.444 (EF), while for TNG, it fluctuates between 0.096 (T) and 0.281 (EF). In all cases, the difference between the two models is statistically significant (p<0.05). TNG is superior, because its performance is fine-tuned by just two parameters: the size of n-grams (n) and the similarity measure. TN additionally involves the aggregation function and the weighting scheme, increasing drastically its possible configurations. In general, *every configuration parameter acts as a degree of freedom for a representation model; the higher the overall number of parameters is, the more flexible the model gets and the less robust it is expected to be with respect to its configuration.*

Comparing the character-based instantiations of bag and graph models, we notice that their difference in Mean Map is statistically insignificant. For CNG, it fluctuates between 0.368 (TF) and 0.477 (R), while for CN, it ranges from 0.334 (TF) to 0.436 (RC). This implies that *there is no benefit in considering global contextual*

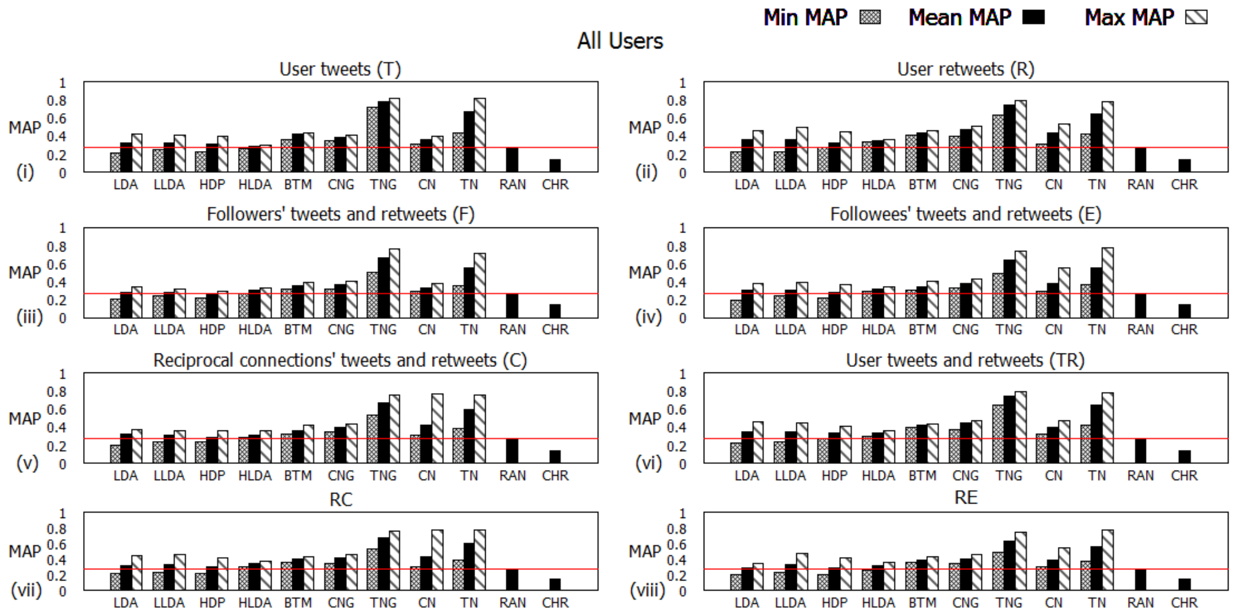

Figure 3: Effectiveness of the nine representation models over All Users in combination with the five individual representation sources and their three best performing pairwise combinations with respect to MAP. Higher bars indicate better performance. The red line corresponds to the performance of the best baseline, RAN.

information for representation models that are based on character n-grams. The strength of these models lies in the local contextual information that is captured in the sequence of characters.

Regarding robustness, the relative sensitivity of character-based models exhibits the same patterns as their token-based counterparts: the bag models are significantly less robust than the graph ones, due to their larger number of parameters and configurations. In more detail, the MAP deviation ranges from 0.061 (T) to 0.114 (RF) for CNG and from 0.077 (T) to 0.476 (RC) for CN.

Concerning the topic models, we observe that BTM consistently achieves the highest effectiveness across all representation sources. Its Mean MAP fluctuates between 0.340 (EF) and 0.434 (R). All other topic models exhibit practically equivalent performance: their highest Mean MAP ranges from 0.337 (for HDP with TR) to 0.360 (for LLDA with R), whereas their lowest Mean MAP fluctuates between 0.265 (for HDP over F) and 0.270 (for LLDA over TF). As a result, HDP, LDA, LLDA and HLDA outperform only CHR to a large extent. This indicates that *recency alone constitutes an inadequate criterion for recommending content in microblogging platforms. Any model that considers the personal preferences of a user offers more accurate suggestions.*

Compared to the second baseline (RAN), HDP, LDA, LLDA and HLDA are more effective, but to a minor extent. The Mean MAP of RAN amounts to 0.270, thus, some configurations of these topic models perform consistently worse than RAN, across all representation sources. Most of these configurations correspond to the absence of pooling (NP), where every tweet is considered as an individual document. In these settings, these four topic models fail to extract distinctive patterns from any representation source, producing noisy user and document models. This suggests that *sparsity is the main obstacle to most topic models.*

Regarding robustness, we can distinguish the 5 topic models into two categories: the first one involves 3 models that are highly sensitive to their configuration, namely LDA, LLDA and HDP. Their MAP deviation starts from 0.119, 0.075, and 0.077, respectively, and raises up to 0.250, 0.264 and 0.211, respectively. These values are extremely high, when compared to their absolute Mean MAP. This means that *extensive fine-tuning is required for successfully applying most topic models to text-based PMR.* In contrast, MAP deviation fluctuates between 0.034 and 0.109 for both HLDA and BTM. For the former, this is probably caused by the limited number of configurations that satisfied our time constraint, while for the latter, it should be attributed to its Twitter-specific functionality.

Discussion. We now discuss the novel insights that can be deduced from our experimental analysis. We start by comparing token- with character-based models. We observe that the former are significantly more effective than the latter for both bag and graph models. At first, this seems counter-intuitive, as CNG and CN are in a better position to address Challenge C1: they extract more features from sparse documents than TNG and TN, respectively [48]. They are also better equipped to address Challenges C2 and C4: by operating at a finer granularity, they can identify similarities even between noisy and non-standard tokens. Yet, the character-based models seem to accumulate noise when aggregating individual tweet models into a user model. Their similarity measures fail to capture distinctive information about the real interests of a user, yielding high scores for many irrelevant, unseen documents. The lower n is, the more intensive is this phenomenon. In fact, most bigrams are shared by both relevant and irrelevant examples, which explains why the poorest performance corresponds to n=2 for both CNG and CN. The only advantage of character-based models over their token-based counterparts is their higher robustness. However, their lower values for MAP deviation are probably caused by their lower absolute values for MAP.

Among the topic models, BTM consistently performs best with respect to effectiveness and robustness. Its superiority stems from the two inherent characteristics that optimize its functionality for the short and noisy documents in Twitter: *(i)* it considers pairs of words (i.e., biterms), instead of individual tokens, and *(ii)* it bypasses sparsity (Challenge C1) by capturing topic patterns at the level of entire corpora, instead of extracting them from individual documents. Compared to context-based models, though, BTM is significantly less effective than the token-based bag and graph models. Its performance is very close to the character-based models, especially CNG, with their difference in terms of effectiveness and robustness being statistically insignificant.

Table 6: Performance of all 13 representation sources over the 4 user types with respect to Min(imum), Mean and Max(imum) MAP across all configurations of the 9 representation models. The rightmost column presents the average performance per user type.

Generally, we can conclude that all topic models fail to improve the token-based bag and graph models in the context of Content-based PMR. Both TN and TNG achieve twice as high Mean MAP, on average, across all representation sources. The poor performance of topic models is caused by two factors: *(i)* they disregard the contextual information that is encapsulated in word ordering, and *(ii)* the Challenges C1 to C4 of Twitter. Indeed, most topic models were originally developed to extract topics from word co-occurrences in individual documents, but the sparse and noisy co-occurrence patterns in the short text of tweets reduce drastically their effectiveness.

User Types. We notice that the *relative* performance of representation models for IP, BU and IS remains practically the same as in Figure 3. Yet, there are significant differences in their *absolute* performance. On average, across all models and representation sources, IP users have higher Mean MAP than IS and BU users by 30% and 13% respectively, while BU surpasses IS by 15%. Compared to All Users, IP increases Mean MAP by 12%, BU by just 1%, while IS decreases it by 11%, on average, across all models and representation sources. These patterns are also demonstrated in the rightmost column of Table 6, which essentially expresses the average values for Min(imum), Mean and Max(imum) MAP per user type across all combinations of representation models, configurations and representation sources.

Therefore, we can conclude that *the more information an individual user produces, the more reliable are the models that represent her interests*, and vice versa: *taciturn users are the most difficult to model.* This should be expected for R and T, since the posting activity of a user increases the content that is available for building their models. However, this pattern applies to the other representation sources, too, because IP users are typically in closer contact with their followees, followers and reciprocal users, who thus can represent their interests effectively. The opposite holds for IS users. In the middle of these two extremes lie BU users, which exhibit a balanced activity in all respects.

Overall, these patterns suggest that the user categories we defined in Section 2 have a real impact on the performance of Content-based PMR. Therefore, they should be taken into account when designing a Content-based PMR approach, as different user types call for different recommendation methods.

Representation Sources. We now examine the relative effectiveness of the five representation sources and their eight pairwise combinations. Table 6 reports the performance for every combination of a user type and a representation source with respect to Min(imum), Mean and Max(imum) MAP over all configurations of the nine representation models.

Starting with individual representation sources, we observe that R consistently achieves the highest Mean MAP across all user types. This suggests that *retweets constitute the most effective means of capturing user preferences under all settings*, as users repost tweets that have attracted their attention and approval.

The second best individual source is T. This applies to all user types, except for IP, where T actually exhibits the worst performance across all individual sources. These patterns suggest that *the tweets of a user offer valuable information for her interests as long as her posting ratio is lower than 2*; such users post their messages thoughtfully, when they have something important to say. Instead, the IP users are hyperactive, posting quite frequently careless and noisy messages that do not reflect their preferences, e.g., by engaging into irrelevant discussions with other users.

Among the remaining individual sources, C achieves the best performance, followed by E and F. This pattern is consistent across all user types, with the differences being statistically significant in most cases. We can deduce, therefore, that *the reciprocal connections in Twitter reflect friendships between users that share common interests to a large extent.* Instead, the one-way connections offer weaker indications of common tastes among users, especially when they are not initiated by the ego user: the followers' posts (F) invariably result in noisy user models.

For the eight pairs of sources, we observe the following patterns: *(i)* All combinations of R with another source X result in higher performance for X, with the difference being statistically significant. Hence, R is able to enrich any representation source with valuable information about user preferences. *(ii)* All combinations of T with another source result in a (usually insignificant) lower performance in all cases but two, namely TF over IS and BU. This means that T typically conveys noisy, irrelevant information. *(iii)* For both R and T, all pairwise combinations degrade their own performance. The only exception is TR, which improves the effectiveness of T.

On the whole, we can conclude that *a user's retweets (R) should be used as the sole information source for building her model.* There is no need to combine it with T.

Time Efficiency. Figures 4(i) and (ii) depict the minimum, average and maximum values for $TTime$ and $ETime$, respectively, for every representation model across all configurations, representation sources and users. The vertical axes are logarithmic, with lower values indicating better performance.

Among the global context-aware models, we observe that on average, TNG is faster than CNG with respect to both $ETime$ and $TTime$ by 1 and 2 orders of magnitude, respectively. Similarly, among the local context-aware models, TN is faster than CN

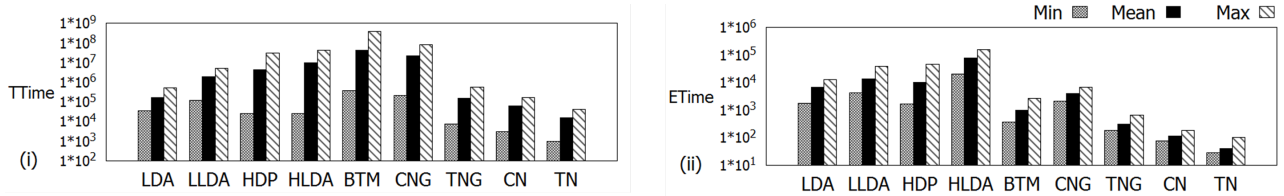

Figure 4: Time efficiency of the 9 representation models with respect to *(i)* Training Time ($TTime$), and *(ii)* Testing Time ($ETime$), on average across all configurations, representation sources and users. Lower bars indicate better performance.

by 4 and 3 times, respectively. The reason in both cases is the relative dimensionality of token- and character-based models. Typically, the latter yield a much larger feature space than the former, depending, of course, on the size of the n-grams – the larger n is, the more character n-grams are extracted from a corpus [48] and the more time-consuming is their processing.

Among the topic models, BTM exhibits the highest $TTime$. The reason is that it operates on the level of biterms, which result in a much higher dimensionality than the individual tokens that lie at the core of the other topic models. However, our analysis does not consider the most time-consuming configurations of the second worst model (HLDA), as they violated the time constraint. In practice, HLDA is expected to be slower than BTM, since its nonparametric nature lies in exploring the possible L-level hierarchical trees during topic inference. On the other extreme, LDA is the fastest topic model, while LLDA is almost 5 times faster than HDP, on average, due to its simpler models.

These patterns are slightly altered in the case of $ETime$. The worst performance by far corresponds to HLDA, due to its nonparametric functionality, while BTM turns out to be the fastest model. Unlike the other topic models, which perform Gibbs sampling for topic inference, BTM simply iterates over the biterms in a document d in order to calculate $P(z|d)$ for each topic $z \in Z$.

Comparing the model categories between them, we observe that the graph models are more time-consuming than their bag counterparts: on average, TNG and CNG are 1 and 2 orders of magnitude slower than TN and CN, respectively, for both $TTime$ and $ETime$. This should be attributed to the contextual information they incorporate in their edges, whose number is much larger in the case of CNG. Similarly, most topic models are at least 1 order of magnitude slower than their base model, TN, for both time measures, due to the time required for topic inference. Overall, *TN is consistently the most efficient representation model, due to the sparsity of tweets and the resulting low dimensionality.*

These patterns are consistent across all user types and representation sources. For the latter, we also observed that the size of the train set affects directly $TTime$ for all representation models: the more tweets are used to build a user model, the more patterns are extracted, degrading time efficiency.

6 RELATED WORK

There has been a bulk of work on recommender systems over the years [2, 3]. Most recent works focus on microblogging platforms and Social Media, employing the bag model in order to suggest new followees [13], URLs [15] and hashtags [40]. Others employ topic models for the same tasks, e.g., hashtag recommendations [27]. In the latter case, emphasis is placed on tackling sparsity through *pooling techniques*, which aggregate short texts that share similar content, or express similar ideas into lengthy pseudo-documents [4, 44]. E.g., Latent Dirichlet Allocation [10] and the Author Topic Model [52] are trained on individual messages and on messages aggregated by user and hashtag in [33].

Content-based PMR has attracted lots of interest in the data management community [14, 16, 22, 55, 63], where many works aim to improve the time efficiency of topic models. [16] parallelizes the training of HLDA through a novel concurrent dynamic matrix and a distributed tree. [14] scales up LDA through the WarpLDA algorithm, which achieves $O(1)$ time complexity per-token and fits the randomly accessed memory per-document in the L3 cache. Along with other state-of-the-art LDA samplers, this work is incorporated into LDA*, a high-end system that scales LDA training to voluminous datasets, using different samplers for various types of documents [63]. Another approach for the massive parallelization of LDA is presented in [57]. Other works facilitate real-time content recommendations in Twitter. This is done either by partitioning the social graph across a cluster in order to detect network motifs in parallel [30], or by holding the entire graph in the main memory of a single server in order to accelerate random walk-based computations on a bipartite interaction graph between users and tweets [55].

On another line of research, external resources are employed in order to augment text representation and improve their performance in various tasks. For short text clustering, Dual Latent Dirichlet Allocation learns topics from both short texts and auxiliary documents [37]. For personalized Twitter stream filtering, tweets can be transformed into RDF triples that describe their author, location and time in order to use ontologies for building user profiles [38]. User profiles can also be enriched with Wikipedia concepts [41] and with concepts from news articles that have been read by the user [34]. These approaches lie out of the scope of our analysis, which focuses on recommendations based on Twitter's internal content.

To the best of our knowledge, no prior work examines systematically Content-based PMR with respect to the aforementioned parameters, considering a wide range of options for each one.

7 CONCLUSIONS

We conclude with the following five observations about Content-based Personalized Microblog Recommendation: *(i)* The token-based vector space model achieves the best balance between effectiveness and time efficiency. In most cases, it offers the second most accurate recommendations, while involving the minimum time requirements both for training a user model and applying it to a test set. On the flip side, it involves four parameters (i.e., degrees of freedom), thus being sensitive to its configuration. *(ii)* The token n-gram graphs achieve the best balance between effectiveness and robustness. Due to the global contextual information they capture, they consistently outperform all other representation models to a significant extent, while exhibiting limited sensitivity to their configuration. Yet, they are slower than the vector space model by an order of magnitude, on average. *(iii)* The character-based models underperform their token-based counterparts, as their similarity measures cannot tackle the noise that piles up when assembling document models into user models. *(iv)* The topic models exhibit much lower effectiveness than the token-based bag models for three reasons: *1)* most of them are not crafted for the sparse, noisy and multilingual content of Twitter, *2)* they depend heavily on their configuration, and *3)* they are context-agnostic, ignoring the sequence of words in documents. Their processing is time-consuming, due to the inference of topics, requiring parallelization techniques to scale to voluminous data [16, 57, 63]. *(v)* All representation models perform best when they are built from the retweets of hyperactive users (information producers).

In the future, we plan to expand our comparative analysis to more recommendation tasks for microblogging platforms.

ABSTRACT

Existing works for truth discovery in categorical data usually assume that claimed values are mutually exclusive and only one among them is correct. However, many claimed values are not mutually exclusive even for functional predicates due to their hierarchical structures. Thus, we need to consider the hierarchical structure to effectively estimate the trustworthiness of the sources and infer the truths. We propose a probabilistic model to utilize the hierarchical structures and an inference algorithm to find the truths. In addition, in the knowledge fusion, the step of automatically extracting information from unstructured data (e.g., text) generates a lot of false claims. To take advantages of the human cognitive abilities in understanding unstructured data, we utilize crowdsourcing to refine the result of the truth discovery. We propose a task assignment algorithm to maximize the accuracy of the inferred truths. The performance study with real-life datasets confirms the effectiveness of our truth inference and task assignment algorithms.

1 INTRODUCTION

Automatic construction of large-scale knowledge bases is very important for the communities of database and knowledge management. Knowledge fusion (KF) [8] is one of the methods used to automatically construct knowledge bases (a.k.a. knowledge harvesting). It collects the possibly conflicting values of objects from data sources and applies *truth discovery* techniques for resolving the conflicts in the collected values. Since the values are extracted from unstructured or semi-structured data, the collected information exhibits error-prone behavior. The goal of the *truth discovery* used in knowledge fusion is to infer the true value of each object from the noisy observed values retrieved from multiple information sources while simultaneously estimating the reliabilities of the sources. Two potential applications of knowledge fusion are web source trustworthiness estimation and data cleaning [10]. By utilizing truth discovery algorithms, we can evaluate the quality of web sources and find systematic errors in data curation by analyzing the identified wrong values.

Truth discovery with hierarchies: As pointed out in [6, 8, 25], the extracted values can be hierarchically structured. In this case, there may be multiple correct values in the hierarchy for an object even for functional predicates and we can utilize them to find the most specific correct value among the candidate values. For example, consider the three claimed values of 'NY', 'Liberty Island' and 'LA' about the location of the Statue of Liberty in Table 1. Because Liberty Island is an island in NY, 'NY' and 'Liberty Island' do not conflict with each other. Thus, we can conclude that the Statue of Liberty stands on Liberty Island in NY.

Table 1: Locations of tourist attractions

Object	Source	Claimed value
Statue of Liberty	UNESCO	NY
Statue of Liberty	Wikipedia	Liberty Island
Statue of Liberty	Arrangy	LA
Big Ben	Quora	Manchester
Big Ben	tripadvisor	London

We also observed that many sources provide generalized values in the real-life. Figure 1 shows the graph of the generalized accuracy against the accuracy of the sources in the real-life datasets *BirthPlaces* and *Heritages* used for experiments in Section 5. The accuracy and the generalized accuracy of a source are the proportions of the exactly correct values and hierarchically-correct values among all claimed values, respectively. If a source claims exactly correct values without generalization, it is located at the dotted diagonal line in the graph. This graph shows that many sources in real-life datasets claim with generalized values and each source has its own tendency of generalization when claiming values.

Most of the existing methods [7, 9, 30, 38, 39] simply regard the generalized values of a correct value as incorrect. Thus, it causes a problem in estimating the reliabilities of sources. According to [8], 35% of the false negatives in the data fusion task are produced by ignoring such hierarchical structures. Note that there are many publicly available hierarchies such as WordNet [32] and DBpedia [1]. Thus, a truth discovery algorithm to incorporate hierarchies is proposed in [2]. However, it does not consider the different tendencies of generalization and may lead to the degradation of the accuracy. Another drawback is that it needs a threshold to control the granularity of the estimated truth.

We propose a novel probabilistic model to capture the different generalization tendencies shown in Figure 1. Existing probabilistic models [7, 9, 30, 39] basically assume two interpretations of a claimed value (i.e., correct and incorrect). By introducing three interpretations of a claimed value (i.e., exactly correct, hierarchically correct, and incorrect), our proposed model represents the generalization tendency and reliability of the sources.

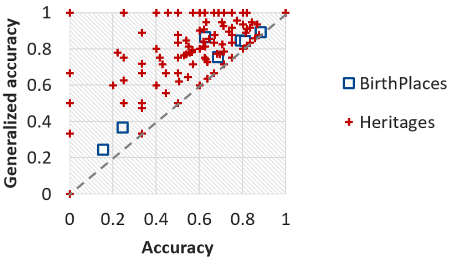

Figure 1: Generalization tendencies of the sources

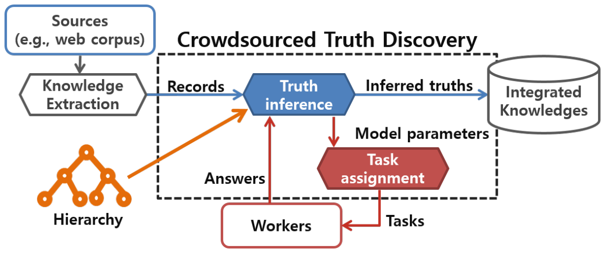

Figure 2: Crowdsourced truth discovery in KF

Crowdsourced truth discovery: It is reported in [8] that upto 96% of the false claims are made by extraction errors rather than by the sources themselves. Since crowdsourcing is an efficient way to utilize human intelligence with low cost, it has been successfully applied in various areas of data integration such as schema matching [12], entity resolution [34], graph alignment [17] and truth discovery [39, 41]. Thus, we utilize crowdsourcing to improve the accuracy of the truth discovery.

It is essential in practice to minimize the cost of crowdsourcing by assigning proper tasks to workers. A popular approach for selecting queries in active learning is *uncertainty sampling* [3, 18, 19, 39]. It asks a query to reduce the uncertainty of the confidences on the candidate values the most. However, it considers only the uncertainty regardless of the accuracy improvement. QASCA algorithm [41] asks a query with the highest accuracy improvement, but measures the improvement without considering the number of collected claimed values. It can be inaccurate since an additional answer may be less informative for an object which already has many records and answers.

Assume that there are two candidate values of an object with equal confidences. If only a few sources provide the claimed values for the object, an additional answer from a crowd worker will significantly change the confidence distribution. Meanwhile, if hundreds of sources already provide the claimed values for the object, the influence of an additional answer is likely to be very little. Thus, we need to consider the number of collected answers as well as the current confidence distribution. Based on the observation, we develop a new method to estimate the increase of accuracy more precisely by considering the number of collected records and answers. We also present an incremental EM algorithm to quickly measure the accuracy improvement and propose a pruning technique to efficiently assign the tasks to workers.

An overview of our truth discovery algorithm: By combining the proposed task assignment and truth inference algorithms, we develop a novel *crowdsourced truth discovery algorithm using hierarchies*. As illustrated in Figure 2, our algorithm consists of two components: *hierarchical truth inference* and *task assignment*. The hierarchical truth inference algorithm finds the correct values from the conflicting values, which are collected from different sources and crowd workers, using hierarchies. The task assignment algorithm distributes objects to the workers who are likely to increase the accuracy of the truth discovery the most. The proposed *crowdsourced truth discovery algorithm* repeatedly alternates the truth inference and task assignment until the budget of crowdsourcing runs out. As discussed in [20], some workers answer slower than others and increase the latency. However, we do not investigate how to reduce the latency in this work since we can utilize the techniques proposed in [13].

Our contributions: The contributions of this paper are summarized below.

- We propose a truth inference algorithm utilizing the hierarchical structures in claimed values. To the best of our knowledge, it is the first work which considers both the reliabilities and the generalization tendencies of the sources.
- To assign a task which will most improve the accuracy, we develop an incremental EM algorithm to estimate the accuracy improvement for a task by considering the number of claimed values as well as the confidence distribution. We also devise an efficient task assignment algorithm for multiple crowd workers based on the quality measure.
- We empirically show that the proposed algorithm outperforms the existing works with extensive experiments on real-life datasets.

2 PRELIMINARIES

In this section, we provide the definitions and the problem formulation of *crowdsourced truth discovery in the presence of hierarchy.*

2.1 Definitions

For the ease of presentation, we assume that we are interested in a single attribute of objects although our algorithms can be easily generalized to find the truths of multiple attributes. Thus, we use ‘the target attribute value of an object’ and ‘the value of an object’ interchangeably.

A *source* is a structured or unstructured database which contains the information on target attribute values for a set of objects. In this paper, a *source* is a certain web page or website and a *worker* represents a human worker in crowdsourcing platforms. The information of an object provided by a source or a worker is called a *claimed value.*

Definition 2.1. A *record* is a data describing the information about an object from a source. A record on an object o from a source s is represented as a triple (o, s, v_o^s) where v_o^s is the claimed value of an object o collected from s. Similarly, if a worker w answers that the truth on an object o is v_o^w, the *answer* is represented as (o, w, v_o^w).

Let S_o be the set of the sources which claimed a value on the object o and V_o be the set of candidate values collected from S_o. Each worker in W_o answers a question about the object o by selecting a value from V_o.

In our problem setting, we assume that we have a hierarchy tree H of the claimed values. If we are interested in an attribute related to locations (e.g., birthplace), H would be a geographical hierarchy with different levels of granularity (e.g., continent, country, city, etc.). We also assume that there is no answer with the value of the root in the hierarchy since it provides no information at all (e.g., Earth as a birthplace). We summarize the notations to be used in the paper in Table 2.

Example 2.2. Consider the records in Table 1. Since the source Wikipedia claims that the location of the Statue of Liberty is Liberty Island, it is represented by v_o^s =‘Liberty Island’ where o =‘Statue of Liberty’ and s =‘Wikipedia’. If a human worker ‘Emma Stone’ answered Big Ben is in London, it is represented by v_o^w =‘London’ where o =‘Big Ben’ and w =‘Emma Stone’.

2.2 Problem Definition

Given a set of objects O and a hierarchy tree H, we define the two subproblems of the crowdsourced truth discovery.

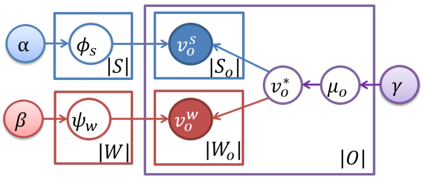

Figure 3: A graphical model for truth inference

Definition 2.3 (Hierarchical truth inference problem). For a set of records R collected from the sources and a set of answers A from the workers, we find the most specific true value v_o^* of each object $o \in O$ among the candidate values in V_o by using the hierarchy H.

Definition 2.4 (Task assignment problem). For each worker w in a set of workers W, we select the top-k objects from O which are likely to increase the overall accuracy of the inferred truths the most by using the hierarchy H.

We present a hierarchical truth inference algorithm in Section 3 and a task assignment algorithm in Section 4.

3 HIERARCHICAL TRUTH INFERENCE

For the hierarchical truth inference, we first model the trustworthiness of sources and workers for a given hierarchy. Then, we propose a probabilistic model to describe the process of generating the set of records and the set of answers based on the trustworthiness modeling. We next develop an inference algorithm to estimate the model parameters and determine the truths.

3.1 Our Generative Model

Our probabilistic graphical model in Figure 3 expresses the conditional dependence (represented by edges) between random variables (represented by nodes). While the previous works [5, 15, 31, 35] assume that all sources and workers have their own reliabilities only, we assume that each source or worker has its generalization tendency as well as reliability. We first describe how sources and workers generate the claimed values based on their trustworthiness. We next present the model for generating the true value. Finally, we provide the detailed generative process of our probabilistic model.

Model for source trustworthiness: For an object o, let v_o^* be the truth and v_o^s be the claimed value reported by a source s. Recall that V_o is the set of candidate values for an object o. Furthermore, we let $G_o(v)$ denote the set of candidate values which are ancestors of a value v except for the root in the hierarchy H.

Table 2: Notations

Symbol	Description
s	A data source
w	A crowd worker
v_o^s	Claimed value from s about o
v_o^w	Claimed value from w about o
R	Set of all records collected from the set of sources S
A	Set of all answers collected from the set of workers W
V_o	Set of candidate values about o
S_o	Set of sources which post information about o
W_o	Set of workers who answered about o
O_s	Set of objects that source s provided a value
O_w	Set of objects that worker w answered to
$G_o(v)$	Set of values in V_o which are ancestors of a value v except the root in the hierarchy H
$D_o(v)$	Set of values in V_o which are descendants of v

There are three relationships between a claimed value v_o^s and the truth v_o^*: (1) $v_o^s = v_o^*$, (2) $v_o^s \in G_o(v_o^*)$ and (3) otherwise. Let $\phi_s = (\phi_{s,1}, \phi_{s,2}, \phi_{s,3})$ be the *trustworthiness distribution* of a source s where $\phi_{s,i}$ is the probability that a claimed value of the source s corresponds to the i-th relationship. In each relationship, a claimed value is generated as follows:

- **Case 1 ($v_o^s = v_o^*$):** The source s provides the exact true value with a probability $\phi_{s,1}$.
- **Case 2 ($v_o^s \in G_o(v_o^*)$):** The source s provides a *generalized true value* v_o^s with a probability $\phi_{s,2}$. In this case, the claimed value is an ancestor of the truth v_o^* in H. We assume that the claimed value is uniformly selected from $G_o(v_o^*)$.
- **Case 3 (*otherwise*):** The source s provides a wrong value v_o^s not even in $G_o(v_o^*)$. The claimed value is uniformly selected among the rest of the candidate values in V_o.

The probability distribution ϕ_s is an initially-unknown model parameter to be estimated in our inference algorithm. Accordingly, the probability of selecting an answer v_o^s among the values in V_o for an object o is represented by

$$P(v_o^s|v_o^*, \phi_s) = \begin{cases} \phi_{s,1} & \text{if } v_o^s = v_o^*, \\ \phi_{s,2}/|G_o(v_o^*)| & \text{if } v_o^s \in G_o(v_o^*), \\ \phi_{s,3}/(|V_o| - |G_o(v_o^*)| - 1) & \text{otherwise.} \end{cases} \quad (1)$$

For the prior of the distribution ϕ_s, we assume that it follows a Dirichlet distribution $Dir(\alpha)$, with a hyperparameter $\alpha = (\alpha_1, \alpha_2, \alpha_3)$, which is the conjugate prior of categorical distributions.

Let O_H be the set of objects who have an ancestor-descendant relationship in their candidate set. In practice, there may exist some objects whose candidate values do not have an ancestor-descendant relationship. In this case, the probability of the second case (i.e., $\phi_{s,2}$) may be underestimated. Thus, if there is no ancestor-descendant relationship between the claimed values about o (i.e., $o \notin O_H$), we assume that a source generates its claimed value v_o^s with the following probability

$$P(v_o^s|v_o^*, \phi_s) = \begin{cases} \phi_{s,1} + \phi_{s,2} & \text{if } v_o^s = v_o^*, \\ \phi_{s,3}/(|V_o| - 1) & \text{otherwise.} \end{cases} \quad (2)$$

Model for worker trustworthiness: Let v_o^w be the claimed value chosen by a worker w among the candidates in V_o for an object o. Similar to the model for source trustworthiness, we also assume the three relationships between a claimed value v_o^w and the truth v_o^*: (1) $v_o^w = v_o^*$, (2) $v_o^w \in G_o(v_o^*)$ and (3) otherwise. Each worker w has its *trustworthiness distribution* $\psi_w = (\psi_{w,1}, \psi_{w,2}, \psi_{w,3})$ where $\psi_{w,i}$ is the probability that an answer of the worker w corresponds to the i-th relationship. We assume that the trustworthiness distribution is generated from $Dir(\beta)$ with a hyperparameter $\beta = (\beta_1, \beta_2, \beta_3)$.

Since it is difficult for the workers to be aware of the correct answer for every object, a worker can refer to web sites to answer the question. In such a case, if there is a widespread misinformation across multiple sources, the worker is also likely to respond with the incorrect information. Similar to [9, 30], we thus exploit the *popularity* of a value in Cases 2 and 3 to consider such dependency between sources and workers.

- **Case 1 ($v_o^w = v_o^*$):** The worker w provides the exact true value with a probability $\psi_{w,1}$.
- **Case 2 ($v_o^w \in G_o(v_o^*)$):** The worker w provides a generalized true value with a probability $\psi_{w,2}$. We assume that

$$f^v_{o,s}=\frac{P(v^s_o|v^*_o=v,\phi_s)\cdot\mu_{o,v}}{\sum_{v'\in V_o}P(v^s_o|v^*_o=v',\phi_s)\cdot\mu_{o,v'}}$$

$$f^v_{o,w}=\frac{P(v^w_o|v^*_o=v,\psi_w)\cdot\mu_{o,v}}{\sum_{v'\in V_o}P(v^w_o|v^*_o=v',\psi_w)\cdot\mu_{o,v'}}$$

$$g^1_{o,s}=\frac{\phi_{s,1}\cdot\mu_{o,v^s_o}}{\sum_{v\in V_o}P(v^s_o|v^*_o=v,\phi_s)\cdot\mu_{o,v}}$$

$$g^2_{o,s}=\begin{cases}\dfrac{\sum_{v\in D_o(v^s_o)}\frac{\phi_{s,2}}{|G_o(v)|}\cdot\mu_{o,v}}{\sum_{v\in V_o}P(v^s_o|v^*_o=v,\phi_s)\cdot\mu_{o,v}} & \text{if } o\in O_H\\ \dfrac{\phi_{s,2}\cdot\mu_{o,v^s_o}}{\sum_{v\in V_o}P(v^s_o|v^*_o=v,\phi_s)\cdot\mu_{o,v}} & \text{otherwise}\end{cases}$$

$$g^3_{o,s}=\frac{\sum_{v\in\neg D_o(v^s_o)}\frac{\phi_{s,3}}{|V_o-G_o(v)|-1}\cdot\mu_{o,v}}{\sum_{v\in V_o}P(v^s_o|v^*_o=v,\phi_s)\cdot\mu_{o,v}}$$

$$g^1_{o,w}=\frac{\psi_{w,1}\cdot\mu_{o,v^w_o}}{\sum_{v\in V_o}P(v^w_o|v^*_o=v,\psi_w)\cdot\mu_{o,v}}$$

$$g^2_{o,w}=\begin{cases}\dfrac{\sum_{v\in D_o(v^w_o)}\psi_{w,2}\cdot Pop_2(v^w_o|v^*_o=v)\cdot\mu_{o,v}}{\sum_{v\in V_o}P(v^w_o|v^*_o=v,\psi_w)\cdot\mu_{o,v}} & \text{if } o\in O_H\\ \dfrac{\psi_{w,2}\cdot\mu_{o,v^w_o}}{\sum_{v\in V_o}P(v^w_o|v^*_o=v,\psi_w)\cdot\mu_{o,v}} & \text{otherwise}\end{cases}$$

$$g^3_{o,w}=\frac{\sum_{v\in\neg D_o(v^w_o)}\psi_{w,3}\cdot Pop_3(v^w_o|v^*_o=v)\cdot\mu_{o,v}}{\sum_{v\in V_o}P(v^w_o|v^*_o=v,\psi_w)\cdot\mu_{o,v}}$$

Figure 4: E-step for the proposed truth inference algorithm

the claimed value v^w_o is selected according to the popularity $Pop_2(v^w_o|v^*_o)=\frac{|\{s|s\in S_o,v^s_o=v\}|}{|\{s|s\in S_o,v^s_o\in G_o(v^*_o)\}|}$ which is the proportion of the records whose claimed value is v^w_o out of the records with generalized values of v^*_o.

- **Case 3** (*otherwise*)**:** The claimed value is selected from the wrong values according to the popularity $Pop_3(v^w_o|v^*_o)=\frac{|\{s|s\in S_o,v^s_o=v\}|}{|\{s|s\in S_o,v^s_o\notin G_o(v^*_o),v^s_o\neq v^*_o\}|}$.

By the above model, the probability of selecting an answer v^w_o for the truth v^*_o of an object o is formulated as

$$P(v^w_o|v^*_o,\psi_w)=\begin{cases}\psi_{w,1} & \text{if } v^w_o=v^*_o,\\ \psi_{w,2}\cdot Pop_2(v^w_o|v^*_o) & \text{if } v^w_o\in G_o(v^*_o),\\ \psi_{w,3}\cdot Pop_3(v^w_o|v^*_o) & \text{otherwise.}\end{cases} \quad (3)$$

Similar to the model for source trustworthiness, if there is no ancestor-descendant relationship in the candidate values of an object o, the probability of selecting a claimed value v^w_o is

$$P(v^w_o|v^*_o,\psi_w)=\begin{cases}\psi_{w,1}+\psi_{w,2} & \text{if } v^w_o=v^*_o,\\ \psi_{w,3}\cdot Pop_3(v^w_o|v^*_o) & \text{otherwise.}\end{cases} \quad (4)$$

Model for truth: We introduce the probability distribution over the candidate answers to determine the truth, called *confidence distribution.* Each object o has a confidence distribution $\mu_o=\{\mu_{o,v}\}_{v\in V_o}$ where $\mu_{o,v}$ is the probability that the value $v\in V_o$ is the true answer for o. We also use a dirichlet prior $Dir(\gamma_o)$ for the confidence distribution μ_o where $\gamma_o=\{\gamma_{o,v}\}_{v\in V_o}$ is a hyperparameter.

Based on the above three models, the generative process of our model works as follows.

Generative process: Given a set of objects O, a set of sources S and a set of workers W, our proposed model assumes the following generative process for the set of records R and the set of answers A:

(1) Draw $\phi_s\sim Dir(\alpha)$ for each source $s\in S$
(2) Draw $\psi_w\sim Dir(\beta)$ for each worker $w\in W$
(3) For each object $o\in O$
  (a) Draw $\mu_o\sim Dir(\gamma_o)$
  (b) Draw a true value $v^*_o\sim Categorical(\mu_o)$
  (c) For each source $s\in S_o$
    (i) Draw a value v^s_o following $P(v^s_o|v^*_o,\phi_s)$
  (d) For each worker $w\in W_o$
    (i) Draw a value v^w_o following $P(v^w_o|v^*_o,\psi_w)$

3.2 Estimation of Model Parameters

We now develop an inference algorithm for the generative model. Let $\Theta=\boldsymbol{\phi}\cup\boldsymbol{\psi}\cup\boldsymbol{\mu}$ be the set of all model parameters where $\boldsymbol{\phi}=\{\phi_s|s\in S\}$, $\boldsymbol{\psi}=\{\psi_w|w\in W\}$ and $\boldsymbol{\mu}=\{\mu_o|o\in O\}$. We propose an EM algorithm to find the maximum a posteriori (MAP) estimate of the parameters in our model.

The maximum a posteriori (MAP) estimator: Recall that $R=\{(o,s,v^s_o)\}$ is the set of records from the sources and $A=\{(o,w,v^w_o)\}$ is the set of answers from the workers. For every object o, each source $s\in S_o$ and each worker $w\in W_o$ generates its claimed values independently. Then, the likelihood of R and A based on our generative model is

$$P(R,A|\Theta)=\prod_{o\in O}\prod_{s\in S_o}P(v^s_o|\phi_s,\mu_o)\cdot\prod_{o\in O}\prod_{w\in W_o}P(v^w_o|\psi_w,\mu_o)$$

where the probability of generating a claimed value by a source or a worker becomes

$$P(v^s_o|\phi_s,\mu_o)=\sum_{v\in V_o}P(v^s_o|\phi_s,v^*_o=v)\cdot\mu_{o,v} \quad (5)$$

$$P(v^w_o|\psi_w,\mu_o)=\sum_{v\in V_o}P(v^w_o|\psi_w,v^*_o=v)\cdot\mu_{o,v}. \quad (6)$$

Consequently, the MAP point estimator is obtained by maximizing the log-posterior as

$$\hat{\Theta}=\arg\max_{\Theta}\{\log P(R,A|\Theta)+\log P(\Theta)\}=\arg\max_{\Theta}\mathbb{F} \quad (7)$$

where the objective function $\mathbb{F}$ is

$$\begin{aligned}\mathbb{F}=&\sum_{o\in O}\sum_{s\in S_o}\log\sum_{v\in V_o}P(v^s_o|\phi_s,v^*_o=v)\cdot\mu_{o,v}\\ &+\sum_{o\in O}\sum_{w\in W_o}\log\sum_{v\in V_o}P(v^w_o|\psi_w,v^*_o=v)\cdot\mu_{o,v}\\ &+\sum_{s\in S}\log p(\phi_s|\alpha)+\sum_{w\in W}\log p(\psi_w|\beta)+\sum_{o\in O}\log p(\mu_o|\gamma_o).\end{aligned} \quad (8)$$

Note that although we assumed that each claimed value is generated independently according to its probability distribution defined in Eq. (5) and (6), the dependencies between sources and workers are already considered in $Pop_2(v^w_o|v^*_o)$ and $Pop_3(v^w_o|v^*_o)$.

The EM algorithm: We introduce a random variable C_v to represent the type of the relationship between the claimed value v and the truth v^*_o. It is defined as follows:

$$C_v=\begin{cases}1 & \text{if } v=v^*_o,\\ 2 & \text{if } v\in G_o(v^*_o),\\ 3 & \text{otherwise.}\end{cases}$$

In the **E-step**, we compute the conditional distributions of the hidden variables $C_{v^s_o}$, $C_{v^w_o}$ and v^*_o under our current estimate of the parameters Θ. Let $f^v_{o,s}$, $f^v_{o,w}$, $g^t_{o,s}$ and $g^t_{o,w}$ denote the conditional probabilities $P(v^*_o=v|v^s_o,\mu_o,\phi_s)$, $P(v^*_o=v|v^w_o,\mu_o,\psi_w)$, $P(C_{v^s_o}=t|\mu_o,\phi_s)$ and $P(C_{v^w_o}=t|\ \mu_o,\psi_w)$, respectively. Using Bayes' rule, we can update the conditional probabilities as shown in Figure 4 where $D_o(v)=\{v'|v\in G_o(v')\wedge v'\in V_o\}$ is the set of descendants of v among the candidate values and $\neg D_o(v)=$

$V_o - D_o(v) - \{v\}$ is the set of candidate values each of which is neither a descendant of the value v nor the v itself.

In the **M-step**, we find the model parameters Θ that maximize our objective function $\mathbb{F}$. We first add Lagrange multipliers to enforce the constraints of model parameters.

$$\mathbb{L} = \mathbb{F} + \sum_{s \in S} \lambda_{\phi,s} \left(1 - \sum_{t=1}^{3} \phi_{s,t}\right) + \sum_{w \in W} \lambda_{\psi,w} \left(1 - \sum_{t=1}^{3} \psi_{w,t}\right) + \sum_{o \in O} \lambda_{\mu,o} \left(1 - \sum_{v \in V_o} \mu_{o,v}\right)$$

We obtain the following equations for updating the model parameters Θ by taking the partial derivative of the Lagrangian $\mathbb{L}$ with respect to each model parameter and setting it to zero:

$$\mu_{o,v} = \frac{\sum_{s \in S_o} f_{o,s}^{v} + \sum_{w \in W_o} f_{o,w}^{v} + \gamma_{o,v} - 1}{|S_o| + |W_o| + \sum_{v' \in V_o} (\gamma_{o,v'} - 1)} \tag{9}$$

$$\phi_{s,t} = \frac{\sum_{o \in O_s} g_{o,s}^{t} + \alpha_t - 1}{|O_s| + \sum_{t'=1}^{3} (\alpha_{t'} - 1)} \tag{10}$$

$$\psi_{w,t} = \frac{\sum_{o \in O_w} g_{o,w}^{t} + \beta_t - 1}{|O_w| + \sum_{t'=1}^{3} (\beta_{t'} - 1)} \tag{11}$$

where O_s and O_w are the sets of objects claimed by s and w, respectively. We infer the truth by choosing the value with the maximum confidence among the candidate values as

$$v_o^* = \arg\max_{v \in V_o} \mu_{o,v}. \tag{12}$$

Extension to numerical data: In the world wide web, numerical data also have an implicit hierarchy due to the significant digits which carry meaning contributing to its measurement resolution. For example, even though the area of Seoul is $605.196km^2$, different websites may represent the area in various forms depending on the significant figures (e.g., $605.2km^2$, $605km^2$). An existing algorithm [21] to handle numerical data utilizes a weighted sum of the claimed values to consider the distribution of the claimed values. However, such method is sensitive to outliers and thus need a proper preprocessing to remove the outliers. To overcome the drawbacks, we generate the underlying hierarchy in the numerical data by assuming that v_d is a descendant of v_a if a value v_a can be obtained by rounding off a value v_d. Then, we can use our TDH algorithm to find the truths in numerical data by taking into account the relationship between the values in the implicit hierarchy. Our algorithm is also robust to the outliers with extremely small or large value since we estimate the truth by selecting the most probable value from the candidate values rather than computing a weighted average of the claimed values.

4 TASK ASSIGNMENT TO WORKERS

In this section, we propose a task assignment method to select the best objects to be assigned to the workers in crowdsourcing systems. We first define a quality measure of tasks called *Expected Accuracy Increase (EAI)* and develop an incremental EM algorithm to quickly estimate the quality measure. Finally, we present an efficient algorithm for assigning the k questions to each worker w in a set of workers W based on the measure.

4.1 The Quality Measure

Given a worker w, our goal is to choose an object to be assigned to the worker w which is likely to increase the accuracy of the estimated truths the most. Thus, we define a quality measure for a pair of worker and an object based on the improvement of the accuracy. As discussed in [41], the improvement of the accuracy by a task can be estimated by using the difference between the highest confidence as follows:

$$(Accuracy\ improvement) = \{\max_v \mu_{o,v|w} - \max_v \mu_{o,v}\}/|O| \tag{13}$$

where $\mu_{o,v|w}$ is the estimated confidence on v if the worker w answers about an object o.

The quality measure used by QASCA: The QASCA[41] algorithm calculates the estimated confidence by using the current confidence distribution and the likelihood of the answer v_o^w given the truth $v_o^* = v$ as

$$\mu_{o,v|w} \propto \mu_{o,v} \cdot p(v_o^w = v' | v_o^* = v)$$

where v' is a sampled claimed value. There are two drawbacks in the quality measure of QASCA. First, since it computes the estimated confidence $\mu_{o,v|w}$ based on a sampled answer $v_o^w = v$, the value of the quality measure is very sensitive to the sampled answer. In addition, QASCA does not consider the number of claimed values collected so far and the estimated confidence $\mu_{o,v|w}$ may not be accurate. For instance, assume that there exist two objects which have identical confidence distributions. If one of the objects already has many collected claimed values, an additional answer is not likely to change the confidence significantly. Thus, task assignment algorithms should select another object who has a smaller number of collected records and answers.

Our quality measure: To avoid the sensitiveness caused by sampling answers, we develop a new quality measure *Expected Accuracy Improvement (EAI)* which is obtained by taking the expectation to Eq. (13). That is,

$$EAI(w,o) = \{E[\max_v \mu_{o,v|w}] - \max_v \mu_{o,v}\}/|O|. \tag{14}$$

By the definition of expectation, $E[\max_v \mu_{o,v|w}]$ becomes

$$E[\max_v \mu_{o,v|w}] = \sum_{v' \in V_o} P(v_o^w = v' | \psi_w, \mu_o) \cdot \max_v \mu_{o,v|v_o^w = v'}. \tag{15}$$

where $\mu_{o,v|v_o^w=v'}$ is the conditional confidence when a worker w answers with v' about the object o.

Since $P(v_o^w = v' | \psi_w, \mu_o)$ can be computed by Eq. (6), to compute $E[\max_v \mu_{o,v|w}]$ by Eq. (15), we need the estimation of the conditional confidence $\mu_{o,v|v_o^w=v'}$ with an additional answer $v_o^w = v'$. Recall that the estimated confidence computed by QASCA may not be accurate because it does not consider the collected records and answers so far. To reduce the error, we use them to compute the conditional confidence $\mu_{o,v|v_o^w=v'}$. We can compute the conditional confidence $\mu_{o,v|v_o^w=v'}$ by applying the EM algorithm in Section 3.2 with the collected records and answers including $v_o^w = v'$. However, since it is computationally expensive, we next develop an *incremental EM algorithm.*

4.2 The Incremental EM Algorithm

Let $\mathbb{F}_{v_o^w=v'}$ be the objective function in Eq. (7) after obtaining an additional answer (o, w, v'). Then, we have

$$\mathbb{F}_{v_o^w=v'} = \mathbb{F} + \log \sum_{v \in V_o} P(v_o^w = v' | \psi_w, v_o^* = v) \cdot \mu_{o,v}$$

by adding the related term of the additional answer (log likelihood of the additional answer) to Eq. (8). Instead of running the iterative EM algorithm in Section 3.2, we incrementally perform a *single EM-step* to speed up for only the additional answer with the current model parameters and the above objective function.

E-step: Since we use the current model parameters, the probabilities of the hidden variables for collected records and answers are not changed. Thus, we only need to compute the conditional probabilities of the hidden variable given the additional answer as

$$f_{o,w|v_o^w=v'}^{v} = \frac{P(v_o^w = v' | v_o^* = v, \psi_w) \cdot \mu_{o,v}}{\sum_{v'' \in V_o} P(v_o^w = v' | v_o^* = v'', \psi_w) \cdot \mu_{o,v''}} \tag{16}$$

based on the equation for $f^{v}_{o,w}$ used at the E-step in Figure 4.

M-step: For the objective function $\mathbb{F}_{v_o^w=v'}$, we obtain the following equation of the M-step for the confidence distribution μ_o with the additional answer $v_o^w = v'$

$$\mu_{o,v|v_o^w=v'} = \frac{\sum_{s\in S_o} f^{v}_{o,s} + \sum_{w'\in W_o} f^{v}_{o,w'} + f^{v}_{o,w|v_o^w=v'} + \gamma_{o,v} - 1}{|S_o| + |W_o| + 1 + \sum_{v''\in V_o}\left(\gamma_{o,v''} - 1\right)}$$

by adding the related terms $f^{v}_{o,w|v_o^w=v'}$ and 1 to the numerator and the denominator of the update equation in Eq. (9), respectively. Let $N_{o,v}$ and D_o be the numerator and the denominator in Eq. (9), respectively. Then, the above equation can be rewritten as

$$\mu_{o,v|v_o^w=v'} = \frac{N_{o,v} + f^{v}_{o,w|v_o^w=v'}}{D_o + 1}. \tag{17}$$

By substituting $f^{v}_{o,w|v_o^w=v'}$ in Eq. (17) with Eq. (16), the conditional confidence becomes

$$\mu_{o,v|v_o^w=v'} = \frac{N_{o,v} + \frac{P(v_o^w=v'|v_o^*=v,\psi_w)\cdot\mu_{o,v}}{\sum_{v''\in V_o} P(v_o^w=v'|v_o^*=v'',\psi_w)\cdot\mu_{o,v''}}}{D_o + 1}. \tag{18}$$

Since $N_{o,v}$ and D_o are proportional to the number of the existing claimed values, the confidence will be changed very little if there are many claimed values already. Thus, we can overcome the second drawback of QASCA. Since $N_{o,v}$s and D_os are repeatedly used to compute $\mu_{o,v|v_o^w=v'}$, our truth inference algorithm keeps $N_{o,v}$s and D_os in main memory to reduce the computation time.

Time complexity analysis: To calculate $E[\max_v \mu_{o,v|w}]$ by Eq. (15), $P(v_o^w = v'|\psi_w, \mu_o)$ is computed $|V_o|$ times and $\mu_{o,v|v_o^w=v'}$ is calculated for every pair of v and v' (i.e., $O(|V_o|^2)$ times). Moreover, computing $P(v_o^w = v'|\psi_w, \mu_o)$ and $\mu_{o,v|v_o^w=v'}$ take $O(|V_o|)$ time. Thus, it takes $O(|V_o|^3)$ time to compute $EAI(w, o)$ by Eq. (14). In reality, $|V_o|$ is very small compared to $|O|$,$|S|$ and $|W|$. In addition, by utilizing the pruning technique in the next section, we can significantly reduce the computation time. Therefore, the task assignment step can be performed within a short time compared to the truth inference. The execution time for each step will be presented in the experiment section.

4.3 The Task Assignment Algorithm

To find the k objects to be assigned to each worker, we need to compute $EAI(w, o)$ for all pairs of w and o. To reduce the number of computing $EAI(w, o)$, we develop a pruning technique by utilizing an upper bound of $EAI(w, o)$.

An upper bound of EAI: We provide the following lemma which allows us to compute an upper bound $U_{EAI}(o)$.

Lemma 4.1. (Upper Bound of Expected Accuracy Increase) *For an object o and a worker w, we have*

$$EAI(w, o) \le U_{EAI}(o) = \frac{1 - \max_v \mu_{o,v}}{|O| \cdot (D_o + 1)}. \tag{19}$$

Proof. From Eq. (18), since $\sum_{v'} P(v_o^w=v'|\psi_w, \mu_o) = 1$, we get

$$\begin{aligned} E[\max_v \mu_{o,v|w}] &= \sum_{v'\in V_o} P(v_o^w=v'|\psi_w, \mu_o) \cdot \max_v \mu_{o,v|v_o^w=v'} \\ &\le \max_{v,v'} \mu_{o,v|v_o^w=v'} \cdot \sum_{v'\in V_o} P(v_o^w=v'|\psi_w, \mu_o) \\ &= \max_{v,v'} \mu_{o,v|v_o^w=v'}. \end{aligned} \tag{20}$$

Moreover, from Eq. (17), we obtain

$$\mu_{o,v|v_o^w=v'} = \frac{N_{o,v} + f^{v}_{o,w|v_o^w=v'}}{D_o + 1} \le \frac{N_{o,v} + 1}{D_o + 1}. \tag{21}$$

Algorithm 1 Task Assignment

```
Input: set of workers $W$, number of questions $k$
 1: Compute the upper bound $U_{EMCI}(o)$ for $o \in O$
 2: $h_{UB} \leftarrow$ BuildMaxHeap($\{\langle U_{EAI}(o), o\rangle | o \in O\}$)
 3: Sort workers in the decreasing order of $\psi_{w,1}$
    (i.e., $\psi_{1,1} \ge \psi_{2,1} \ge \cdots \ge \psi_{|W|,1}$).
 4: for $w$ = 1 to $|W|$ do
 5:     $h_{EAI}[w] \leftarrow$ BuildMinHeap({})
 6: while True do
 7:     $\langle U_{EAI}(o), o\rangle \leftarrow h_{UB}$.extractMax()
 8:     if $h_{EAI}[|W|].size = k$ and $h_{EAI}[w].min > U_{EAI}(o)$ for all $w$ then
 9:         break
10:     for $w$ = 1 to $|W|$ do
11:         if $w$ already answered on $o$ or $h_{EAI}[w].min > U_{EAI}(o)$ then
12:             continue
13:         Compute $EAI(w, o)$
14:         $h_{EAI}[w]$.insert($\langle EAI(w, o), o\rangle$)
15:         if $h_{EAI}[w].size \le k$ then
16:             break
17:         $o \leftarrow h_{EAI}[w]$.extractMin().value()
```

By substituting Eq. (21) for $\mu_{o,v|v_o^w=v'}$ in Eq. (20), we derive

$$E[\max_v \mu_{o,v|w}] \le \max_{v,v'} \mu_{o,v|v_o^w=v'} \le \frac{\max_v N_{o,v} + 1}{D_o + 1}. \tag{22}$$

In addition, by applying Eq. (22) to Eq. (14), we get

$$EAI(w, o) \le (\tfrac{\max_v N_{o,v}+1}{D_o+1} - \max_v \mu_{o,v})/|O|.$$

Since $\mu_{o,v} = \frac{N_{o,v}}{D_o}$, we finally obtain the upper bound of $EAI(w, o)$.

$$\begin{aligned} EAI(w, o) &\le (\tfrac{\max_v N_{o,v}+1}{D_o+1} - \tfrac{\max_v N_{o,v}}{D_o})/|O| \\ &= \frac{1 - \frac{\max_v N_{o,v}}{D_o}}{|O|\cdot(D_o+1)} = \frac{1 - \max_v \mu_{o,v}}{|O|\cdot(D_o+1)} = U_{EAI}(o). \end{aligned}$$

□

We devise an algorithm to assign the best k objects to each available worker in crowdsourcing systems. Since a single answer is sufficient to find the correct value for some objects, we assign an object to only a single worker in each round. If the answer is not sufficient to find the correct value of the object, we assign the object to another worker in the next round.

Our task assignment algorithm sequentially assigns each object to a worker by scanning the objects o with non-increasing order of the upper bound $U_{EAI}(o)$. To allocate an object to a worker, since $\psi_{w,1}$ is the probability of answering the truth, we consider the workers w with non-increasing order of $\psi_{w,1}$. After assigning an object to a worker w, if the number of assigned objects to the worker w exceeds k, we remove the object o with the minimum $EAI(w, o)$ and assign the deleted object to the next worker and perform the same step. While scanning the objects, we stop the assignment if the upperbound $U_{EAI}(o)$ is smaller than the minimum $EAI(w, o')$ among the $EAI(w, o')$s of all assigned objects and each worker has k assigned objects. The reason is that the $EAI(w, o)$ of the remaining objects o can be larger than that of any assigned object.

The pseudocode: It is shown in Algorithm 1. We first compute the upper bound $U_{EAI}(o)$ for every object $o \in O$ by Lemma 4.1 and build a maxheap h_{UB} of all objects by using $U_{EAI}(o)$ as the key to assign the objects to workers in the decreasing order of $U_{EAI}(o)$ (in lines 1-2). The workers are sorted in the decreasing order of $\psi_{w,1}$ to give a higher priority to reliable workers (in line 3). We next initialize a minheap $h_{EAI}[w]$ for each worker w to contain the k assigned objects (in lines 4-6). Then, we repeatedly extract an object from h_{UB} and assign the object to a worker in the sorted order of $\psi_{w,1}$ (in lines 12-18). Before assigning an object o, if the heaps $h_{EAI}[w]$s of all workers are full and the minimum value of $EAI(w, o')$ of the objects o' in all $h_{EAI}[w]$s is larger than the upper bound $U_{EAI}(o)$, we stop immediately.

5 EXPERIMENTS

The experiments are conducted on a computer with Intel i5-7500 CPU and 16GB of main memory.

Datasets: We collected the two real-life datasets publicly available at http://kdd.snu.ac.kr/home/datasets/tdh.php.

BirthPlaces: We crawled 13,510 records about the birthplaces of 6,005 celebrities from 7 websites (sources). For the gold standard data to evaluate the correctness of discovered birthplaces, we used IMDb biography which is available at *http://www.imdb.com.* Moreover, the geographical hierarchy was created by using the IMDb data. For example, if there is a person who was born in 'LA, California, USA', we assigned 'LA' as a child of 'California' and 'California' as a child of 'USA'. The hierarchy contains 4,999 nodes (e.g., countries, cities and etc.) and its height is 5.

Heritages: This is a dataset of the locations of World Heritage Sites provided by UNESCO World Heritage Centre, available at *http://whc.unesco.org*. We queried about the locations of 785 World Heritage Sites with Bing Search API and obtained 4,424 claimed values from 1,577 distinct websites. The hierarchy was created in the same way as we did for *BirthPlaces* and it has 1,027 nodes. The height of this hierarchy tree is 6.

Quality Measures: We use *Accuracy*, *GenAccuracy* and *AvgDistance* to evaluate the truth discovery algorithms. Let t_o be the truth of the object o in the gold standard and v_o^* be the estimated truth by an algorithm. Note that t_o may not exist in the set of candidate values. In this case, the most specific candidate value among the ancestors of the truth is assumed to be t_o. *Accuracy* is the proportion of objects that the algorithm discovers the truth exactly. It is actually used in [10, 39–41] to evaluate truth discovery algorithms.

$$(Accuracy) = \Sigma_{o \in O} I(v_o^* = t_o)/|O|$$

The ancestors of t_o are less informative but still correct values. Thus, we develop an evaluation measure named *GenAccuracy* which is the proportion of objects o whose estimated truth v_o^* is either the truth t_o or an ancestor of the truth.

$$(GenAccuracy) = \Sigma_{o \in O} I(v_o^* \in G_H(t_o) \cup \{t_o\})/|O|$$

Ancestors of the truth have a different level of informativeness depending on the distance to the truth. For example, 'New York' is more informative than 'USA' as the location of the Statue of Liberty. Thus, we utilize another evaluation measure named *AvgDistance* which weights the estimated truth based on the distance from the ground truth. More specifically, it is the average number of edges $d(v_o^*, t_o)$ between the truth t_o and the estimated truth v_o^* in the hierarchy H.

$$(AvgDistance) = \Sigma_{o \in O} d(v_o^*, t_o)/|O|$$

AvgDistance is robust to the case where the ground truth is less specific than the estimated truth. The estimated truth is regarded as a wrong value when we compute *Accuracy* and *GenAccuracy* even though the estimate truth is correct and more specific. Since the distance between the less specific ground truth and the estimated truth is generally small, *AvgDistance* compensates the drawback of *Accuracy* and *GenAccuracy*.

Settings for simulated crowdsourcing: To evaluate the truth discovery algorithms with varying the quality of the answers from workers, we conducted experiments with simulated crowd workers. In our simulation, we assumed that each simulated worker answers a question correctly with its own probability p_w and randomly selects an answer from the candidate values with probability $1-p_w$. We sampled the probability p_w from a uniform distribution ranging from $\pi_p-0.05$ to $\pi_p+0.05$ where the default value of π_p is 0.75. In the experiments, each of 10 worker answers 5 questions for each round.

5.1 Implemented Algorithms

We implemented 10 truth inference algorithms and 4 task assignment algorithms in Python for comparative experiments. The truth inference algorithms are referred to as follows:

- TDH: This is our algorithm proposed in Section 3. For the prior distribution $Dir(\alpha)$, we set the hyperparameter $\alpha = (3, 3, 2)$ since correct values are more frequent than wrong values for most of the sources. For the other hyperparameters β and γ, we set every dimension of β and γ to 2.
- ACCU: It is the algorithm proposed in [7] which considers the dependencies between sources to find the truths. The algorithm exploits Bayesian analysis to find the dependencies.
- POPACCU: This denotes the algorithm in [9] which extends ACCU. It computes the distribution of the false values from the records while ACCU assumes that it is uniform.
- LFC: This algorithm is proposed in [31] and utilizes a confusion matrix to model a source's quality.
- CRH: It is proposed in [22] to resolve conflicts in heterogeneous data containing categorical and numerical attributes.
- LCA: It is a probabilistic model proposed in [30]. We select GuessLCA to be compared in this paper which is one of the best performers among the 7 algorithms proposed in [30].
- ASUMS: This is proposed in [2] by adapting an existing method SUMS [29] to hierarchical truth discovery.
- MDC: This denotes the truth discovery method designed for medical diagnose from non-expert crowdsourcing in [24].
- DOCS: This is the state-of-the-art technique presented in [39] that suggests the domain-sensitive worker model.
- VOTE: This is a baseline that selects a value with the highest frequency in the claimed values.

We implemented the following task assignment algorithms.

- *EAI*: This is our proposed algorithm in Section 4.
- *MB*: It is the task assignment algorithm used by DOCS [39].
- *QASCA*: It is a task assignment algorithm proposed in [41].
- *ME*: This is our baseline algorithm which utilizes an uncertainty sampling. It selects an object o^* whose confidence distribution has the maximum entropy. (i.e., $o^* = argmax_{o \in O}$ $(-\sum_{v \in V_o} \mu_{o,v} \cdot \log \mu_{o,v}))$

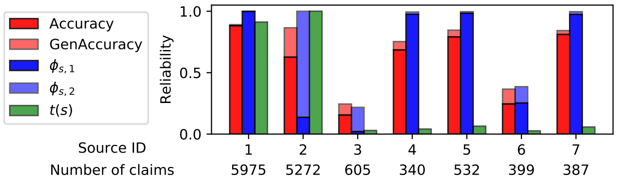

Figure 5: Source reliability distribution in *BirthPlaces*

Note that *EAI* and *MB* are the task assignment algorithms specially designed to work with *TDH* and *DOCS*, respectively. *QASCA* can work with truth inference algorithms based on probabilistic models such as *TDH*, *DOCS*, *LCA*, *ACCU* and *POPACCU*. All the truth inference algorithms can be combined with *ME*.

5.2 Truth Inference

We first provide the performances of the truth inference algorithms without using crowdsourcing in Table. 3.

***BirthPlaces*:** Our TDH outperforms all other algorithms in terms of all quality measures since TDH finds the exact truths by utilizing the hierarchical relationships. Since TDH estimates the reliabilities of the sources and workers by considering the hierarchies, it does not underestimate the reliabilities of the sources and workers. Thus, TDH also finds more correct values including the generalized truths. We will discuss the reliability estimation in detail at the end of this section by comparing TDH with ASUMS. LCA is the second-best performer and VOTE shows the lowest *Accuracy* among all compared algorithms. However, in terms of *GenAccuracy*, VOTE performs the second-best. It is because many websites claim the generalized values rather than the most specific value.

***Heritages*:** In terms of *AvgDistance* and *Accuracy*, TDH performs the best among those of the compared algorithms. VOTE shows the highest *GenAccuracy* because many sources provide the generalized truths. In fact, a high *GenAccuracy* with low *Accuracy* and *AvgDistance* can be easily obtained by providing the most general values for the truths. However, such values usually are not informative. Since our algorithm shows much higher *Accuracy* and much lower *AvgDistance* than VOTE, we can see that the estimated truth by TDH is more accurate and precise than the result from VOTE. *Heritages* contains many sources and most of the sources have a few claims. Thus, it is very hard to estimate the reliability of each source accurately. Therefore, most of the compared algorithms show worse performance than VOTE in terms of *AvgDistance*. In particular, ACCU has the lowest *Accuracy*. The reason is that ACCU requires many shared objects between two sources in order to accurately determine the dependency between the sources. The average accuracy of the sources in *Heritages* is 58.0% while that of the sources in *BirthPlaces* is 72.1%. Thus, every algorithm shows a lower *Accuracy* in this dataset than in *BirthPlaces*.

Comparison with ASUMS: Since ASUMS [2] is the only existing algorithm which utilizes hierarchies for truth inference, we show the statistics related to the reliability distributions estimated by TDH and ASUMS for *BirthPlaces* dataset in Figure 5. *Accuracy* and *GenAccuracy* represent the actual reliabilities of each source computed from the ground truths. Recall that $\phi_{s,1}$ and $\phi_{s,2}$ are the estimated probabilities of providing a correct value and a generalized correct value respectively for a source s by our TDH, as defined in Section 3. In addition, $t(s)$ is the estimated reliability of a source s by ASUMS which ignores the generalization level of each source. The reliabilities of the sources 4, 5 and 7 computed by ASUMS (i.e. $t(s)$) are quite different from the actual reliabilities (i.e., *Accuracy*). As we discussed in Section 1, for a pair of sources that provide different claimed values with an ancestor-descendant relationship in a hierarchy, existing methods may assume that one of the claimed values is incorrect. Thus, the reliability of the source with the assumed wrong value tends to become lower by the existing methods. ASUMS suffers from the same problem and underestimates the reliabilities of the sources 4, 5 and 7 which provide a small number of claimed values. Meanwhile, our proposed algorithm TDH accurately estimates the reliabilities of the sources by introducing another class of the claimed values (generalized truth).

Figure 6: Evaluation of task assignment algorithms

5.3 Task Assignment

Before providing the full comparison of all possible combinations of truth inference algorithms and task assignment algorithms, we first evaluate the task assignment algorithms with our proposed truth inference algorithm. We plotted the average *Accuracy* of the truth discovery algorithms with different task assignment algorithms for every 5 round in Figure 6. The points at the 0-th round represent the *Accuracy* of the algorithms without crowdsourcing. All algorithms show the same *Accuracy* at the beginning since they use the same truth inference algorithm TDH. As the round progresses, the *Accuracy* of TDH+EAI increases faster than those of all other algorithms. The *Accuracy* of TDH+ME is the lowest since ME selects a task based only on the uncertainty without estimating the accuracy improvement by the task.

As discussed in Section 4.1, our task assignment algorithm EAI estimates the accuracy improvement by considering the number of existing claimed values and the confidence distribution whereas QASCA considers the confidence distribution only. We plotted the actual and estimated accuracy improvements by EAI and QASCA in Figure 7. The graphs show that the estimated accuracy improvement by EAI is similar to the actual accuracy improvement while QASCA overestimates the accuracy improvement at every round. On average, the absolute estimation errors

Figure 10: *AvgDistance* with crowdsourced truth discovery

from EAI are 0.08 and 0.26 percentage points (pps) while those errors from QASCA are 0.28 and 2.66 pps in *BirthPlaces* and *Heritages* datasets, respectively. This result confirms that EAI outperforms QASCA by effectively estimating the accuracy improvement. In terms of the other quality measures *GenAccuracy* and *AvgDistance*, our proposed EAI also outperforms the other task assignment algorithms in both datasets. Due to the lack of space, we omit the results with the other quality measures.

5.4 Simulated Crowdsourcing

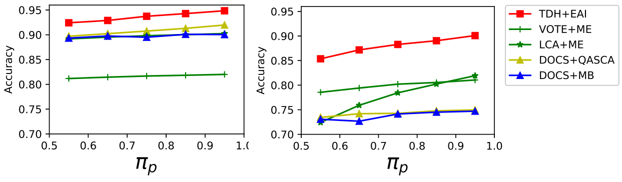
We evaluate the performance of crowdsourced truth discovery algorithms with the simulated crowdsourcing.

For all possible combinations of the implemented truth inference and task assignment algorithms, we show the *Accuracy* after 50 rounds of crowdsourcing in Table 4 where the impossible combinations are denoted by '-'. As expected, TDH+EAI has the highest *Accuracy* in both datasets for all possible combinations. The result also shows that both TDH and EAI contribute to increasing *Accuracy*. The improvement obtained by EAI can be estimated by comparing the result of TDH+EAI to that of the second performer TDH+QASCA. The accuracies of TDH+EAI in *BirthPlaces* and *Heritages* datasets are 1 and 3 percentage points (pps) higher than those of TDH+QASCA, respectively. In addition, for each combined task assignment algorithm, the improvement by TDH can be inferred by comparing the results with those of other truth inference algorithms. In both datasets, TDH shows the highest *Accuracy* among the applicable truth inference algorithms for each task assignment algorithm. For example, TDH+QASCA shows 2.6 and 13 pps higher *Accuracy* in *BirthPlaces* and *Heritages* datasets, respectively, than the second performer DOCS+QASCA among the combinations with QASCA. In the rest of the paper, we report *Accuracy*, *GenAccuracy* and *AvgDistance* of TDH+EAI, DOCS+MB, DOCS+QASCA, LCA+ME and VOTE+ME only since these combinations are the best or the second-best for each task assignment algorithm.

Cost efficiency: We plotted the average *Accuracy* of the tested algorithms for every 5 rounds in Figure 8. TDH+EAI shows the highest *Accuracy* for every round in both datasets. For the *BirthPlaces* dataset, DOCS+QASCA was the next best performer which achieved 0.9341 of *Accuracy* at the 50-th round. Meanwhile, TDH+EAI only needs 17 rounds of crowdsourcing to achieve the same *Accuracy*. Thus, TDH+EAI saved 66% of crowdsourcing cost compared to the second-best performer DOCS+ QASCA. Likewise, TDH+EAI reduced the crowdsourcing cost 74% in *Heritages* dataset compared to the next performer. In terms of *GenAccuracy* and *AvgDistance*, TDH+EAI also outperforms all the other algorithms as plotted in Figure 9 and Figure 10. The results confirm that TDH+EAI is the most efficient as it achieves the best qualities in terms of both *Accuracy* and *GenAccuracy*.

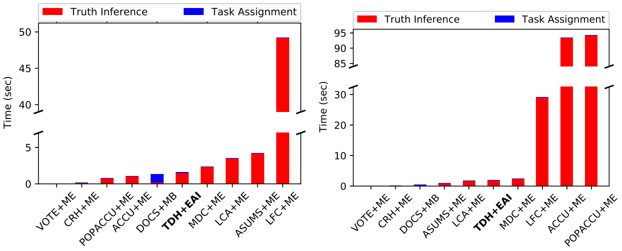
Varying π_p: We plotted the average *Accuracy* of all algorithms with varying the probability of correct answer π_p of simulated workers for *BirthPlaces* and *Heritages* datasets in Figure 11(a) and Figure 11(b), respectively. As we can easily expect, the accuracies increase with growing π_p for most of the algorithms. For both datasets, TDH+EAI achieves the best accuracy with all values of π_p. In Heritages dataset, a source provided less than 10 claims on average and it makes difficult for truth discovery algorithms to estimate the reliabilities of sources. Therefore, the baseline VOTE+ME shows good performance on Heritages dataset. Meanwhile, the performance of the state-of-the-art DOCS is significantly degraded on the Heritages dataset.

Execution times: We plotted the average execution times of the tested algorithms over every round in Figure 12. VOTE, CRH+ME, DOCS+MB and TDH+EAI run in less than 2.0 seconds per round on average for both datasets. Other algorithms except for ACCU+ME, POPACCU+ME and LFC+ME also take less than 5 seconds, which is acceptable for crowdsourcing. Since LFC builds the confusion matrix whose size is the square of the number of candidate values, LFC is the slowest with *BirthPlaces* data. On the other hand, for *Heritages* dataset which is collected



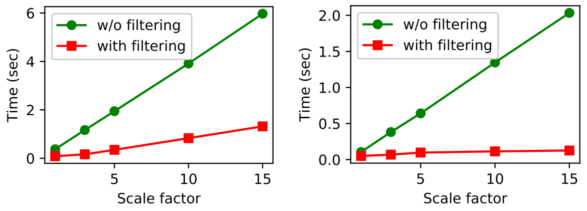
(a) *BirthPlaces* (b) *Heritages*

Figure 11: Varying π_p



(a) *BirthPlaces* (b) *Heritages*

Figure 12: Execution time per round



(a) *BirthPlaces* (b) *Heritages*

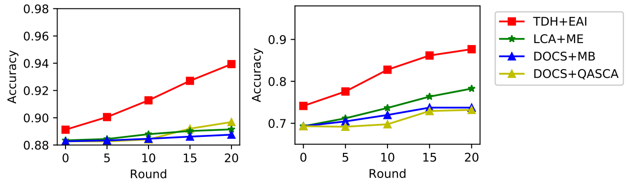
Figure 13: Execution time for task assignment per round

from much more sources than *BirthPlaces* dataset, ACCU and POPACCU take longer time for truth inference to calculate the dependencies between sources.

Effects of the filtering for task assignments: To test the scalability of our algorithm, we increase the size of both datasets by duplicating the data by upto 15 times. In Figure 13, with increasing data size, we plotted the execution times of our task assignment algorithm EAI with and without exploiting the upper bound proposed in Section 4.3. The filtering technique saved 78% and 94% of the computation time for the task assignment at the scale factor 15. The graphs show that the proposed upper bound enables us to scale for large data effectively. For the total execution time, including the truth inference, the filtering reduced 21% and 6% of the execution time on *BirthPlaces* and *Heritages* respectively at the scale factor 15.

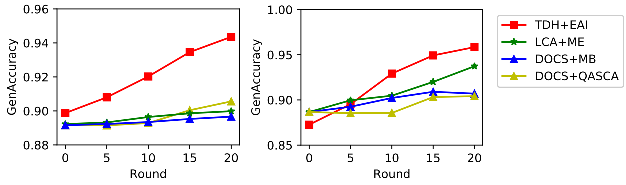
5.5 Crowdsourcing with Human Annotators

We evaluated the performance of the truth discovery algorithm by crowdsourcing real human annotations. For this experiment, we selected DOCS+QASCA, DOCS+MB and LCA+ME for comparison with the proposed algorithm TDH+EAI. This is because they are the best existing algorithms for each task assignment algorithm. We conducted this experiment with 10 human annotators for 20 rounds on our own crowdsourcing system. For each worker, we assigned 5 tasks in each round. Figure 14,15 and 16 show the performances of the algorithms against the rounds.



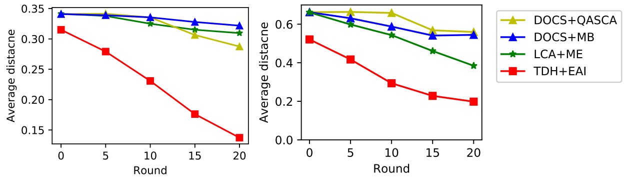
(a) *BirthPlaces* (b) *Heritages*

Figure 14: *Accuracy* with human annotations



(a) *BirthPlaces* (b) *Heritages*

Figure 15: *GenAccuracy* with human annotations



(a) *BirthPlaces* (b) *Heritages*

Figure 16: *AvgDistance* with human annotations

For both of the datasets, the results confirm that the proposed TDH+EAI algorithm outperforms the compared algorithms as in the previous simulations. Without crowdsourcing, the other algorithms show a higher *GenAccuracy* than TDH for *Heritages* dataset, because these algorithms tend to estimate the truths with more generalized form than TDH does. However, TDH+EAI shows the highest *GenAccuracy* after the 3rd round because it correctly estimates the reliabilities and the generalization levels of the sources by using the hierarchy. For *BirthPlaces* dataset, *Accuracies* of the algorithms increase a little bit faster than those in the experiment with simulated crowdsourcing. However, for *Heritages* dataset, *Accuracies* of the algorithms increase much slower than in the experiment with simulated crowdsourcing. It seems that finding the locations of a world heritages is a quite harder task than finding the birthplaces of celebrities because the birthplaces are often big cities (such as LA), which are familiar to workers, but World Cultural Heritages and World Natural Heritages are often located in unfamiliar regions.

5.6 Crowdsourcing with AMT

We evaluate the performances of TDH+EAI, DOCS+QASCA, DOCS+MB and LCA+ME based on the answers collected from Amazon Mechanical Turk (AMT). We collected answers for all objects in *Heritages* dataset from 20 workers in AMT. We made the collected answers available at http://kdd.snu.ac.kr/home/datasets/tdh.php. To evaluate the algorithms based on the collected answers, we assign 5 tasks for each worker in a round. We plotted the performance of the algorithms in Figure 17. Since we use more workers than we did in Section 5.5, the performances

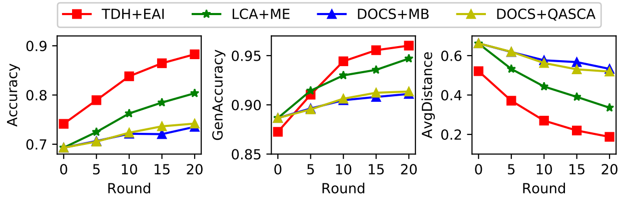


Figure 17: Crowdsourced truth discovery in *Heritages*

improve a little bit faster, but the trends are very similar to those with 10 human annotators in the previous section. We observe that our TDH+EAI outperforms all compared algorithms even with a commercial crowdsourcing platform.

5.7 Multi-truths Discovery Algorithms

Since there are multiple correct values including generalized values, we also implement multi-truth discovery algorithms such as DART[27], LFC[31] and LTM[38] to compare with our TDH algorithm. Since the multi-truths discovery algorithms independently generate the correct values, they may output the true values where there exist a pair of true values without ancestor-descendant relationship in the hierarchy. For example, from the given claimed values in Table 1, the multi-truth algorithms can answer that the 'Statue of Liberty' is located in LA and Liberty island. In this case, we cannot evaluate the result by our evaluation measures *Accuracy*, *GenAccuracy* and *AvgDistance*. Thus, to evaluate the performance of the tested algorithms, we utilize precision, recall and F1-score which are the evaluation measures typically used for multi-truths discovery. To use the multi-truths algorithms and the evaluation measures, we treat the ancestors of v and v itself as the multi-truths of v. LFC can work as either a single truth algorithm or a multi-truths algorithm. We refer to the multi-truth version of LFC as LFC-MT to avoid the confusion.

Table 5: Performance of truth discovery algorithms

		Dataset					
		BirthPlaces			*Heritages*		
Algorithm		Precision	Recall	F1	Precision	Recall	F1
Single truth	TDH	**0.899**	**0.921**	**0.910**	0.873	0.795	**0.832**
	VOTE	0.892	0.804	0.846	**0.899**	0.717	0.798
	LCA	0.892	0.913	0.903	0.878	0.711	0.786
	DOCS	0.892	0.913	0.902	0.887	0.722	0.796
	ASUMS	0.857	0.888	0.872	0.741	0.660	0.698
	POPACCU	0.847	0.858	0.852	0.859	0.694	0.768
	LFC	0.874	0.838	0.856	0.808	0.727	0.765
	MDC	0.844	0.853	0.848	0.807	0.792	0.800
	ACCU	0.830	0.842	0.836	0.766	0.631	0.692
	CRH	0.827	0.833	0.830	0.883	0.716	0.791
Multi -truths	LFC-MT	0.763	0.723	0.742	0.898	0.684	0.777
	DART	0.590	0.855	0.698	0.357	**0.994**	0.525
	LTM	0.780	0.472	0.588	0.871	0.672	0.759

Table 6: Performance evaluation for numerical data

	Change rate		Open price		EPS	
Algorithm	MAE	R/E	MAE	R/E	MAE	R/E
TDH	**0.0006**	**0.1011**	**0.0195**	**0.0354**	**0.0352**	**1.9513**
LCA	**0.0006**	**0.1011**	**0.0195**	**0.0354**	0.3831	16.2212
CRH	0.0020	1.6339	**0.0195**	**0.0354**	0.0610	1.9882
CATD	0.0104	2.3529	0.0211	0.0395	0.0803	3.2059
VOTE	**0.0006**	**0.1011**	**0.0195**	**0.0354**	0.0765	2.8402
MEAN	0.2837	30.8747	0.4047	0.5782	0.1762	7.3937

Table 5 shows the performance of the truth discovery algorithms in terms of precision, recall and F1-score. For both datasets, the TDH algorithm is the best in terms of F1-score. Recall that the VOTE algorithm tends to find a generalized value of the exact truth. Since a generalized truth generates a small number of multi-truths, the VOTE algorithm shows the highest precision in *Heritages* dataset. However, since its recall is much lower than that of our TDH algorithm, the F1-score of the VOTE algorithm is lower than that of the TDH algorithm. Similarly, although the DART algorithm has the highest recall in *Heritages* dataset, the precision of the DART algorithm is the smallest among the precisions of all compared algorithms.

5.8 Performance on a Numerical Dataset

To evaluate the extension to numerical data, we conducted an experiment on the stock datatset [23] which is trading data of 1000 stock symbols from 55 sources on every work day in July 2011. The detailed description of the data can be found in [23]. As we discussed at the end of Section 3.2, we can utilize our TDH algorithm for numeric dataset with implied hierarchy. We select three attributes 'change rate', 'open price' and 'EPS' of the dataset, and compared our TDH algorithm with the LCA, CRH, CATD[21], VOTE and MEAN algorithms. Among the second best performers DOCS and LCA in Table 4, we use only LCA for this experiment since DOCS requires the domain information while it is not available for this dataset. In addition to LCA, we implemented and tested the two algorithms CRH[22] and CATD[21] which are designed to find the truth in numerical data. Recall that VOTE is a baseline algorithm which selects the candidate value collected from majority sources. We also implemented a baseline algorithm, called MEAN, which estimates the correct value as the average of the claimed numeric values.

Table 6 shows the mean squared error (MAE) and the relative error (R/E) of the tested algorithms. The TDH algorithm performs the best for every attribute. The MEAN and CATD algorithms show worse performance than the other algorithms. Since they utilize an average or a weighted average of the claimed values, they are sensitive to outliers. The result confirms that our TDH algorithm is effective even for numerical data.

6 RELATED WORK

The problem of resolving conflicts from multiple sources (i.e., truth discovery) has been extensively studied [4, 5, 5, 7, 9, 16, 22, 24, 26, 27, 31, 33, 35–39, 42]. Truth discovery for categorical data has been addressed in [5, 7, 9, 22, 24, 31, 36, 39]. According to a recent survey [40], LFC[31] and CRH[22] perform the best in an extensive experiment with the truth discovery algorithms [4, 5, 16, 21, 35, 40, 42]. There exist other interesting algorithms [7, 9, 24, 39] which are not evaluated together in [40]. Accu[7] and PopAccu[9] combine the conflicting values extracted from different sources for the knowledge fusion [8]. They consider the dependencies between data sources to penalize the copiers' claims. DOCS[39] utilizes the domain information to consider the different levels of worker expertises on various domains. MDC[24] is a truth discovery algorithm devised for crowdsourcing-based medical diagnosis. The works in [26, 33, 37] studied how to resolve conflicts in numerical data from multiple sources.

The truth discovery algorithms in [30, 37–39] are based on probabilistic models. Resolving the conflicts in numerical data is addressed in [37] and discovering multiple truths for an object is studied in [38]. Probabilistic models for finding a single truth for each object is proposed in [30, 39]. However, none of those algorithms exploit the hierarchical relationships of claimed values for truth discovery. The work in [2] adopts an existing algorithm to consider hierarchical relationships.

Task assignment algorithms[3, 11, 14, 28, 39, 41] in crowdsourcing have been studied widely in recent years. The works in [3, 39, 41] can be applied to our crowdsourced truth discovery. For task assignment, AskIt[3] selects the most uncertain object for a worker. Meanwhile, the task assignment algorithm in [39] selects the object which is expected to decrease the entropy of the confidence the most. QASCA [41] chooses an object which is likely to most increase the accuracy. Since QASCA outperforms AskIt in the experiments presented in [39, 41], we do not consider AskIt in our experiments. In [14], task assignment for binary classification was investigated but it is not applicable to our problem to find the correct value among multiple conflicting values. Meanwhile, the task assignment algorithm is proposed in [28] for the case when the required skills for each task and the skill set of every worker is available. However, it is not applicable to our problem. A task assignment algorithm proposed in [11] assigns every object to a fixed number of workers. However, since we already have claimed values from sources, we do not have to assign all objects to workers.

7 CONCLUSION

In this paper, we first proposed a probabilistic model for truth inference to utilize the hierarchical structures in claimed values and an inference algorithm for the model. Furthermore, we proposed an efficient algorithm to assign the tasks in crowdsourcing platforms. The performance study with real-life datasets confirms the effectiveness of the proposed algorithms.

ABSTRACT

Location-based apps provide users with personalized services tailored to their geographical position. This is highly-beneficial for mobile users, who are able to find points of interest close to their location, or connect with nearby friends. However, sharing location data with service providers also introduces privacy concerns. An adversary with access to fine-grained user locations can infer private details about individuals. *Geo-indistinguishability (GeoInd)* adapts the popular *differential privacy (DP)* model to make it suitable for protecting users' location information. However, existing techniques that implement GeoInd have major drawbacks. Some solutions, such as the planar Laplace mechanism, significantly lower data utility by adding excessive noise. Other approaches, such as the optimal mechanism, achieve good utility, but only work for small sets of candidate locations due to the use of computationally-expensive linear programming. In most cases, locations are used to answer online queries, so a quick response time is essential. In this paper, we propose a technique that achieves GeoInd and scales to large datasets while preserving data utility. Our central idea is to use the composability property of GeoInd to create a multiple-step algorithm that can be used in conjunction with a spatial index. We preserve utility by applying accurate GeoInd mechanisms and we achieve scalability by pruning the solution search space with the help of the index when seeking high-utility outcomes. Our extensive performance evaluation on top of real location datasets from social media apps shows that the proposed technique outperforms significantly the benchmark in terms of utility and/or computational overhead.

1 INTRODUCTION

The unprecedented growth in the area of mobile apps allows users to enjoy personalized services and receive information customized to their locations. In return for sharing their locations with the service provider, users can find restaurants and shopping malls nearby, can plan their travel itinerary with ease, or can connect with nearby friends. While the benefits of personalized location services are clear, there are also increasing risks associated with the sharing of fine-grained individual locations. A significant body of research [15–17, 21] shows that uncontrolled sharing of users' whereabouts can lead to a wide range of attacks, from stalking and assault, to various privacy breaches that may disclose sensitive personal details such as one's health status, political or religious orientation, etc.

The need for protecting users' locations has been the subject of intense study by the research community for more than a decade. Initial approaches considered cloaking of user locations to decrease the precision of coordinate reporting. However, it has been shown [15, 17] that this category of solutions does not provide sufficient protection, especially when dealing with sophisticated adversaries with access to background knowledge. Another category of techniques uses encryption [15]. While the privacy strength achieved with encryption is high, there are two drawbacks: first, only simple queries (e.g., nearest-neighbors) can be answered; second, the computational overhead of processing encrypted queries is high and requires extensive server-side changes.

The prominent model of *differential privacy (DP)* [13] has become the de-facto standard for data protection in the last few years. While there is work that shows how location can be protected with DP, these solutions (and in fact, the model itself) assume an aggregate release, where data are pooled together from a population of users over a period of time, and then aggregates are disclosed covering various regions of the dataspace. The objective of this publication model is to hide the presence of an individual in a released dataset, but cannot be used in operational mode (i.e., to protect the location attributes of a specific user asking a query). The more recent model of *Geo-indistinguishability (GeoInd)* [1, 2, 5] extends DP with a new distinguishability metric [6] which captures precisely the operational setting, and prevents the association of a user with an exact location. Specifically, GeoInd adds random noise to the actual user location in a way that prevents an adversary from inferring with high probability the user's whereabouts, *regardless* of the amount of background knowledge available to the attacker. Its powerful semantic protection guarantees derived from DP make GeoInd the only viable approach available at the present time for protecting locations in the operational setting[1].

Despite GeoInd being a promising model, existing techniques that implement it have some important drawbacks. We provide a simplified argument, without going into technical details, as the formal aspects of GeoInd will only be introduced in Section 2. In essence, GeoInd achieves protection by adding noise, but noise also decreases data utility. In addition, the protection achieved is independent of the adversary's background knowledge, further referred to as *prior*. However, an interesting result in [2] shows that, if one is aware of the adversary's prior, then it is possible to construct a GeoInd mechanism that improves utility considerably, while still providing protection for *any* prior. This result is important, because in practice locations where a user is expected to be are not random. For instance, datasets derived from social media apps show that users *check in* (i.e., report their location) at a set of well-defined *points of interests (POI)*. This discrete set of POI, combined with some other background knowledge factors (e.g., popularity of various POI) effectively functions as the adversary's prior. One can construct mechanisms for enforcing GeoInd in two ways: at one extreme, completely ignore the prior, and simply generate a reported location by adding (planar) Laplace noise to the actual location [1]. This approach is very efficient computationally, but can yield poor utility by generating large

[1] Another model exists which functions in the operational setting [24], but it only works against a well-defined set of adversarial prior knowledge. Constructing such a detailed prior is often not feasible in practice.

noise. At the other extreme, one can take into account the prior and attempt to add the *optimal* amount of noise to any possible user location such that the expected distance between actual and reported locations is minimized (while still preserving GeoInd). The latter is called *optimal mechanism* [2] and is implemented using linear programming (LP).

Consider a regular grid on top of a set of locations of interest in a city area (grid partitioning is used for ease of presentation, the concept we convey remains valid for any set of discrete, or *logical* locations [12]). Each cell has a certain prior value, corresponding, for instance, to the weighted popularity of all POI in the respective cell. An optimal GeoInd protection mechanism will produce an output given by a linear program that considers all possible combinations of actual and reported cells, with specific constraints related to location protection. The computational complexity is cubic to the number of cells. Even for a relatively small search space, such as $12 \times 12 = 144$ cells, the execution time for LP solvers can be in the order of hours (we provide exact measurement results in Section 6). Such an approach is too slow.

Our proposed approach uses a multi-step algorithm that applies GeoInd recursively along a data indexing structure, according to the *composability* property of DP (see Section 2 for details). We illustrate this in Figure 1, on a three-level index. The actual location is the black dot. Level A consists of nine cells, and assume $A5$ is selected by the mechanism in the first step. In step two, we "zoom in" cell $A5$, and re-apply the mechanism on top of a four-cell grid this time. Finally, at the third level, $C3$ is chosen for release. The privacy budget is split across the three levels. Our approach can work with a relatively fine-grained grid at the leaf level; in this example, at the leaf level we obtain 144 cells, same as in the non-hierarchical case. However, in our case the size of the problem at each step consists of nine, four and four cells, respectively, so our approach will perform much faster. Also, since index node selection is performed at each step according to the output of the mechanism at the previous index level, GeoInd is preserved. Note that, the actual location may fall outside the selected cell at each level, but that is less likely to occur at the higher (i.e., coarser) index levels, so utility will not suffer significantly.

Although the underlying concept is simple, our approach raises a number of difficult challenges. Specifically, one must take carefully into account several factors that affect utility and performance, such as: how to determine the parameters of the index, such as height and fan-out; and how to decide how to split the privacy budget across distinct index levels. We provide an analytical model to synthesize important relationships between system parameters on one hand, and performance metrics such as utility and computational overhead on the other.

Our specific contributions include:

- We identify important drawbacks of existing techniques for geo-indistinguishability in terms of utility and/or computational overhead.
- We propose a multi-step algorithm that applies GeoInd mechanisms in conjunction with an index data structure in order to prune the search space when seeking optimal solutions.
- We develop an analytical cost model to characterize the utility-performance trade-off, and to select an appropriate set of parameter values for our approach.
- We perform an extensive experimental evaluation to measure utility and execution time on real datasets, and we show that the proposed approach significantly outperforms the benchmark.

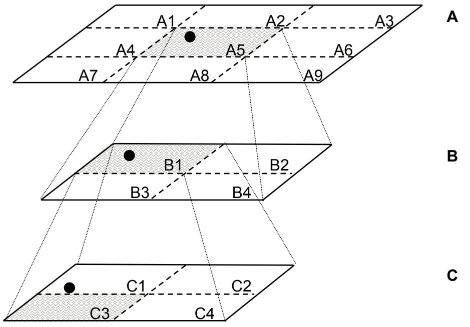

Figure 1: Multi-Step Approach Overview

The rest of the paper is organized as follows: Section 2 provides essential background information, followed by an overview of our approach in Section 3. We provide the details of our algorithm in Section 4. We derive an analytical model for performance characterization in Section 5 and we present a detailed experimental evaluation in Section 6. We survey related work in Section 7 and conclude with directions for future research in Section 8.

2 PRELIMINARIES

We introduce fundamental concepts used in the rest of the paper, such as the privacy model we adopt, and the mechanisms that implement it. We also discuss utility metrics, as well as the important property of *composability* on which our proposed multi-step algorithm for location protection relies.

2.1 GeoInd Definition

Geo-indistinguishability (GeoInd) was first introduced in [1], and extends the popular protection model of differential privacy (DP) [13]. DP is designed to prevent an adversary from learning with significant probability whether an individuals' data is present or not in a dataset. DP is achieved by adding random noise to the result of aggregate queries (e.g., count or sum). The fundamental concept behind DP is to bound the probability of distinguishing between the results of computations performed on *neighboring* datasets, defined as sets of records that differ in at most one entry. More formally, when the Hamming distance between two candidate datasets D_1 and D_2 is 1, then an adversary cannot determine with significant probability whether D_1 or D_2 was used to produce a certain result. The corresponding probabilities P_1 and P_2 are similar within a small multiplicating factor e^{ε}, where ε is called *privacy budget* (lower ε values correspond to tighter privacy settings).

However, DP is not suitable to protect the locations of mobile users in the *online* setting, for two reasons: first, DP works only for aggregate queries, and cannot be directly used for sanitizing individual records; second, DP can hide the presence of an individual record in a dataset, but it cannot protect the attribute values of individual data records, due to the *distinguishability metric* used (Hamming distance). The work in [4] extends DP by proposing a more flexible distinguishability metrics, resulting to the GeoInd definition.

Consider a set $\mathcal{X}$ of possible user locations, a set $\mathcal{Z}$ of possible reported locations (the two sets $\mathcal{X}$ and $\mathcal{Z}$ may coincide), and a distance metric $d_{\mathcal{X}}$. A probabilistic mechanism $K : \mathcal{X} \to \mathcal{P}(\mathcal{Z})$

takes as input a location in $\mathcal{X}$, and obfuscates it to produce some location $\mathcal{Z}$, which is reported to a location-based service (since K is a probabilistic function, its co-domain is the power-set of $\mathcal{Z}$, as it assigns each output location a probability of being reported). Mechanism K is said to achieve geo-indistinguishability with privacy level ε if for all $x, x' \in \mathcal{X}, z \in \mathcal{Z}$:

$$K(x)(z) \leq e^{\varepsilon d_{\mathcal{X}}(x,x')} \cdot K(x')(z) \tag{1}$$

Intuitively, Eq. (1) specifies that, given a reported value z, an adversary cannot distinguish whether the user location is x or x' by a factor larger than $e^{\varepsilon d_{\mathcal{X}}(x,x')}$. In practice, one appropriate choice for the $d_{\mathcal{X}}$ metric is the Euclidean distance, denoted in the rest of the paper as $d(\cdot, \cdot)$. Effectively, geo-indistinguishability enforces a constraint on the distributions $K(x)$, $K(x')$ produced by two different points x, x'. The authors in [5] also propose a practical interpretation of this definition: for all locations x' within a radius r from x, the user enjoys εr-indistinguishability. For small values of r, the adversary gains little information, i.e., s/he cannot pinpoint the user within a small region of a city (e.g., specific bar, restaurant, building). However, for large r values, the probability of locating the user within a circle of radius r increases, which preserves utility of location reporting. In other words, the mobile user is still able to retrieve information relevant to her current city or neighborhood, at a coarser granularity.

2.2 Utility and Composability

Utility. In order to enforce GeoInd, actual user locations must be perturbed through addition of random noise. Inherently, there is utility loss associated to this process: location-based services will return information relevant to the reported location, instead of the actual one. Ideally, a GeoInd mechanism should add the minimum amount of noise to achieve the GeoInd constraints, so utility is maximized and the deterioration in the quality of service received by the user is constrained. Inspired from previous work [1, 2, 5] we use the following practical measures of utility loss[2]:

- *Euclidean distance d:* this utility metric measures the Euclidean distance between the reported and actual user locations. It is a natural metric to describe the additional distance traveled by the user as a result of location obfuscation (assuming free-space movement). For instance, the nearest-neighbor Italian restaurant of the *reported* location could be several hundred meters away from the user location, even though there is another one situated only meters away from the user.
- *Squared Euclidean distance d^2:* the square of the Euclidean distance between reported and actual locations is also important, as it estimates the number of results that a user receives in a certain area. In practice, the user—knowing that the location will be obfuscated—may ask for more results. For instance, instead of asking for restaurants in a 200 meters radius, the user may increase the range to increase the chance that a nearby POI is actually returned. The size of the result set, and the effort required to filter the results, are estimated to increase linearly with the area of search, so the squared Euclidean distance may be a good predictor of utility loss.

Composability. An important property of GeoInd (inherited from its parent model DP) is *composability*. Specifically, if two mechanisms are applied in succession with budgets ε_1 and ε_2, the net amount of privacy obtained is equivalent to a privacy budget $(\varepsilon_1 + \varepsilon_2)$. Conversely, given a total privacy budget ε, we can split it into several terms and assign each term to a separate processing step, effectively obtaining a combined multiple-step algorithm that achieves the same amount of protection.

2.3 GeoInd Mechanisms

The GeoInd definition specifies the constraints that a protection technique must satisfy in order to obtain strong privacy guarantees. A GeoInd *mechanism* is a specific construction that achieves the GeoInd requirements. Next, we enumerate the most prominent mechanisms that implement GeoInd, introduced in [1, 5]. These mechanisms achieve various trade-offs in terms of performance and utility.

Planar Laplace Mechanism (PL). The simplest approach to preserving GeoInd is the Laplace mechanism [1]. The key idea is to perturb the exact user location by additive random noise drawn from a bi-variate Laplacian distribution with density defined as:

$$D_\varepsilon(x, z) = \frac{\varepsilon^2}{2\pi} e^{-\varepsilon d(x,z)} \tag{2}$$

Drawing an element from this distribution can be done by (i) switching to polar coordinates, (ii) selecting an angle θ uniformly from $[0, 2\pi)$, and (iii) selecting a radius r from the Gamma distribution $\Gamma_\varepsilon^{-1}(p)$, where $\Gamma_\varepsilon^{-1}(p) = 1 - (1 + \varepsilon p)^{(-\varepsilon p)}$, and p is uniformly chosen from (0,1). Finally, the reported location is $z = x + (r \cos\theta, r \sin\theta)$.

If only a restricted set of reported locations is allowed (e.g., discrete set $\mathcal{Z}$), the location produced by the mechanism can be mapped back to the closest element in the set. Although the Laplace mechanism provides an easy and practical way of achieving geo-indistinguishability, its utility may be low, as it introduces large noise.

Optimal Mechanism (OPT). While the PL mechanism is simple to implement and efficient to execute, it does not provide any optimality guarantees for utility. As a result, its resulting utility may be low in practice. To address this issue, the optimal mechanism of GeoInd (denoted further by *OPT*) has been introduced in [2]. We provide the details of OPT in Section 3.2. In a nutshell, OPT uses information about an adversary's prior knowledge, such as the likelihood of a user being present at a certain location. For instance, a user is more likely to be found in a city center area where there is a high concentration of POI, rather than in a secluded area near a suburb. OPT uses such prior information to produce a reported location z that minimizes utility loss. The disadvantage of OPT is that it has high computational overhead, as it requires solving a linear program with complexity cubic in the number of possible locations. In contrast, our multi-step algorithm allows us to reduce overhead by applying OPT recursively on an index structure.

A remarkable property of GeoInd related to the OPT mechanism is the following: even if the mechanism is tuned for a specific prior, it still preserves the privacy constraint for *any* prior. If the prior is not known by a GeoInd mechanism, then the utility cannot be improved significantly compared to PL. If the prior is known, then it can boost utility. Furthermore, GeoInd is satisfied even if the assumed prior and the adversary's background knowledge are different. In contrast, privacy models such as the one in [24] can

[2] We emphasize that a utility loss metric is a *different* concept than a distinguishability metric. Although the Euclidean distance can serve as both, the purpose of the two types of metrics is different: distinguishability metrics characterize the ability of an adversary to attack location privacy, whereas utility loss metrics measure the decrease in quality experienced by the user.

Table 1: Summary of Notations

Notation	Definition
x	*Actual* user location
z	*Reported* user location
$\mathcal{X}, \mathcal{Z}$	Set of actual and reported user locations
$\mathbb{G}, \mathbb{G}_i$	Set of grid cells (global, and at index level i)
$\hat{x}$	*Actual* location cell of user
$\hat{z}$	*Reported* location cell of user
g	Grid granularity
L	Side length of the square spatial region
h	Height of hierarchical grid index
ϵ_i	Privacy budget for grid level i
$\mathcal{B}$	Array storing budget at each index level
$d(x, z)$	Euclidean distance between locations x and z

only provide protection if the assumed prior and the adversary's knowledge coincide.

3 APPROACH OVERVIEW

In Section 3.1 we provide an overview of our system model; in Section 3.2 we introduce a baseline approach that applies the optimal mechanism of GeoInd on top of a regular grid. Table 1 summarizes the notations used in our presentation.

3.1 System Model

We consider an *online* scenario where mobile users are interested in retrieving points of interest relevant to their current location from an untrusted server. Based on the actual user location $x \in \mathcal{X}$, the sanitization algorithm computes a *reported* location $z \in \mathcal{Z}$. Both $\mathcal{X}$ and $\mathcal{Z}$ are assumed to be discrete and finite sets. Discrete locations, also called *logical* locations [12], are often used in the location privacy literature. In practice, this can be achieved by snapping continuous coordinates to an arbitrary granularity grid. We note that, in many existing geosocial network applications, the reported locations take the form of *check-ins* at discrete sets of two-dimensional coordinates corresponding to restaurants, coffee shops or other POIs. Our model is fully compatible with that setting.

In our model, the location sanitization is performed online at the user's mobile device. This approach is made possible by the properties of the GeoInd model, and it is an important advantage compared to other types of solutions that require a trusted centralized service, such as spatial k-anonymity (SKA) [16, 21]. Thus, the system model is much simpler, and it does not rely on unrealistic security assumptions, such as the presence of a trusted third party that performs anonymization, or the presence of a collaborating set of other mobile users who participate in the formation of cloaking regions. Furthermore, there are no changes required on the processing side at the server, which is an advantage compared to approaches that use encryption [15]. However, due to the fact that location protection is performed at the mobile device, the computational overhead incurred by sanitization is a very important concern. In our design, we focus on this constraint.

The mobile device will execute our sanitization technique before reporting its location (i.e., at runtime), and will also download in advance (*offline*) a set of objects that are required to support our technique, such as a set of maps annotated with additional pre-computed information (e.g., the properties of a certain city map and associated details required to construct a balanced index structure, as discussed in Section 5). This offline component is common for many software packages that support location-based apps, e.g., navigation services. Furthermore, in our approach, the amount of data that needs to be downloaded offline is small (in the order of tens of megabytes).

3.2 Baseline Approach

We provide a detailed description of the optimal GeoInd mechanism *OPT* [2] adapted to a regular grid. OPT is used as a building block in our multi-step approach, and also as a baseline in our evaluation. OPT produces the maximum utility achieveable under a given prior while preserving GeoInd. Specifically, given a privacy budget ε, a distinguishability metric $d_{\mathcal{X}}(\cdot,\cdot)$, a utility (or quality) metric $d_Q(\cdot,\cdot)$, and a prior Π defined over set $\mathcal{X}$, OPT determines mechanism K as the solution to the following linear programming problem:

Minimize:

$$\sum_{x \in \mathcal{X}, z \in \mathcal{Z}} \Pi_x \cdot K(x)(z) \cdot d_Q(x, z) \tag{3}$$

Subject to:

$$K(x)(z) \le e^{\epsilon d_{\mathcal{X}}(x,x')} \cdot K(x')(z) \qquad x, x', z \in \mathcal{X} \tag{4}$$

$$\sum_{z \in \mathcal{X}} K(x)(z) = 1 \qquad x \in \mathcal{X} \tag{5}$$

$$K(x)(z) \ge 0 \qquad x, z \in \mathcal{X} \tag{6}$$

This linear optimization problem can be solved by using standard techniques such as the Simplex or the Interior Point methods. However, the number of linear constraints in the program is $O(|\mathcal{X}|^2 \times |\mathcal{Z}|)$ (or cubic in the total number of locations, assuming that actual and reported locations belong to the same set). As a result, the method is unfeasible even when the set of locations has low cardinality (i.e., several hundred). In previous work [5] the cardinality of $\mathcal{X}$ is reduced by using a coarser grid, and locations in $\mathcal{X}$ are snapped to the centers of the grid cells. Let L denote the side length of the dataset (assumed to be a square, but any rectangular region can be scaled to suit the assumption). Grid granularity g is achieved by splitting the data domain into a regular grid with $g \times g$ cells, each with dimensions $L/g \times L/g$. While this approach reduces computational overhead, it also decreases utility, as all locations are snapped to the coarse grid.

Figure 2: An instance of $K(\mathcal{X})(\mathcal{Z})$ for a 3×3 grid.

Next, we focus on the application of OPT on top of a grid. Denote by $\mathbb{G}$ the set of grid cells, which represent the logical locations from which both actual and reported locations are selected, i.e., $\mathcal{X} = \mathcal{Z} = \mathbb{G}$. The prior is also defined with respect to $\mathbb{G}$. We can abstract an invocation of the OPT mechanism as a function call with the following parameters: $OPT(\epsilon, \mathbb{G}, \Pi, d_Q)$.

To provide an in-depth understanding of how OPT works, we consider the example of a regular grid of granularity $g = 3$, i.e., a total of nine cells. We illustrate in Figure 2 the layout of the stochastic matrix $K(\mathcal{X})(\mathcal{Z})$ from Eq.(4). We represent three of the nine rows of matrix K, corresponding to cells x_1, x_4 and x_9. The box at the top of the diagram illustrates the constraint in Eq. (5), representing the normalization condition, namely: the sum of probabilities in each matrix row must be 1 (each input cell must be mapped to some output cell). Likewise, the box in the middle of the diagram illustrates one of the $|\mathcal{X}|^3 = 81$ ε-geo-indistinguishability constraints corresponding to Eq. (4) in the linear program of the optimal mechanism.

The main drawback of OPT is its prohibitively high computational cost. To illustrate this drawback, we show in Figure 3 the trade-off between performance and utility when varying granularity, using a state-of-the-art commercial linear program solver on the Gowalla dataset (please see Section 6 for experimental setup details). As grid granularity increases, the utility improves but at the expense of a sharp rise in computation time. For the next higher granularity $g = 12$ (not shown in the graph), the optimization program was terminated after 24 hours without a solution.

The objective of our approach is to address these conflicting trends between utility and performance. Next, we present our *multi-step mechanism (MSM)* which operates on top of a hierarchical index structure and achieves a good compromise between utility and performance.

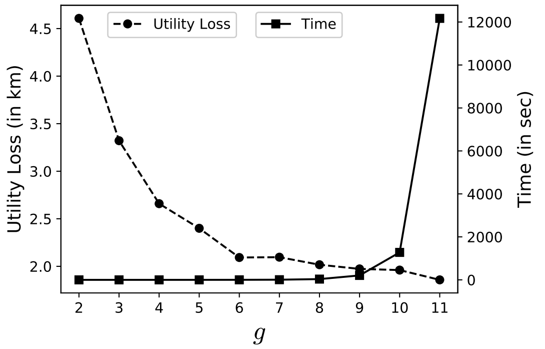

Figure 3: Effect of g on utility and running time of *OPT*

4 MULTI-STEP MECHANISM (MSM)

We introduce the multi-step mechanism (MSM) which operates over a *GeoInd-preserving Hierarchical Index (GIHI)* and transforms the user location according to OPT at each index level. The user inputs the total privacy budget ε to the algorithm, according to her privacy requirement. A separate component of our solution, the budget allocation strategy (discussed in detail in Section 5), determines how to distribute the privacy budget among the index levels. The output of the budget allocation procedure consists of the index height h, and the amount of privacy budget allocated to each level $B_i \in \mathcal{B}$, where $\mathcal{B}$ is the set of budget amounts per level, and $h = |\mathcal{B}|$. In the rest of the section, we focus on how the mechanism operates given the index height and budget splits.

Given granularity g and height parameter h, a GIHI is constructed over a data domain of size L^2 in a top-down fashion[3]. Each intermediate cell points to g^2 cells at the lower level that lie inside its spatial extent. Figure 4 illustrates the index structure[4] for $g = 2$ and $h = 3$. The cells in the hierarchical grid are labeled per level, and also within each level, as shown for level 1 in the diagram (to improve readability, we do not include the labels at lower levels). For instance, the leaf cell $C3_{3,0}$ is a child of $C2_{1,0}$, which in turn is a child of node $C1_{0,0}$. MSM iteratively visits each level of the hierarchical structure, starting with the virtual root node that covers the entire region. The root node is not a level in the tree, but it serves the purpose of simplifying the presentation, so that the algorithm can be expressed recursively starting from a single node. We denote as $\hat{x}_i$ the logical location of the user snapped to the center of the enclosing cell in the grid of granularity $g^i \times g^i$ at level i. Likewise, $\hat{z}_i$ denotes the logical location of the user output by the mechanism at level i. We define two simple procedures: *EnclosingCell*(x, i), which returns the cell at level i enclosing the input location x, and *centerOf*(C), which takes as input a cell C and returns the logical location at its center.

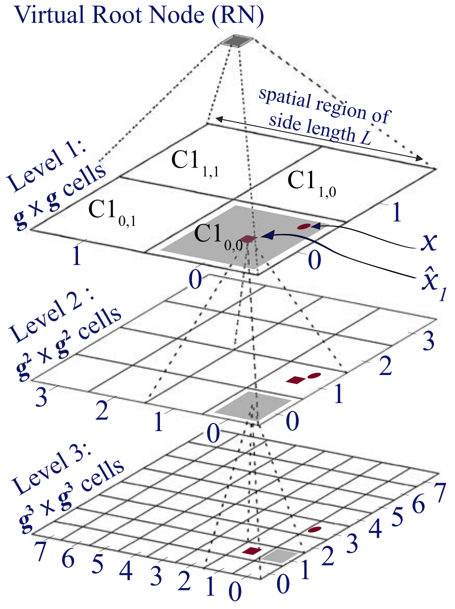

Figure 4: GeoInd preserving Hierarchical Index (GIHI)

Algorithm 1 presents the pseudo-code of our multi-step iterative process of location sanitization. In each iteration, the algorithm takes as input the location $\hat{z}_{i-1}$ selected in the previous iteration (in the first iteration it is set to the center of the virtual root node) and determines the cell that encloses $\hat{z}_{i-1}$, denoted by C (lines 4-6). Next, it translates the user's actual location x to a logical location $\hat{x}_i$ in the current level (lines 7-8) and constructs a partial grid $\mathbb{G}_i$ of g^2 cells within the spatial extent of C. Next (lines 11-13), MSM computes the matrix $K(\mathcal{X}_i)(\mathcal{Z}_i)$ as the solution to a linear optimization problem over the logical locations $\mathcal{X}_i, \mathcal{Z}_i \in \mathbb{G}_i$, consuming the privacy budget ε_i allocated to level i. MSM marks the end of the iteration at the current level by outputting $\hat{z}_i$ as a sample from the distribution $K(\hat{x}_i)(\mathcal{Z}_i)$. These iterations repeat for the entire height of the GIHI, consuming the entire privacy budget $\varepsilon = \varepsilon_1 + ... + \varepsilon_h$. After the final iteration (at the leaf level

[3] If the input dataset domain is not square, it can be scaled in advance of executing our algorithm to equalize the range in each dimension.

[4] For simplicity, we focus in this paper on an hierarchical grid, but the MSM concept applies to any hierarchical data structure without node overlap, e.g., R^+-trees or k-d-trees.

of the index), the output is the sanitized location that is reported to the service provider (line 14).

Note that, the actual location x may fall outside the selected cell at one or more levels of the index. This is an effect of the privacy requirement imposed by GeoInd, and thus a necessary aspect of protecting locations. However, it may also increase utility loss, as the distance between reported and actual cell may be large. To control the amount of utility loss, the objective of our budget allocation strategy (Section 5) is to split the budget in such a way that it is less likely for this event to occur at the higher (i.e., coarser) index levels. If this objective is achieved, utility will not decrease significantly.

Algorithm 1 Multi-Step Mechanism (MSM)

11:         $\epsilon_i \leftarrow \mathcal{B}[i]$
12:         $K(\mathcal{X}_i)(\mathcal{Z}_i) \leftarrow OPT(\epsilon_i, \mathbb{G}_i, \Pi(\mathcal{X}_i), d_Q(.))$
13:         $\hat{z}_i \leftarrow$ sample from distribution $K(\hat{x}_i)(\mathcal{Z}_i)$
14:     return location $\hat{z}$ to the service provider
```

We illustrate the proposed mechanism with a running example over the GIHI structure from Figure 4. The exact location of the user x is depicted as a red-colored dot, while the logical locations (snapped to cell centers) $\hat{x}$ are shown as red colored squares. The shaded cells depict the cells enclosing the output location ($\hat{z}$) of each iteration. The algorithm first takes as input the entire dataspace domain (represented as the root node), and splits it into a grid $\mathbb{G}_1$ consisting of cells $\{C1_{i,j} : 0 \leq i, j \leq 1 \wedge C1_{i,j} \in RN\}$. Next, it maps the user's exact location x to $\hat{x}_1$ at the center of its enclosing cell at level 1, i.e., $C1_{0,0}$. Then, MSM computes $K(\mathcal{X}_1)(\mathcal{Z}_1)$, and outputs a location $\hat{z_1}$ sampled from the distribution $K(\hat{x}_1)(\mathcal{Z}_1)$.

Denote the selected cell as $\hat{z_1}$ = *centerOf*($C1_{0,0}$). In the next iteration, $\mathbb{G}_2$ is composed of the set of $g \times g$ cells within the spatial extent of $C1_{0,0}$, which is the enclosing cell of the output in the previous iteration. Location $\hat{z_2}$ is selected as output. Suppose $\hat{z_2}$ =*centerOf*($C2_{0,0}$), which implies that for the purposes of the last iteration, the actual location x falls outside the spatial extent of the cell enclosing $\hat{z_2}$. In this situation the user's location is assumed to be a random cell (e.g., $C3_{1,1}$) in $\{C3_{i,j} : 0 \leq i, j \leq 1\}$. The remainder part of the iteration continues by outputting $\hat{z_3}$ =*centerOf*($C3_{1,0}$). Finally, $\hat{z_3}$ is reported to the service provider, with a quality loss $d_Q(x, \hat{z_3})$.

A consequence of the grid based discretization scheme is that, the position of every user is always approximated by the center of the enclosing cell before being obfuscated by the mechanism. For example, consider that a user with his exact coordinates at a random location in a 1km^2 cell, requests the nearest bar to his position. In this case, he will receive an answer that is tailored, in the best case, to the center of his cell, which is on average 0.38km [14] away from the current location of the user. It is clear that the situation gets more problematic as the grid cells are larger, i.e., at coarser granularities. This is often the case when applying the conventional optimal mechanism [2] over a coarse grid (as discussed in Section 3.2, OPT can work only for very coarse grids, otherwise the execution time is extremely high). In contrast, our approach operates on a much finer-grained grid at the leaf level, thus gaining significantly in terms of utility. MSM also limits the size of the linear optimization problem, given that there are exactly g^2 logical locations at each step. This enables efficient computation of the linear program, making the overall execution time practical.

We end this section by informally discussing the fact that MSM preserves GeoInd. MSM is a textbook example of applying the *composability* property [19, 20] of differential privacy. The initial iteration of MSM takes as input the real user location, and the final iteration outputs the perturbed location. At each index level i, the OPT mechanism is applied with a fraction ε_i of the total privacy budget ε. The output of each MSM step (i.e., level) is pipelined into the input of the following step (at the next level). According to the composability property introduced in Section 2, MSM satisfies GeoInd with budget $\sum_{i=1}^{h} \varepsilon_i = \varepsilon$.

5 BUDGET ALLOCATION STRATEGY

The utility of MSM depends on important system parameters such as the height of the index and the budget allocation across levels. In this section, we provide an analytical cost model of utility that guides our decision on how to choose GIHI parameters. We assume we are given as input the size of the data domain specified as side length L, the grid granularity g (corresponding to a fanout of g^2 at each level), and the total budget ε. The objective is to determine index height h and the budget allocation ε_i for each level $i, 1 \leq i \leq h$.

A fundamental factor that guides our allocation strategy is the observation that if the actual location is mapped to a reported location in another cell, the utility loss is likely to be larger when the grid cell size is also large. Consequently, the utility loss is much larger when this event occurs near the root of the index, compared to the case when it occurs at the leaf level. Intuitively, the impact on utility of the event occurring at level i is g times higher than the same event occurring at level $i+1$. Consider a stochastic obfuscation mechanism that satisfies geo-indistinguishability, and denote its probability of mapping location (i.e., cell) x to z by $Pr[z|x]$. The probability density function of the output is indeed the distribution $K(x)(z)$, as discussed in Section 2. The proposed budget allocation strategy aims to precisely control $Pr[x|x]$, i.e. the probability of reporting cell x when the actual location is also within x. Based on the earlier observation, to reduce utility loss it is important to maintain $Pr[x|x]$ high at the upper levels of the index.

To calculate $Pr[x|x]$ precisely, we can solve the $|\mathcal{X}|^3$ constraints in the linear optimization program of Eq. (3), according to the input prior Π. However, estimating $Pr[x|x]$ in isolation poses a challenge, since it is not feasible to narrow down the effect on a single location of all other cells (as per Eq. (4)). Hence, we devise a method to estimate this value to an arbitrary precision. We denote the approximation of $Pr[x|x]$ as $\Phi(x)$, and compute it by estimating its complement, i.e., the probability of mapping x to another grid cell.

$$\Phi(x) = \frac{1}{\sum_n \exp\left(-\frac{\varepsilon L}{g}\sqrt{n}\right)} \qquad n = a^2 + b^2, (a,b) \in \mathbb{Z}^2 \tag{7}$$

where $\mathbb{Z}^2$ denotes the 2-dimensional infinite integer lattice whose points are tuples of integers. Switching to coordinates with origin at zero, and defining $\hat{0} \triangleq x$, the denominator can be understood to be the sum over the exponents of the *multiplicative distances* between $Pr[\hat{0}|\hat{0}]$ and $Pr[\hat{0}|\hat{n}]$. $\Phi(x)$ is constrained to the integer lattice to ensure that the probability mass of the entire cell is assigned to the center of the cell, giving us a close estimate of our desired probability.

While $\Phi(x)$ needs to be summed over the infinite lattice, the function $T(\varepsilon, g) \triangleq \sum_n \exp(-\varepsilon L/g\sqrt{n})$ converges quickly. In order to approximate this value within a factor of $\exp(-N)$ for any arbitrarily large N, we need only $O(N^2 f/\varepsilon L)$ terms. However, when the value of ε is small, which is often the case in differential privacy literature (with values of $\varepsilon \leq 0.5$ being the most common settings to achieve a reasonable privacy protection), straightforward computation of this value can be prohibitive. To this end, we can apply the two-dimensional Poisson summation to expand the series, followed by taking its Fourier transform, to obtain an efficient approximation when $0 \leq \varepsilon \leq \frac{2\pi g}{L}$:

$$T(\epsilon, g) = \frac{2\pi g^2}{\varepsilon^2 L^2} + \sum_{k=1}^{\infty} c_{2k-1}\left(\frac{\varepsilon L}{g}\right)^{2k-1} \tag{8}$$

where the coefficients $c_1, c_3, c_5, \ldots$ are given by

$$c_{2k-1} = 4\binom{-3/2}{k-1}(2\pi)^{-2k}\zeta\left(k+\frac{1}{2}\right)L\left(k+\frac{1}{2}, \chi_4\right). \tag{9}$$

where ζ is the Riemann zeta function [23] and $L(\cdot, \chi_4)$ is the Dirichlet L-series[25] of the non-principal Dirichlet character χ_4 (mod 4), which is known to converge absolutely as

$$L(s, \chi_4) = \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n+1)^s} = 1 - \frac{1}{3^s} + \frac{1}{5^s} - \frac{1}{7^s} + - \cdots. \tag{10}$$

Since we can approximate $T(\varepsilon, g)$ efficiently, the same is true of $\Phi(x)$. In order to configure the budget at each level of the grid, we formulate our problem as follows:

PROBLEM 1. *Given a desired value of $Pr[x|x]$ as ρ, and the grid parameters: side length L, and the granularity g, estimate the minimum budget ε_i that ensures at least ρ percent chance of remaining within the boundaries of the current cell at level i. The budget ε_i can be calculated according to the following optimization problem:*

Minimize:

$$\text{Privacy Budget } \varepsilon \tag{11}$$

Subject to:

$$\begin{gathered} \left(\sum_n \exp\left(-\frac{\varepsilon L}{g}\sqrt{n}\right)\right)^{-1} - \rho \geq 0, \\ \varepsilon > 0, \\ 0 \leq \rho \leq 1 \end{gathered} \tag{12}$$

Since $T(\varepsilon, g)$ can not be written in a closed form, solving directly for ε is not achievable. Nevertheless, the expression in Eq. (12) is monotonic in ε, hence we can utilize a simple branch-and-bound technique [10] to efficiently get an answer with arbitrary precision.

Algorithm 2 summarizes the functionality of the proposed budget allocation strategy. Procedure *getGridParameters* calculates the minimum budget required for each level of the grid, such that with probability at least ρ a location enclosed within cell x is mapped to the same grid cell. For every iteration of the while loop, the procedure determines if there is any budget remaining for additional levels of the multi-step mechanism. Finally, the process halts when it expends all the budget, returning the height h and the budget allocated at each level of the grid.

Algorithm 2 Grid Configuration

```
Input: $\varepsilon, g$
Output: height $h$, budgets $\varepsilon_1, \varepsilon_2, \cdots, \varepsilon_h$
procedure GETGRIDPARAMETERS
    $v \leftarrow \varepsilon$                                    ▷ stores the remaining budget
    $i \leftarrow 1$                                    ▷ denotes the current grid level
    $\mathcal{B} \leftarrow \emptyset$                                    ▷ stores the budget for each level
    while true do
        $\mathcal{B}[i] = \varepsilon_i \leftarrow \max\{\text{solution to Problem 1}, v\}$
        $v = v - \varepsilon_i$
        $i = i + 1$
        if $v \leq 0$ then                                    ▷ budget expended
            return $\mathcal{B}$
```

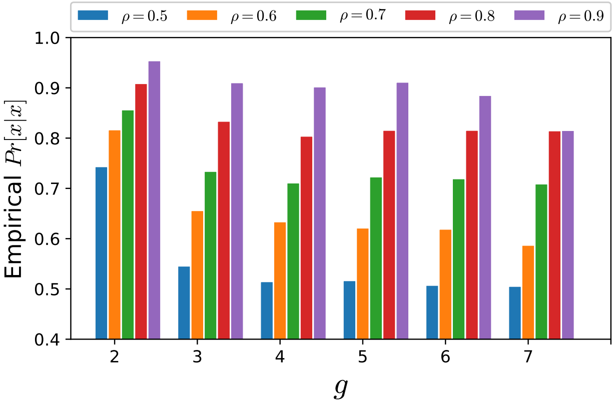

Figure 5: Accuracy of estimated Φ for varying g

We conclude this section by providing a numerical result to validate our analytical model. We illustrate the precision with which our budget allocation algorithm estimates an effective configuration of the grid for MSM (we defer the details of the experimental setup to Section 6.1). We plot the probability $Pr[x|x]$ for various levels of ρ and granularity g using the Gowalla dataset. Figure 5 shows the results, assuming a uniform global prior as input. Excluding the case when the granularity is 2, the predicted value of Φ is within ±5 percent of $Pr[x|x]$ reported in $K(\mathcal{X}, \mathcal{Z})$, thus validating the efficacy of the budget allocation scheme.

6 EXPERIMENTAL EVALUATION

In this section we evaluate the performance of our proposed Multi-Step Mechanism (MSM) in terms of utility and computational overhead. In Section 6.1 we present the details of the experimental setup. We provide the results of comparison with benchmarks in Section 6.2, followed by an in-depth analysis of MSM behavior when varying system parameters in Section 6.3.

6.1 Experimental Setup

Datasets. We use two real datasets collected from the operation of two prominent geo-social apps, namely *Gowalla* and *Yelp*. Each dataset consists of a set of user check-ins. Every check-in is described by a record consisting of user identifier, the latitude and longitude of the check-in location. The *Gowalla* dataset is a subset of the user check-ins collected by the SNAP project [9] from a location based social networking website. In our experiments, to simulate a realistic environment of a city and its suburbs, we focus on check-ins within a single urban area, namely Austin, Texas. In particular, we consider a large geographical region covering a $20 \times 20\text{km}^2$ area bounded to the South and North by latitudes 30.1927 and 30.3723, and to the West and East by longitudes -97.8698 and -97.6618. The selected data contains a total of $265,571$ check-ins from $12,155$ unique users during a time period between February 2009 and October 2010. The *Yelp* dataset was made available to the public by Yelp, Inc [3] as part of a dataset challenge, and contains user ratings for various points of interest. Again, to simulate a typical urban area, we utilize location data within the city of Las Vegas, NV and its surroundings. The filtered dataset contains $81,201$ check-ins from $7,581$ unique users within a $20 \times 20\text{km}^2$ area bounded between latitudes 36.0645, 36.2442 and longitudes -115.291, -115.069.

Implementation. All algorithms were implemented in C++ on a Ubuntu Linux 14.04 LTS operating system, and executed on an Intel Core 2 Duo 2.0 GHz CPU with 4GB RAM. All data and indices are stored in main memory. For the computation of the linear optimization problem, we utilize the C++ interface of the state-of-the-art commercial linear program solver in the Gurobi Optimization Suite [22]. We used the dual simplex method of solving linear programs throughout our evaluation since it consistently outperformed the primal simplex and interior-point methods in terms of numerical stability.

Prior Modeling. We compute a *global prior* for the Gowalla and Yelp dataset partitions with the help of a regular grid superimposed on top of the data domains. The grid granularity varies to match the grid structure used in each specific experiment. For a given granularity, we count the number of check-ins in every cell relative to total number of check-ins in the entire grid (a similar approach was taken in [2, 5]). The global prior Π describes the behavior of an average user (as a vector of probabilities for each grid cell), and is used in the computation of the optimal mechanism. We store a global prior on the finest effective granularity grid used in the experiments and aggregate this information to obtain priors on coarser grids. This procedure mimics the scenario where the aggregate information about past users of the service is made available from the service provider.

6.2 Comparison with Benchmarks

We evaluate our proposed MSM approach in comparison with two benchmarks: the basic optimal mechanism *OPT* introduced in [2] and described in detail in Section 3.2; and the planar Laplace (PL) mechanism, for which we also include a post-processing (or re-mapping) step by projecting its output to the grid (as discussed in [5]).

All evaluated mechanisms are constructed to satisfy GeoInd with privacy budget ε ranging from 0.1 to 0.9, which is a common range used in the majority of differential privacy work [11]. Recall from Section 2 that a smaller ε value corresponds to stronger privacy. Values higher than 1.0 are typically considered insufficient in terms of privacy (i.e., the attacker's gain in distinguishing among candidate locations becomes significant). We consider several granularities of the grid index structure, ranging from $g = 2$ up to $g = 6$ (recall that for our method, the effective fanout is $g \times g$ at each level). We consider a value range for the probability of hashing the user location in the same cell at a certain level (see Section 5 for details) between $\rho = 0.5$ and $\rho = 0.9$ (default value is set to $\rho = 0.8$). In all experiments, we measure the utility loss experienced by a user of a location-based service over a set of $3,000$ requests randomly selected from the set of check-ins corresponding to each dataset. We consider in turn both Euclidean ($d_Q = d$) and squared Euclidean ($d_Q = d^2$) utility metrics. The default value of ε is set to 0.5.

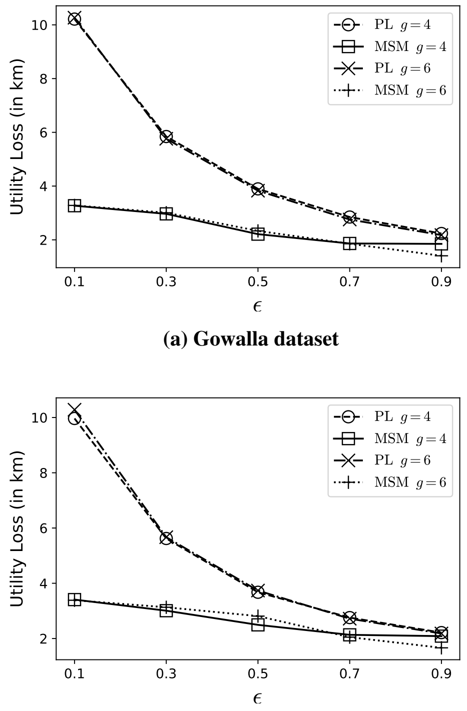
Table 2: MSM comparison against *OPT*, Gowalla dataset

Granularity		Utility Loss (in km)		Time (in sec)	
OPT	MSM	*OPT*	MSM	*OPT*	MSM
4	2	2.29	2.63	0.04	0.008
9	3	1.97	2.22	205.7	0.009
16	4	—	2.02	72hrs+	0.53

First, we compare the proposed MSM approach with the optimal mechanism OPT. Due to the high overhead of OPT, we are only able to perform the comparison in a restricted setting, for which the linear program completes within reasonable time. Table 2 presents the utility loss and execution time values of OPT and MSM for the same effective grid granularity (e.g., 9×9 granularity for *OPT* corresponds to a 3×3 granularity for our method, where the second level of MSM will have the same number of cells as the OPT grid). We focus on the Gowalla dataset for this experiment. We were not able evaluate the performance of OPT for the granularity of 16 (i.e., 256 locations) because the program did not complete within 72 hours. For 121 locations (i.e., 11×11 grid) OPT took 3.3 hours to complete (see Figure 3). Even for a granularity of 9, the optimal method would be completely unfeasible for online queries, given its running time of 205 seconds, whereas our approach achieves sub-second processing times in all runs. In terms of utility, for the same granularity at the leaf level OPT does outperform MSM. This result is not surprising, since our execution time gain is obtained by pruning the search space. However, the additional loss of MSM compared to OPT is not large. Furthermore, in practice, our approach is able to increase utility by using much finer-grained grids (as we show in the next section), whereas OPT can only function for coarse-grained grids. In the rest of our evaluation, we no longer consider OPT, since it is clearly not feasible in practical settings.

Next, we focus on the comparison between MSM and the planar Laplace mechanism (PL). Figures 6a and 6b plot the utility loss of MSM and PL for varying levels of privacy on both Gowalla and Yelp datasets, using d as utility metric. As expected, utility loss decreases for both mechanisms as ε grows: a larger budget corresponds to a weaker privacy requirement, hence less noise is added. The proposed MSM approach clearly outperforms PL in terms of utility, especially at low ε values, which are more important because they provide appropriate privacy. As ε approaches 1, the utility obtained by the two methods becomes similar, but as mentioned earlier, $\varepsilon = 1$ or higher does not provide sufficient protection. The gain of our approach over PL is more pronounced at low ε settings. For $\varepsilon = 0.1$, MSM utility loss is three times better than the one achieved by PL.

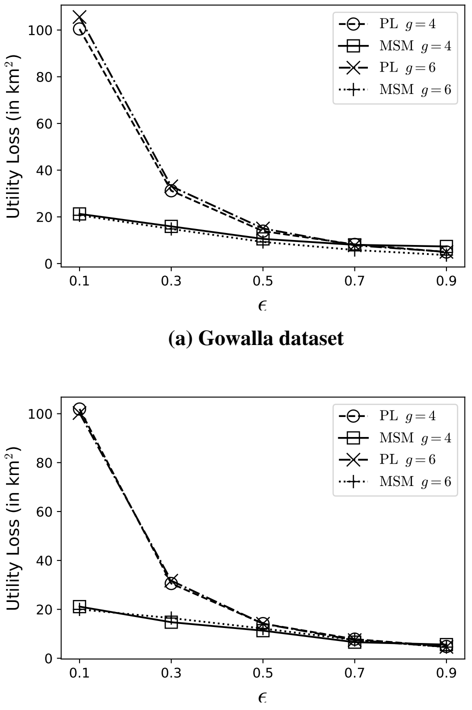
A similar trend can be observed when comparing MSM and PL using the squared Euclidean distance as utilty metric (Figures 7a



(a) Gowalla dataset

(b) Yelp dataset

Figure 6: Effect of ϵ on utility loss (Euclidean utility metric).



(a) Gowalla dataset

(b) Yelp dataset

Figure 7: Effect of ϵ on utility loss (squared Euclidean utility metric).

(b) Yelp Dataset

Figure 8: Effect of varying granularity on the utility loss (Euclidean utility metric).

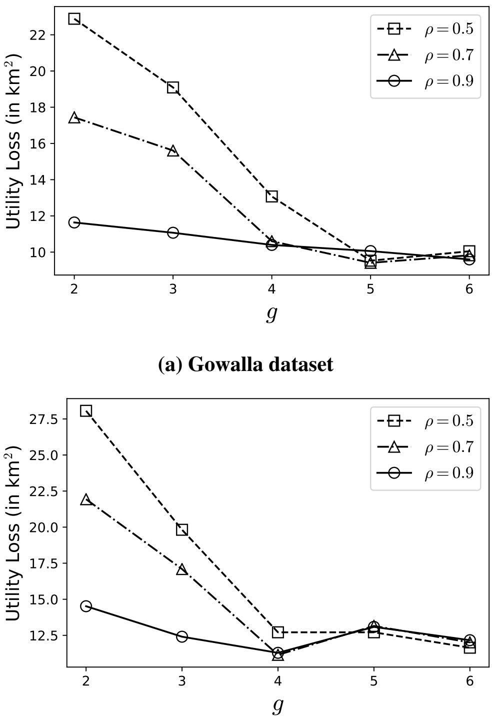
and 7b). This time, the gap between the two approaches is even larger, with MSM outperfoming PL by a factor of 5 at the low end of the privacy budget range. PL does however catch up with our method earlier than in the case of Euclidean utility metric (around the $\varepsilon = 0.5$ threshold). Still, MSM remains clearly superior in the range of tight privacy settings.

Our results show that MSM outperforms significantly the PL benchmark in terms of utility loss. As discussed in Section 2, PL is very fast in terms of execution time, and it takes on average 10 milliseconds to complete. In contrast, our method is more expensive. Still, the execution time is always below 1 second in the worst case (which occurred for the highest considered granularity case $g = 6$ and a large ε value). In most cases, the average runtime of our method is in the range of $100 - 200$ milliseconds. Even though this is higher than PL, $100 - 200$ milliseconds per query is a small price to pay in order to increase utility significantly. Furthermore, recall that this cost will be incurred at the client side, so there is no danger of the server being overloaded due to a spike in request. In terms of user experience, the additional time required for sanitizing locations is barely noticeable.

For the rest of the evaluation, we no longer consider PL, and we focus on analyzing the performance of the proposed MSM method when varying its system parameters values.

6.3 MSM System Parameter Analysis

Next, we evaluate the utility of MSM when varying grid granularity, while also considering several settings of ρ (shown as distinct lines in each graph). Recall that, for MSM the fanout at each level is $g \times g$, hence the first level (below the single virtual root node) has granularity $g \times g$, the second level granularity $g^2 \times g^2$, and



(a) Gowalla dataset

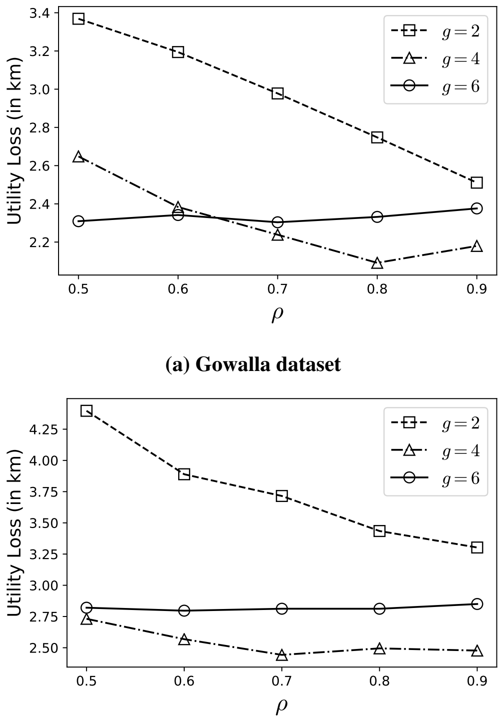
(b) Yelp Dataset

Figure 9: Effect of varying granularity on the utility loss (squared Euclidean utility metric).

so on. Figures 8a and 8b show the obtained results for the two datasets under Euclidean distance utility metric. The general trend is that of a “U”-shaped dependency: utility loss decreases initially as granularity increases, which intuitively is a result of a higher precision in reporting locations. However, after a certain point, the utility loss starts to increase, as a high granularity will determine more cases where the reported and actual locations are in different cells. As a side effect, as the area of each grid cell decreases, more budget is required at a certain level to maintain the same required probability ρ, which can starve lower index levels of privacy budget. We notice that the ideal granularity may also vary with the dataset, as data density typically affects accuracy. For the Gowalla dataset the best-performing granularity is at $g = 5$, whereas for the Yelp dataset it is $g = 4$. For a given granularity, we note that a higher value of ρ typically results in better utility, although there are some exceptions: for instance, at $g = 4$, the $\rho = 0.7$ case outperforms the $\rho = 0.9$ setting, for the reason explained above, namely the top level uses most of the budget, and the lower levels do not receive sufficient budget to accurately execute the linear program.

A similar trend is observed when using squared Euclidean distance as utility metric, as shown in Figures 9a and 9b. A higher ρ results in better utility in the majority of cases.

Finally, we measure the effect of varying parameter ρ, with several distinct settings of granularity (shown as different lines in each graph). Figures 10a and 10b summarize the results for Euclidean distance, whereas results for the squared Euclidean distance are shown in Figures 11a and 11b. For the lowest granularity $g = 2$, we note a clear decreasing trend in utility loss. As the grid



(a) Gowalla dataset

(b) Yelp Dataset

Figure 11: Effect of varying probability ρ on the utility loss (squared Euclidean utility metric).

granularity grows gradually from one level to another, the algorithm for budget allocation is able to allocate budget in a smoother fashion, leading to steady progress as ρ grows (we emphasize that although the trend is more pronounced, the absolute value of utility is worse for the $g = 2$ setting compared to the rest). For the other settings of g, due to the fact that the transition from one level to the other is more abrupt, the net effect of ρ exhibits a not-so-well defined trend. The $g = 4$ case still shows a decreasing trend initially, but then utility loss starts to increase as ρ grows, as a result of budget starvation at lower index levels. In the case of $g = 6$, the budget starvation seems to manifest even at lower ρ values, so the trend is constant to slightly increasing. Note that, starvation is not necessarily a negative effect, in the sense that the utility can still be better than the other settings. Starving lower levels of budget may be a worthwhile choice, as long as the higher levels keep the reported cell close to the actual cell, and in effect the utility loss is low. We insist on the starvation concept mostly to describe the observed trends. We do, however, note that excessive starvation can sometime increase utility loss: in the case of the Yelp dataset for instance, we observe that the utility loss obtained at a finer granularity ($g = 6$) is higher than that obtained with $g = 4$.

7 RELATED WORK

In the past decade, a vast amount of research focused on preserving location privacy. The earliest approaches used *dummy generation* [18, 27] to protect locations of users who issue location-based queries. In [18], the user issues a number of redundant (fake) queries at random locations, thus decreasing the probability that an adversary guesses which is the real location. The work in [27] chooses an *anchor* around the real location, and focuses on how query processing can be done around the anchor in such a way that precise results are obtained with respect to the real location (e.g., exact nearest-neighbor queries). Both approaches are vulnerable to background-knowledge attacks: an adversary who knows the map features or the patterns of user movement can filter out the fake locations and reveal the real one.

The *spatial k-anonymity (SKA)* concept has been introduced in [16] to address the limitations of dummy generation. The main idea behind SKA is to construct a *cloaking region (CR)* that encloses at least *k real* users. This way, it is more difficult for the adversary to filter out locations and narrow down the query source. The work in [21] showed how SKA can be implemented on top of a spatial index, but may be subject to reverse engineering attacks because the CR generation algorithm is deterministic and takes as seed the location of the querying user. Later on, [17] introduced the *reciprocity* property, which shows that as long as the same CR is generated for all k users in an anonymity set, the adversary's probability of identifying the user issuing a query is bounded above by $1/k$. However, all SKA approaches no longer provide protection when users move, or when some users in the anonymity sets disconnect. In addition, they may reveal the exact user locations: for instance, if k users are situated inside a hospital, it is possible for the CR to be completely enclosed by the hospital area. Even if the attacker cannot identify which user issued the query, s/he learns that all users are in a hospital, which is a serious privacy breach. Some later work considered *spatial diversity* [12, 26], which attempted to enlarge cloaking regions such that association with sensitive features (e.g., hospitals, nightclubs) is reduced. However, the limitations of SKA remain in place for spatial diversity when users move or disconnect.

The introduction of the novel semantic model of *differential privacy (DP)* changed the landscape of location privacy approaches. DP is a statistical model designed to address the scenario of *aggregate queries*, where the presence of an individual in a dataset must be hidden. Therefore, it is not directly applicable in the context of online location reporting, which is our problem setting. However, DP can be used in the context of publishing historical datasets of locations or trajectories. For instance, the work in [11] shows how spatial indexes can be used to release geospatial datasets at different granularities. The authors consider quadtrees and *k-d*-trees, and propose a cost model to help allocate budget across different structure levels. While we also consider multiple index levels, our context is a completely different one (that of geo-indistinguishability). Furthermore, their model shows that it is best to allocate smaller budgets towards the root of the index, and preserve a larger proportion of the budget for the leaf level, whereas our findings for the GeoInd setting are exactly the opposite. Due to the fact that an error at the root of the structure has more impact on data utility, we found that it is important to allocate a higher proportion of the budget at the higher index structure levels. Some other work in the context of DP [7, 8] focuses on releasing trajectories using noisy counts of prefixes or n-grams in a trajectory, but similar to [11], the results apply to the offline setting only.

Geo-indistinguishability [1, 2, 5] is a novel and promising semantic model that inherits the powerful guarantees of DP, but adapts them to the setting of online location protection. Since its introduction in 2013, several research efforts focused on finding efficient and utility-preserving techniques for implementing GeoInd. Closest to our work is the research in [5], which proposed several mechanisms and post-processing algorithms to improve utility. However, as we show in our extensive performance evaluation, those techniques are either fast and inaccurate (planar Laplace in conjunction with remapping to grid), or they only work for very small sets of candidate locations (as is the case with the optimal mechanism). In contrast, our multiple-step approach is able to achieve high utility with very reasonable computational overhead.

8 CONCLUSION

We proposed a multiple-step algorithm for protecting location privacy according to the geo-indistinguishability model. By using a multi-level index structure, we are able to prune the solution search space of expensive GeoInd mechanisms, and achieve high utility with low performance overhead. We also derived cost models that show how to judiciously allocate the available privacy budget, and how to choose important index parameters to improve accuracy. The resulting approach outperforms significantly existing benchmarks. In future work, we plan to investigate more advanced cost models to better capture prior information, and thus further improve the accuracy of our approach. We will also investigate more complex index structures (e.g., *k-d*-trees and R^+ trees) which can adjust better to skewed distributions of priors.

ABSTRACT

We study the problem of graph similarity search with a graph edit distance (GED) constraint. Existing solutions adopt a filtering-and-verification framework, with a focus on the filtering phase where a feature-based index is used to reduce the number of candidate graphs to be verified. These solutions suffer from a computationally expensive verification phase. In this paper, we develop a novel technique called Inves that can significantly reduce the time of verifying a candidate graph. Its main idea is to judiciously and incrementally partition a candidate graph based on the query graph, and use the results to compute a lower bound of their distance. If a full GED computation is needed, Inves utilizes the collected information, and uses novel methods and an A* algorithm to search in the space of possible vertex mappings between the graphs to compute their GED efficiently. A main advantage of Inves is that it can be adopted by a plethora of graph similarity search algorithms. Our extensive experiments on both real and synthetic datasets show that Inves can significantly improve the performance of existing techniques by an order of magnitude.

1 INTRODUCTION

Graph data models are widely used in representing complex objects, such as chemical compounds, social networks, and biological structures. Graph search, which finds all occurrences of a query graph in a database of graphs, is a fundamental operation needed in many applications. To tolerate data inconsistency, natural noises, and different data representations in graph search, very often these applications require finding graphs similar to a given query graph. Various similarity measures have been proposed, such as maximum common subgraphs [2, 15], missing edges and features [23, 28], and graph alignment [17]. Among them, one of the commonly used metric is graph edit distance (GED) [5, 6, 22], which can capture the structural difference between graphs, and can be applied to many types of graphs [22, 24]. The GED between two graphs is the minimum number of graph edit operations to transform one to the other, where a graph edit operation is insertion, deletion, or substitution of a single vertex or edge.

The problem of graph similarity search is to find graphs in a database whose GED to a query graph is within a given threshold. This problem is challenging because GED computation between two graphs is NP-hard [22]. Generally, a scan-based approach that directly computes the GED between each data graph and the query graph is computationally prohibitive. Many existing solutions adopt a filtering-and-verification framework. An index structure is typically used to generate candidate graphs in the filtering phase, and each candidate is compared with the query graph to find if it is a true match in the verification phase. Existing studies mainly focus on developing a feature-based index to generate candidates in the filtering phase. For example, c-star [22] and k-AT [19] extract tree-structured features from data graphs and build an inverted index on the extracted features. GSimSearch [25, 26] builds an inverted index on path-based features of graphs. Pars [24] and MLIndex [12] utilize partitions of graphs as features to be indexed.

The performance of existing solutions can suffer from too many candidates and an expensive verification phase. Table 1 shows the performance of 100 queries using one of the index-based search algorithms, Pars [24], on an AIDS dataset containing 42,687 graphs (see Section 5 for details). In the table, we use the number of data graphs that have passed a primitive filter named the global label filter (refer to [25] and Section 3.5 for details of the filter). The number of candidates denotes those candidates that require full GED computations. For example, when the threshold $\tau = 5$, only 15.5% of data graphs are filtered from the index-based filtering phase. Experiments on other solutions show similar behaviors.

Table 1: Performance of Pars

GED threshold τ	1	2	3	4	5
# of data graphs	574	3,335	12,669	34,774	74,937
# of candidates	142	591	4,931	22,846	63,301
# of answers	105	135	161	221	278
Filtering ratio	75.3%	82.3%	61.1%	34.3%	15.5%

To solve this problem, in this paper we develop a novel verification technique, called Inves[1]. Given a set of candidate graphs generated from a filtering phase, the proposed technique can effectively reduce the time for verifying if the GED between each candidate graph and the query graph is within a given threshold. Its main idea is to judiciously and incrementally partition the candidate graph based on the query graph, and use the results to try to prune this pair. If a full GED computation is needed, Inves utilizes the collected information, and uses novel methods and an A* algorithm to search in the space of possible vertex mappings between the graphs to compute their GED efficiently. A main advantage of Inves is that it can be adopted by a plethora of graph similarity search algorithms.

The following are our contributions:

- We propose Inves as a novel incremental partitioning-based verification technique. Given a candidate graph and a query graph with a GED threshold, Inves incrementally isolates subgraphs of the candidate graph that cause mismatches with the query graph. If the number of isolated subgraphs is greater than

[1] It stands for Incremental partitioning-based verification technique for graph edit similarity search.

Series ISSN: 2367-2005

10.5441/002/edbt.2019.21

the threshold, Inves filters out this pair since their GED cannot be within the threshold. In Section 3, we present the details of the incremental partitioning-based verification framework.

- If the pair of graphs cannot be pruned using the generated subgraphs, Inves employs efficient methods based on a well-known A* algorithm for GED computation [14]. It also takes advantage of the partitioning results by first considering those vertices that cause edit errors. In this way, it can significantly reduce the search space of the A* algorithm, thus improve the performance of GED computation (Section 4).
- We conduct extensive experiments to evaluate Inves on both real and synthetic data sets (Section 5). The results show the benefits of the various optimization methods in the technique. In addition, by adopting Inves in existing index-based algorithms, we can significantly reduce the total running time by an order of magnitude.

The rest of the paper is organized as follows: Section 2 provides preliminaries and reviews related work. Section 3 presents the proposed verification framework, and Section 4 provides our GED computation methods. Section 5 presents experimental results, and Section 6 concludes the paper.

2 PRELIMINARIES AND RELATED WORK

2.1 Graph Similarity Search Problem

We focus on undirected labeled simple graphs defined as follows. An undirected labeled simple graph g is a triple (V_g, E_g, L_g), where V_g is a set of vertices, $E_g \subseteq \{(u, v) \mid u \in V_g \wedge v \in V_g \wedge u \neq v\}$ is a set of edges, and L_g is a labeling function that maps vertices and edges to labels. $L_g(v)$ and $L_g(u, v)$ respectively denote the label of a vertex v and the label of an edge (u, v). If there is no edge between u and v, $L_g(u, v)$ returns a unique value λ distinguished from all other edge labels. There are no self-loops nor more than one edge between two vertices. For simplicity, in the rest of the paper, we use graph to denote undirected labeled simple graph.

The graph edit distance (or GED for short) between two graphs x and y, denoted by $ged(x, y)$, is the minimum number of graph edit operations that transform x to y. A graph edit operation is one of the following: (1) insertion of an isolated labeled vertex; (2) deletion of an isolated labeled vertex; (3) substitution of the label of a vertex; (4) insertion of a labeled edge; (5) deletion of a labeled edge; or (6) substitution of the label of an edge.

Example 1. *Figure 1 shows two graphs x and y, which include vertex labels representing atom symbols and edge labels (i.e., single and double lines) representing chemical bonds. Besides vertex labels, the graphs also include vertex identifiers. To transform x into y, we can do the following three graph edit operations on x: insertion of a single-bond edge between u_3 and u_5, and substitutions of labels of u_2 and u_8. Therefore, $ged(x, y)$ is 3.*

We formalize the problem of graph edit similarity search as follows.

Definition 1 (Graph Similarity Search Problem). *For a graph database $\mathcal{D} = \{x_1, \ldots, x_n\}$ and a query graph y with a GED threshold τ, the graph edit similarity search finds every data graph $x_i \in \mathcal{D}$ such that $ged(x_i, y) \leq \tau$.*

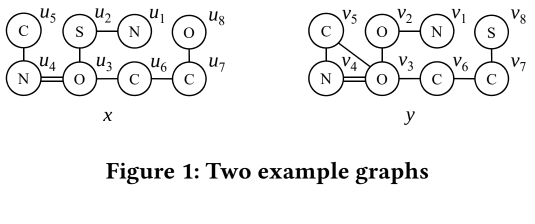

Figure 1: Two example graphs

2.2 A* algorithm for GED Computation

In this section, we review the most widely used algorithm for GED computation [14], which is based on A*. Given a pair of graphs x and y, the A* algorithm basically traverses all possible vertex mappings between x and y in a best-first fashion. It maintains a priority queue that contains states in its state-space tree, where each state in the tree represents a partial vertex mapping between the pair. The priority (or edit distance) of a state is determined by the sum of (1) the existing distance g: the edit operations detected from the initial state to the current state; and (2) an estimated distance h: a heuristic estimation of the edit operations from the current state to the goal. The A* algorithm guarantees that it finds an optimal mapping if h is not overestimated.

```
Algorithm 1: GED($x$, $y$, $\tau$)
  input  : $x$ and $y$ are graphs; $\tau$ is a GED threshold.
  output : if $ged(x,y) \leq \tau$, $ged(x,y)$; otherwise, $\tau$+1
1  $O \leftarrow$ order the vertices in $x$;
2  $Q \leftarrow \emptyset$; $Q$.push($\emptyset$);
3  while $Q \neq \emptyset$ do
4      $M \leftarrow Q$.pop();
5      if complete($M$) then return existingDistance($M$);
6      $u \leftarrow$ next unmapped vertex in $V_x \cup \{\varepsilon\}$ as per $O$;
7      foreach $v \in (V_y \cup \{\varepsilon\})$ s.t. $v \notin M$ do
8          $g \leftarrow$ existingDistance($M \cup \{u \rightarrow v\}$);
9          $h \leftarrow$ estimateDistance($M \cup \{u \rightarrow v\}$);
10         if $g + h \leq \tau$ then $Q$.pushQueue($M \cup \{u \rightarrow v\}$);
11 return $\tau + 1$;
```

The GED computation algorithm is outlined in Algorithm 1. It first determines the order of vertices in x, and pushes the initial state, i.e., an empty mapping, into the queue (Lines 1–2). In the main loop, it removes a mapping M from the queue that has a minimum edit distance (Line 4). If M contains all vertices of x and y, it returns the existing distance of M (Line 5). Otherwise, it expands its state-space tree by mapping the next unmapped vertex u in x (Line 6) to each unmapped vertex v in y (Line 7). It pushes each expanded state into the queue if the edit distance of the state is not greater than τ (Lines 8–10). In the algorithm, ε is used to denote an insertion or a deletion of a vertex. If it fails to find any mapping whose edit distance is not greater than τ, it returns $\tau + 1$ (Line 11).

2.3 Related Work

Previous work on the graph similarity search utilizes small overlapping substructures to establish a filtering condition between dissimilar graphs. Motivated by the gram idea used in string similarity searches, the k-AT algorithm [19] defines a q-gram as a tree rooted at a vertex v with all vertices reachable to v in q hops. A star structure, which is 1-gram defined by k-AT, has been proposed to set up a filtering condition through bipartite matching between star structures [22]. SEGOS [20] is a two-level index structure proposed to efficiently search star structures. The main focus of these approaches has been on the filtering phase to develop efficient index-based filtering methods using those substructures.

GSimSearch [25, 26] proposed a path-based q-gram and developed an index-based filtering technique based on the observation of the algorithm called ED-join [21] in string search. To further reduce the number of candidates, GSimSearch proposed local label filtering in its verification phase. However, this technique is based on small fixed-size substructures of graphs, thus edit errors are mainly captured from label differences, and structural differences are considered inside small substructures only.

There is recent work that makes use of large disjoint substructures of graphs to capture structural differences between graphs. Pars [24] partitions data graphs into disjoint subgraphs, and makes an index on the partitioned subgraphs. Using the index, it identifies data graphs having partitions contained in the query graph, and generates them as candidate graphs. It employs a random-graph-partitioning strategy and refines initial partitioning results based on a query workload. It also dynamically rearranges indexed partitions in a restricted way while searching its index structure. MLIndex [12] was proposed to reduce the number of candidates by indexing a few alternative partitioning results of data graphs. It defines a selectivity of a partition based on vertex and edge label frequencies, and divides a graph in a way to increase selectivities of partitions. Despite the efforts in the previous approaches, their filtering power of partitions is inherently limited because partitions of data graphs are determined offline, and one or a few rigid partitionings of a data graph cannot work well for all queries.

Other related work includes Mixed [27] and LBMatrix [3]. Mixed generates candidates by using small and large disjoint substructures of a query graph. LBMatrix has proposed a q-gram-based matrix index structure that can be stored in external memory to handle very large datasets.

3 INVES: VERIFICATION FRAMEWORK

In this section, we propose the Inves verification framework aiming to efficiently verify if the GED between a pair of graphs is within a given threshold. We first introduce the partition-based verification principle, then present the details of Inves.

3.1 Partition-based Verification Scheme

Due to the high cost of GED computation, it makes the graph similarity search impractical to directly compute the GED between a candidate and the query when there are many candidates generated from an index-based filtering phase. To efficiently verify a pair of graphs, in this paper we use a partition-based lower bound of the GED between the pair before computing the exact GED. We begin with the concept of an induced subgraph for defining graph partitions, then present the verification scheme.

Definition 2 (Induced Subgrpah Isomorphism). *A graph r is induced subgraph isomorphic to another graph s, denoted as $r \sqsubseteq s$, if there exists an injection $f\colon V_r \to V_s$ such that $\forall u \in V_r$, $f(u) \in V_s \wedge L_r(u) = L_s(f(u))$ and $\forall u \in V_r$, $\forall v \in V_r$, $L_r(u,v) = L_s(f(u), f(v))$. In this case, the graph r is called an induced subgraph of s.*

Recall that the edge labeling function $L_g(u,v)$ returns a unique value λ if there is no edge between u and v in a graph g. It enables us to check the inducedness of a subgraph in Definition 2.

Example 2. *Consider the graphs p_1, p_2, and y in Figure 2. $p_1 \sqsubseteq y$, but $p_2 \not\sqsubseteq y$ because $L_{p_2}(u_4, u_6) = \lambda \neq L_y(v_3, v_5) =$ single-bond.*

Given a graph g and a vertex set $V \subseteq V_g$, there is only one induced subgraph p of g such that $V_p = V$. That is, p is uniquely identified by V. Therefore, we use V interchangeably with the induced subgraph of g defined by V.

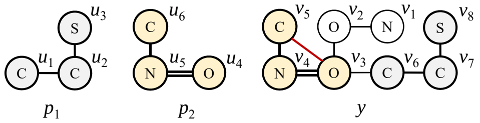

Figure 2: Induced subgraph isomorphism

Definition 3 (Graph Partitioning). *A partitioning of a graph g is $\mathcal{P}(g) = \{p_1, \ldots, p_k\}$ such that $\forall i\ p_i \sqsubseteq g$, $\forall i, j\ i \neq j \Rightarrow V_{p_i} \cap V_{p_j} = \emptyset$, and $V_g = \bigcup_{i=1}^{k} V_{p_i}$.*

Given a pair of graphs x and y, consider a partition $p \in \mathcal{P}(x)$. If $p \sqsubseteq y$, we say p is *matching* with y. Otherwise, we say p is *mismatching* with y. We also simply call p a matching (or mismatching) partition if y is clear from the context. An induced subgraph o of y such that $V_o \subseteq V_y$ is called an *occurrence* of p in y if and only if $p \sqsubseteq o$ and $o \sqsubseteq p$. In Figure 2, for example, $o = \{v_6, v_7, v_8\}$ is an occurrence of p_1 in y.

With the graph partitioning, a lower bound of the GED between a pair of graphs are calculated as follows.

Lemma 1. *Consider a pair of graphs x and y with a graph partitioning $\mathcal{P}(x)$. $lb(x,y) = |\{p \mid p \in \mathcal{P}(x) \wedge p \not\sqsubseteq y\}|$ is a lower bound of the GED between the pair.*

Proof. Since partitions of x share neither a vertex nor an edge, an edit operation on a partition does not affect to another partition. Therefore, each mismatching partition p requires at least one edit operation to transform x to y. □

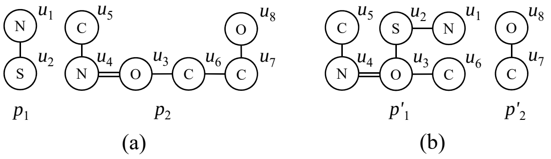
The following corollary states the partition-based verification scheme based on the lower bound in Lemma 1.

Corollary 1. *Given a GED threshold τ, consider a pair of graphs x and y with a graph partitioning $\mathcal{P}(x)$. If $lb(x,y) > \tau$, the pair can be pruned without the GED computation.*

Partition-based lower bounds and their variants have been extensively studied and discussed in the literature of string similarity search (e.g. [8, 11]) and approximate subsequence mapping (e.g. [1, 9, 10]). The same principle is well adopted in recent work for graph similarity search [12, 24, 27]. Our lower bound in Lemma 1 is a simple extension of existing partition-based approaches. While the focus of existing work is on building a partition-based inverted index for the filtering phase, our focus in this paper is on the verification phase to efficiently verify a candidate graph using the partition-based lower bound.

To obtain the lower bound in Lemma 1, we need $|\mathcal{P}(x)|$ induced subgraph isomorphism tests, which are generally NP-hard. However, former studies have empirically showed that subgraph isomorphism test is on average three orders of magnitude faster than GED computation [12, 24], and thus it can be practically used in deriving a partition-based lower bound.

Example 3. *Consider a pair of graphs x and y shown in Figure 1 with a GED threshold $\tau = 1$. If we partition x into $\{p_1, p_2\}$ as depicted in Figure 3(a), $lb(x,y) = 2$ because $p_1 \not\sqsubseteq y$ and $p_2 \not\sqsubseteq y$. Therefore, we can safely prune the pair without GED computation according to Corollary 1. If we partition x into $\{p_1', p_2'\}$ as illustrated in Figure 3(b), $lb(x,y) = 1$ since $p_1' \not\sqsubseteq y$ but $p_2' \sqsubseteq y$. Thus, we need a GED computation between the pair.*



(a) (b)

Figure 3: Two ways to partition x in Figure 1

As shown in the example above, the tightness of $lb(x, y)$ is highly dependent on the way to partition x. However, the graph partitioning problem is in general NP-hard [12, 24] and enumerating every possible partitioning to obtain an optimal partitioning is intractable. In the next section, we introduce a measure for a partitioning to develop a good partitioning technique.

3.2 A Qualitative Measure for a Partitioning

Consider a pair of graph x and y with a partitioning $\mathcal{P}(x)$. An inherent limitation of partition-based approaches is that the containment test of each partition is independent, and thus multiple partitions of x can be matching with y in overlapping areas of y. This limitation makes the partition-based bound loose. However, it is hard to tackle the problem because $lb(x, y)$ can exceed the GED if we use a non-overlapping alignment of partitions, where a mismatching partition p is allowed to be aligned to a subgraph of y whose size is less than the size of p. Finding a legal non-overlapping alignment of partitions (i.e., an alignment that results in a minimum lower bound) is computationally impractical.

Beside this fundamental limitation, the following are major problems that make the partition-based lower bound loose.

- P_1 In partition-based approaches, only one edit error is counted from a mismatching partition. A tighter bound can be calculated as $lb(x, y) = \sum_{p \in \mathcal{P}(x) \wedge p \not\sqsubseteq y} sed(p, y)$, where $sed(p, y)$ denotes the subgraph edit distance [22, 26] between p and y.
- P_2 A substructure of x that causes insertion or deletion errors can be divided into multiple partitions. In this case, those edit errors can be hidden between partitions to make the lower bound loose. They can be detected by enumerating every subgraph of x consisting of adjacent partitions, and investigating the subgraphs through subgraph edit distance computations.
- P_3 Edit errors can be buried in edges connecting different partitions and these errors also make the lower bound loose. To precisely find them, we need to solve the problem of placement of partitions into y.

Due to the complexities of subgraph edit distance and partition alignment, the problems above cannot be efficiently solved. The hardness of the limitation and problems also prevents us from accurately analyzing the tightness of $lb(x, y)$. In fact, there is no given proof on the tightness of existing partition-based bounds [6], and it is hard to measure the tightness of $lb(x, y)$ in a quantitative manner. To the best of our knowledge, the only theoretical analysis on the tightness $lb(x, y)$ is that increasing the number of partitions has more chance to get a tighter bound [12]. However, the analysis is based on an assumption that does not take the problem P_2 into consideration. In this paper, instead of a quantitative measure, we introduce a qualitative measure of goodness of a partitioning as stated in the following claim.

Claim 1. *Given two graphs x and y, a partitioning $\mathcal{P}(x)$ is a good partitioning if every mismatching partition $p \in \mathcal{P}(x)$ meets the following conditions.*

- C_1 *Edit errors in p are indivisible, or edit errors in p cannot be distributed over partitions (indivisibility). Ideally, p is minimal, that is, p loses its edit errors and become a matching partition if any vertex in p is removed (mininality).*
- C_2 *An edit error in an edge connecting p to another partition is captured by p, while preserving the condition C_1.*

The indivisibility constraint in C_1 alleviates the problem P_1 since each partition contains the least number of edit errors it can have. The minimality constraint in C_1 alleviates the problem P_2, because by removing unnecessary vertices that do not contribute to edit errors from a partition, those vertices can be combined with other vertices in another partition and cause edit errors. Claim 1 also has the condition C_2 to alleviate the problem P_3.

Although we develop a qualitative measure for a partitioning, it is hard to make a partitioning that exactly meets the measure because a graph partitioning problem even with a simple condition tends to be intractable [24]. Nonetheless, the measure can be a guideline for producing a partitioning to get a tighter bound. In the following sections, we develop a novel partitioning method based on this measure (Section 3.3 for C_1 and Section 3.4 for C_2).

3.3 Incremental Partitioning

In this section, we present a systematic way to produce mismatching partitions that approximately meet the condition C_1 in Claim 1. We begin with the definition of the incremental partitioning strategy.

Definition 4 (Incremental Partitioning). *Given two graphs x and y, an incremental partitioning of x is to extract mismatching partitions from x as follows. Let $V_x = \{u_1, \ldots, u_n\}$. We move the vertices in V_x one after another into a partition p, which is initially empty, while $p \sqsubseteq y$. Let the last vertex moved from x to p be u_l. We finally move u_{l+1} to p to make $p \not\sqsubseteq y$, and produce $\mathcal{P}(x) = \{p, x \backslash p\}$, where $x \backslash p$ denotes the induced subgraph s of x such that $V_s = V_x - V_p$. We repeat this partitioning strategy with $x \backslash p$ until either $x \backslash p \sqsubseteq y$ or $x \backslash p = \emptyset$.*

A graph partitioning produced by the incremental partitioning strategy in Definition 4 satisfies the following property.

Property 1. *Given a pair of graphs x and y, if x is partitioned into $\mathcal{P}(x) = \{p_1, \ldots, p_{k-1}, p_k\}$ using our incremental partitioning strategy, then $p_1, \ldots, p_{k-1}$ are mismatching with y and the last partition p_k, which can be empty, is matching with y. Therefore, $lb(x, y) = k - 1$.*

The following lemma states that the incremental partitioning strategy generates a partitioning that exactly meets the indivisibility constraint in the condition C_1 in Claim 1.

Lemma 2. *Given a partitioning $\mathcal{P}(x) = \{p_1, \ldots, p_{k-1}, p_k\}$ produced by the incremental partitioning strategy in Definition 4, it is not possible to divide any partition $p_i \in (\mathcal{P}(x) - \{p_k\})$ into two partitions p_{i1} and p_{i2} such that $p_{i1} \not\sqsubseteq y \ \wedge p_{i2} \not\sqsubseteq y$.*

Proof. For each $p_i = \{u_b, \ldots, u_e\}$ except p_k, our incremental partitioning scheme guarantees that $(p' = p_i - \{u_e\}) \sqsubseteq y$. Since u_e cannot be included in both p_{i1} and p_{i2}, either $p_{i1} \sqsubseteq p' \sqsubseteq y$ or $p_{i2} \sqsubseteq p' \sqsubseteq y$ should be satisfied. □

Example 4. *For a pair of graphs x and y in Figure 1, we incrementally partition x by comparing it with y as follows. Assume that vertices of x are investigated from u_1 to u_8. We first make $\mathcal{P}(x)$ by isolating $\{u_1, u_2\}$ from x into p'_1 as shown in Figure 4(a), because $(p'_1 - \{u_2\}) \sqsubseteq y$ but $p'_1 \not\sqsubseteq y$. Given two partitions of x, we further* *partition p_2 into p'_2 and p_3 by isolating a mismatching partition $\{u_3, u_4, u_5\}$ from p_2, as depicted in Figure 4(b). Since $p_3 \sqsubseteq y$, we cannot proceed the incremental partitioning. Hence, $lb(x, y) = 2$.*

Figure 4: Incremental partitioning of x in Figure 1

When the incremental partitioning strategy produces a mismatching partition, an induced subgraph isomorphism test is an essential operation. The common principle on subgraph isomorphism test is to visit vertices based on connectivity of vertices and frequencies of vertices and edges [7, 16]. Following the existing solutions, we investigate vertices of x by considering infrequent vertices and edges early while preserving the connectivity.

Given a mismatching partition p in $\mathcal{P}(x)$ generated from the incremental partitioning strategy, we can find an induced subgraph of p that meets the minimality constraint in the condition C_1 as follows. Since the last vertex in p causes the mismatch, we enumerate every induced subgraph of p containing the last vertex and perform an induced subgraph isomorphism test against y to find a subgraph s such that $s \not\sqsubseteq y$ and $|V_s|$ is minimum. This process is obviously time consuming. Instead of finding a minimal one, we propose a method that refines a mismatching partition in $\mathcal{P}(x)$ to approximately meet the minimality constraint.

After we find a mismatching partition p, we rematch p against y using an alternative vertex ordering of p to remove unnecessary vertices from p that do not contribute to edit errors. Let the mismatching partition p be $\{u_1, \ldots, u_f\}$. Because $\{u_1, \ldots, u_{f-1}\}$ is matching with y by Definition 4, u_f causes the mismatching and edit errors are likely to be clustered in u_f and vertices adjacent to u_f. Therefore, by using the vertex u_f as the start vertex and reordering p in the same way (i.e., considering infrequent vertices and edges early while preserving the connectivity), we have a chance to reduce the size of the mismatching partition. The following example illustrates rematching of a mismatching partition to reduce the size of the mismatching partition.

Example 5. *Consider a pair of graphs x and y in Figure 5. Assume the vertices of x is ordered as $\{u_1, u_2, u_3, u_4, u_5, u_6\}$. Based on the order, we isolate $\{u_1, u_2, u_3, u_4\}$ into a separate partition p. In this case, $x \backslash p$ is matching with y and $lb(x, y) = 1$. We reorder vertices in the mismatching partition p into $\{u_4, u_3, u_2, u_1\}$ by using u_4 as the first vertex and preserving the connectivity of the vertices. By rematching p against y using the vertex ordering, we reduce the mismatching partition p to $\{u_4, u_3\}$. From $x \backslash p$, in this case, we can find one more mismatching partition $\{u_1, u_5\}$, which is refined from $\{u_1, u_2, u_5\}$ by the rematching method, and obtain a tighter bound $lb(x, y) = 2$.*

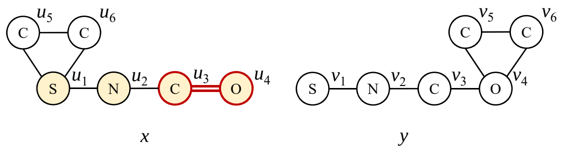

Figure 5: Rematching a mismatching partition

Table 2: Average number of rematching

GED threshold τ	1	2	3	4	5
AIDS	1.41	1.36	1.37	1.38	1.38
PROTEIN	1.50	1.81	1.76	1.69	1.59
PubChem	1.56	1.50	1.47	1.46	1.46

To further reduce the size of a mismatching partition, we repeat rematching while the partition size decreases. As the edit errors are likely to be clustered around the last vertex, we can expect that subgraph isomorphism tests are terminated early and the number of rematching is very small. Table 2 shows the average number of rematching for AIDS, PROTEIN, and PubChem datasets when extracting a mismatching partition (see Section 5 for details of the datasets and queries).

13 return 1+IncrementalPartitioning($x'$, $y$);
```

Algorithm 2 outlines the incremental partitioning algorithm. Given a pair of graphs x and y, the algorithm computes the lower bound $lb(x, y)$ by partitioning x based on the condition C_1 in Claim 1. It first determines the vertex ordering of x using DetermineVertexOrdering (omitted, Line 1) and then perform an induced subgraph isomorphism test of x against y based on the ordering (Line 2). InducedSI, which will be presented at the end of the next section, identifies and returns the least vertex position in x that makes the matching fail. If the position is greater than the number of vertices in x, then $x \sqsubseteq y$, and return $lb(x, y) = 0$ (Line 3). Otherwise, it extracts the vertices causing the mismatch into a partition p (Line 4).

The algorithm reduces the size of the mismatching partition p using the rematching method (Lines 5–9). DetermineRematchingOrdering (omitted, Line 6) is the same with DetermineVertexOrdering except that it uses the last vertex in p as the start vertex. After reordering vertices in p, the algorithm rematches p against y (Line 7). It repeats rematching while the size of the mismatching partition p shrinks (Line 9). The algorithm finally detaches p from x to make x' (Line 10).

After isolating a mismatching partition p from x, the remaining part of x, which is x', often forms a disconnected graph. We observed that a tiny connected component in a disconnected graph can cause a serious performance problem in subgraph isomorphism test. The existing subgraph isomorphism algorithms assume connected graphs, and thus they do not pay attention to this problem. To prevent this worst case in subgraph isomorphism test, the algorithm removes each tiny connected component c from x' such that $|V_c| \leq \alpha$, where α is a tunable parameter (Lines 11–12). Then, it recursively identifies the number of mismatching partitions in x' and returns $lb(x, y)$ (Line 13).

Correctness and Complexity of Algorithm 2: Whenever a mismatching partition is identified, the algorithm increments the lower bound by 1 (Line 13). Therefore, the algorithm correctly returns a lower bound by Lemma 1. Assuming the number of rematching is bound to a constant, the worst case complexity is $\sum_{p \in \mathcal{P}(x)} O((\gamma_p \cdot \gamma_p)^{|V_p|}) = O((\gamma_x \cdot \gamma_x)^{|V_x|})$, which is the same as traditional subgraph isomorphism, where γ_g denotes the maximum vertex degree in a graph g.

3.4 Exploiting Bridges

In this section, we propose a novel technique to detect and exploit edit errors buried in those edges connecting different partitions. With the proposed technique, we develop the *bridge constraint* to meet the condition C_2 in our qualitative measure. We first define bridge and then present formulas to count edit errors in bridges.

Definition 5 (Bridge). *Given a partition p, a bridge of a vertex $u \in p$ is an edge connecting u to a vertex $u' \notin p$.*

Lemma 3. *Given a partition p of a graph x and an occurrence o of p in another graph y, suppose a vertex $u \in p$ is mapped to a vertex $v \in o$.*

(1) The number of edit errors between bridges of u and v is

$$\mathcal{B}_e(u, v) = \Gamma(L_{br}(u), L_{br}(v)),$$

where $L_{br}(w)$ denotes the label multiset of the bridges of a vertex w, and $\Gamma(A, B)$ is $\max(|A - B|, |B - A|)$.

(2) The number of edit errors in bridges of p with respect to o is

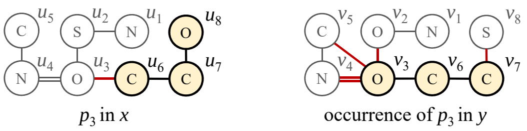
$$\mathcal{B}(p, o) = \mathcal{B}(M) = \sum_{u \to v \in M} \mathcal{B}_e(u, v),$$

where M denotes the vertex mapping between p and o, which are identified during induced subgraph isomorphism test of p.

Proof. (1) Let $D_1 = L_{br}(u) - L_{br}(v)$ and $D_2 = L_{br}(v) - L_{br}(u)$, and assume $|D_1| \geq |D_2|$. To transform $L_{br}(u)$ to $L_{br}(v)$, we need $|D_2|$ substitutions of labels in D_1 and $|D_1| - |D_2|$ deletions of labels in D_1. That is, we need $|D_2| + |D_1| - |D_2| = |D_1| = \Gamma(L_{br}(u), L_{br}(v))$ edit operations. (2) Since no bridge can shared by multiple vertices in p by Definition 5, the number of edit errors in p is the sum of the number of edit errors in the bridges of p. □

The following example illustrates the number of edit errors in bridges of a matching partition.

Example 6. *In Example 4, consider the matching partition $p_3 = \{u_8, u_7, u_6\}$ and its occurrence $o = \{v_3, v_6, v_7\}$ in y as shown in Figure 6. $\mathcal{B}_e(u_8, v_3) = 3$ because u_8 has no bridge while v_3 has 3 bridges. Likewise, $\mathcal{B}_e(u_7, v_6) = 0$ and $\mathcal{B}_e(u_6, v_7) = 0$. Therefore, $\mathcal{B}(p_3, o) = 3 + 0 + 0 = 3$.*



p_3 in x

occurrence of p_3 in y

Figure 6: Bridge errors of a matching partition in Figure 4

Given two partitions p and p' of a graph x, suppose that a bridge e connecting p and p' causes one edit error with respect to another graph y. When we count edit errors in bridges of x, the edit error in e is counted twice (i.e., once in p and once in p'). Hence, we can use half of the edit errors counted in bridges so that we do not over-count edit errors in x. Lemma 4 formally states this observation.

Lemma 4. *Given a pair of graphs x and y, consider a matching partition p in x and an occurrence o of p in y. The mapping between p and o causes at least $\lfloor \mathcal{B}(p, o)/2 \rfloor$ edit errors.*

Proof. In this proof, we consider deletion or substitution errors of bridges in x only. Insertion of bridges to x can be proved similarly. Consider we have a partitioning of x such that the i^{th} partition p_i has e_i bridges. Since each bridge is shared by two partitions, bridges should be distributed in a disjoint manner. We distribute bridges to each partition using the following procedure.

```
initially, all bridges are unassigned;
$p$ ← an arbitrary partition;
while there is an unassigned bridge in $x$ do
    if no unassigned bridge is connected to $p$ then
        $p$ ← an arbitrary partition to which at least one
          unassigned bridge connected;
    $e$ ← an unassigned bridge connected to $p$;
    assign $e$ to $p$;
    $p$ ← the partition connected to $p$ via $e$;
```

The procedure above guarantees that at least $\lfloor e_i/2 \rfloor$ bridges are assigned to p_i because if a partition loses a bridge, another bridge (if exists) is always assigned to the partition. If we consider bridges causing edit errors only (i.e., each of e_i bridges causes an edit error), p_i has at least $\lfloor e_i/2 \rfloor$ edit errors. Since there are $\mathcal{B}(p, o)$ edit errors in the bridges connected to p, we can always assign at least $\lfloor \mathcal{B}(p, o)/2 \rfloor$ edit errors to p using the procedure. □

By pushing edit errors in bridges into a matching partition, we can make a rigorous partition matching condition called the bridge constraint as follows.

Corollary 2. *Given a partition p of a graph x and another graph y, p is matching with y if and only if there exists an induced subgraph o of y such that $V_o \subseteq V_y$, $o \sqsubseteq p$, $p \sqsubseteq o$, and $\mathcal{B}(p, o) < 2$.*

Example 7. *In Example 6, since o is the only occurrence of p_3 in y and $\mathcal{B}(p_3, o) \geq 2$, p_3 is mismatching with y by Corollary 2. Therefore, in Example 4, the graph x is divided into four partitions (three mismatching partitions and one empty partition), and we obtain a tighter lower bound $lb(x, y) = 3$.*

Notice that our bridge constraint detects edit errors much more accurately than the half-edge subgraph isomorphism used in existing techniques [12, 24]. For example, in Example 6 and 7, existing techniques cannot detect any edit errors in p_3 (we omit the precise comparison in the interest of space; refer to Pars[24] for the details of the half-edge subgraph isomorphism).

By integrating the bridge constraint with the induced subgraph isomorphism test, we can detect a mismatching partition early to approximately preserve the indivisibility and minimality constraints in C_1 of Claim 1. Algorithm 3 encapsulates our induced subgraph isomorphism test with the bridge constraint.

Algorithm 3: InducedSI(x, y, M)

```
input  : $x$ and $y$ are graphs;
         $M$ is a mapping vector (initially $\emptyset$).
output : the least position in $x$ where the matching fails.
1  $iteration \leftarrow |M| + 1$;
2  if $iteration > |V_x|$ then return $iteration$ ;
3  $u \leftarrow$ the $iteration^{th}$ vertex in $V_x$;
4  $C \leftarrow \{v \mid v \in y \wedge v \notin M \wedge L_x(u) = L_y(v)\}$;
5  foreach $v \in C$ do
6      if $\forall u' \rightarrow v' \in M\ L_x(u, u') = L_y(v, v')$ and
       $\mathcal{B}(M \cup \{u \rightarrow v\}) < 2$ then
7          $depth \leftarrow$ InducedSI($x$, $y$, $M \cup \{u \rightarrow v\}$);
8          if $iteration < depth$ then $iteration \leftarrow depth$;
9          if $iteration > |V_x|$ then return $iteration$;
10 return $iteration$;
```

Like most existing subgraph isomorphism techniques, our algorithm also adopts the Ullmann's algorithm [18] with a difference that ours returns the least vertex position in a partition where the induced subgraph isomorphism test fails. Given a pair of graphs x and y, the algorithm maps the vertices in x one by one to find a mapping M between x and y. For the current vertex u of x (Line 3), it enumerates all unused vertices $v \in y$ whose label is equivalent to the label of u (Line 4), and test if the vertex mapping $u \rightarrow v$ is valid (Lines 6). Then, the bridge constraint in Corollary 2 is applied to the vertex mapping $M \cup \{u \rightarrow v\}$ (Line 6). If it is a valid mapping, the algorithm goes down to the next vertex of x (Line 7). It keeps track of the least position (or maximum iteration count) in x where the induced subgraph isomorphism will fail (Lines 1, 8), and returns the position if $x \not\sqsubseteq y$ (Line 10). If $x \sqsubseteq y$, the algorithm returns $|V_x| + 1$ (Lines 2, 9).

Example 8. *Given a pair of graph x and y depicted in Figure 7, consider we perform* InducedSI$(x, y, \emptyset)$. *Let us assume the vertex ordering of x is from u_1 to u_6. At the first iteration,* InducedSI *adds $u_1 \rightarrow v_7$ into M, and considers $u_2 \rightarrow v_2$ at the second iteration. Because $L_x(u_2, u_1) = L_y(v_2, v_7)$ and $\mathcal{B}(\{u_1 \rightarrow v_7\} \cup \{u_2 \rightarrow v_2\}) = 1$, it adds $u_2 \rightarrow v_2$ into M. At the third iteration, it maps the next vertex u_3 to v_3, and checks the inducedness: $L_x(u_3, u_1) = L_y(v_3, v_7) = \lambda$ and $L_x(u_3, u_2) = L_y(v_3, v_2)$. Then, it tests the bridge constraint and fails to find an occurrence because $\mathcal{B}(\{u_1 \rightarrow v_7, u_2 \rightarrow v_2\} \cup \{u_3 \rightarrow v_3\}) = 2$. Therefore, it returns its iteration count 3, which denotes $\{u_1, u_2, u_3\}$ is a mismatching with y.*

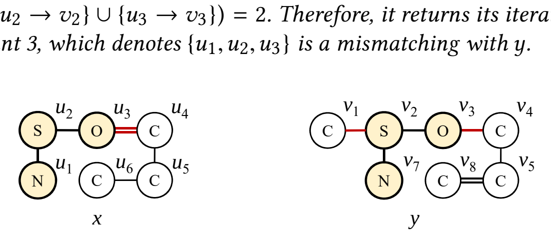


Figure 7: Example of InducedSI

Correctness of Algorithm 3: Given two vertices u and v in a graph g, $L_g(u, v)$ returns a unique value λ when there is no edge between u and v. Therefore, it correctly checks the inducedness of x in Line 6. Mismatching caused by bridge differences is also detected from Line 6, where the correctness is guaranteed by Corollary 2. Because the algorithm basically follows Ullmann's algorithm except the test of inducedness, it correctly computes the induced containment of x. It can be inductively verified the algorithm correctly returns the least position where the isomorphism test fails.

3.5 Verification Algorithm

In this section, we provide Inves verification algorithm. Given a pair of graph x and y and a GED threshold τ, Inves incrementally partitions x to obtain a GED lower bound, and prune the pair if the lower bound is greater than τ. Otherwise, Inves directly calculates the GED between x and y.

Algorithm 4: InvesVerifier(x, y, τ)

```
input  : $x$ and $y$ are graphs; $\tau$ is a GED threshold.
output : a boolean value of $ged(x, y) \leq \tau$
1  if $\Gamma(L_V(x), L_V(y)) + \Gamma(L_E(x), L_E(y)) > \tau$ then
2      return false;
3  $lb \leftarrow$ IncrementalPartitioning($x$, $y$);
4  if $lb > \tau$ then return false;
5  $p \leftarrow$ the last partition of $\mathcal{P}(x)$;
6  if $|V_p|/|V_x| > \beta$ then
7      $M \leftarrow$ vertex mapping between $V_p$ and $V_y$;
8      if GEDPartial($M, x, y, \tau$) $\leq \tau$ then return true;
9  return GED($x, y, \tau$) $\leq \tau$;
```

Algorithm 4 shows the details of Inves verification algorithm. Using the label differences of vertices and edges, it first computes a loose GED lower bound and prune the pair if the bound is greater than τ, where $L_V(g)$ and $L_E(g)$ denote the label multisets of vertices and edges in a graph g respectively (Lines 1–2). This technique is originated from the letter-count filter in the problem of DNA read mapping [1, 4] and exploited recently in graph similarity search as a name of the global label filter [25]. Because the global label filter is very simple and highly selective, it is essentially used in graph similarity search (e.g., [24, 25]). After applying the global label filter, Algorithm 4 uses IncrementalPartitioning presented in Algorithm 2 to obtain a partition-based lower bound (Line 3). If the lower bound is greater than τ, it prune the pair (Line 4). We remark that it is obviously optimized by pushing the threshold into IncrementalPartitioning and terminating the partitioning process as soon as $\tau + 1$ mismatching partitions are found.

If the algorithm fails to prune the pair, the last partition $p \in \mathcal{P}(x)$, which can be an empty partition, is matching with y according to Property 1 (Line 5), and a vertex mapping M between p and y is obtained from InducedSI (Line 7). The algorithm exploits this mapping to compute the GED by using it as the initial state of the A* algorithm (i.e., pushing the mapping into the queue instead of an empty mapping in Line 2 of Algorithm 1) (GEDPartial, Line 8). This procedure is called a *partial GED computation.* Notice that the distance calculated by the partial GED computation is an upper bound of the GED of the pair. If it finds the pair meets τ through the partial GED computation, therefore, it can save the time for traversing vertices in M. To prevent frequent invocations of partial GED computation for false positives, we use the partial GED computation only when the size of matching partition is big enough (the tunable parameter β in Line 6). If it fails to identify if $ged(x, y) \leq \tau$ from the partial GED computation, it finally performs a full GED computation between x and y (Line 9).

Correctness of Algorithm 4: It can be seen GEDPartial correctly returns a GED upper bound. Hence, the correctness of the algorithm is guaranteed by Lemma 1 and Corollary 1.

4 INVES: EFFICIENT GED COMPUTATION

In this section, we develop new methods on top of Algorithm 1 to improve the performance of GED computation. We first propose a method to accurately calculate an estimated distance of a vertex mapping. We then propose a vertex ordering technique that takes advantage of the partitioning results of InvesVerifier.

The performance of the A* algorithm in Algorithm 1 depends on the accuracy of an estimated distance of unmapped vertices and edges. Riesen et al. proposed a bipartite heuristic [14], which gives a lower bound of the distance between unmapped parts with bipartite matching. GSimSearch [25, 26] show that the lower bound of the bipartite heuristic is exactly the same as the label difference in unmapped parts in the unweighted case. This approach does not improve the accuracy of the estimation, but it is significantly faster than the bipartite heuristic because the bipartite heuristic uses the Hungarian algorithm [13] with a high complexity of $O(n^3)$.

To improve the accuracy of the estimated distance, in this paper we distinguish bridges of mapped vertices (i.e., edges connecting mapped vertices to unmapped vertices) from unmapped edges. For a vertex mapping M, each $u \to v \in M$ has $\mathcal{B}_e(u, v)$ edit errors in bridges. Since two different mapped vertices in a graph cannot share any bridges, the total edit errors in the bridges of M are $\mathcal{B}(M)$. Therefore, the estimated distance of M, denoted by $h(M)$, can be calculated by the sum of $\mathcal{B}(M)$ and the label difference in unmapped vertices and unmapped edges except bridges. Formally:

$$h(M) = \mathcal{B}(M) + \Gamma(L_V(x'), L_V(y')) + \Gamma(L_E(x'), L_E(y')),$$

where x' and y' respectively denote the unmapped part of x and y except bridges. The following example illustrates that our method accurately calculates an estimated distance.

Example 9. For the graphs x and y in Figure 8, consider a vertex mapping $\{u_1 \to v_1, u_2 \to v_2, u_3 \to v_3, u_4 \to v_4\}$ is given. The existing distance in the mapping is 1 (due to the label difference between u_2 and v_2). The estimated distance can be calculated in the following two different ways, where the first is the technique used in the previous work while the second is ours.

(1) If we use the label difference of unmapped parts of x and y, we calculate an estimated distance 1 because x has one more single bond (u_5, u_7) in its unmapped part.
(2) If we use the bridge method, the number of edit errors in the bridges is 2 because $\mathcal{B}_e(u_2, v_2) = 1$ and $\mathcal{B}_e(u_4, v_4) = 1$. By using the label difference of the unmapped vertices and the unmapped edges except the bridges, we get an additional edit error 1. By adding the two distances from the bridge method and label filtering, the estimated distance becomes 3.

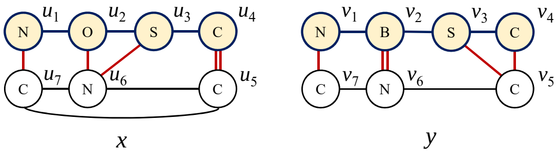

Figure 8: Estimating distance using bridges

The second method is to reorder vertices of the graph x (Line 1 in Algorithm 1). Similar to the problem of subgraph isomorphism, a proper vertex order is also crucial in the GED computation. Since most candidates generated from the filtering phase are false positives, we limit our discussion here to a false positive only (i.e., $ged(x, y) > \tau$). In general, as a vertex mapping M contains more edit errors, the search space of A* algorithm is reduced. For example, consider all edit errors in M and there is no edit error in the remaining vertices and edges. In this case, the A* algorithm can abandon M immediately. To make M contain as many edit errors as possible, therefore, we first consider vertices and edges causing edit errors by placing vertices in the mismatching partitions in the front positions. Since our partitioning method makes the size of a mismatching partition as small as possible, the A* algorithm accurately identifies many edit errors at higher levels of the state-space tree. It is worth noting that our first method is essential to detecting edit errors in those mismatching partitions isolated due to edit errors in bridges.

```
Algorithm 5: GEDVertexOrder($\mathcal{P}(x)$)
  input  : $\mathcal{P}(x)$ is the partitioning result of $x$.
  output : $O$ is an ordered set of vertices in $x$
1 $O \leftarrow \emptyset$;
2 foreach mismatch partition $p \in \mathcal{P}(x)$ do  $O \leftarrow O \cup V_p$;
3 DetermineVertexOrdering($O$);
4 $O \leftarrow O \cup V_x \backslash O$;
5 Return $O$;
```

Another consideration is the connectivity among vertices traversed by the A* algorithm. To reduce the search space, it is important to select the next vertex (Line 8 of Algorithm 1) that is connected to a vertex in M. Algorithm 5 is the vertex ordering algorithm. It first pushes vertices in mismatching partitions to O (Lines 1–2). Then, it orders the vertices in O using DetermineVertexOrdering, which traverses the vertices as described in Section 3 (Line 3). It finally places the remaining vertices (i.e., vertices in a matching partition) at the end (Line 4).

5 EXPERIMENTS

5.1 Experimental Setup

We used the following public real datasets.

- AIDS is an antiviral screen compound dataset containing 42, 687 chemical compounds, published by National Cancer Institute[2]. The dataset contains graphs with large size variation. It is a popular benchmark used in many graph search techniques.
- PROTEIN is a protein dataset from the Protein Data Bank[3], containing 600 protein structures. It contains denser and less label-informative graphs.
- PubChem is a chemical compound dataset from the PubChem Project[4]. We used a subset of PubChem consisting of 22, 794 chemical compounds. Graphs in the PubChem dataset contain repeating substructures and have less size variation compared with the AIDS and PROTEIN datasets.

Table 3 summarizes the datasets, where N_{L_v} and N_{L_e} denote the number of distinct vertex and edge labels in the dataset, respectively.

Table 3: Statistics of datasets

Dataset	$\lvert\mathcal{D}\rvert$	$\lvert V\rvert_{\text{avg}}$	$\lvert E\rvert_{\text{avg}}$	$\lvert V\rvert_{\text{max}}$	$\lvert E\rvert_{\text{max}}$	N_{L_v}	N_{L_e}
AIDS	42,687	25.60	27.60	222	247	62	3
PROTEIN	600	32.63	62.14	126	149	3	5
PubChem	22,794	48.11	50.56	88	92	10	3

For the scalability test, we also used synthetic datasets (see Section 5.3). For each dataset, we conducted experiments using a workload of 100 queries graphs randomly sampled from the dataset[5]. Candidates requiring GED computation, query response time, incremental partitioning time, and GED computation time are measured and reported on the basis of these 100 queries.

All experiments were run on a machine with 32GB RAM, and an Intel core i7 at 3.4 GHz, running a 64-bit Ubuntu OS. We implemented Inves in C++, and compiled it using GCC 4.4.3 with the -O3 flag[6]. By scanning each dataset once, we pre-computed vertex and edge frequencies, label multisets of vertices and edges of each graph, and the label multiset of edges connected to each vertex. This pre-computation was performed offline and excluded from the query time.

5.2 Evaluating Optimization Methods in Inves

We first evaluated various optimization methods used in Inves. Since the technique is orthogonal to how candidates are generated, we scanned each dataset, and directly applied InvesVerifier on each graph to measure the query time. Notice that y-axis is log-scaled in all experiments.

5.2.1 Methods in Incremental Partitioning.

5.2.1 Methods in Incremental Partitioning. Figure 9(a) and (d) show the effect of the bridge constraint on the AIDS and PubChem datasets. -BR is the InducedSI without the bridge constraint in Corollary 2, and +BR denotes the case where the bridge constraint is added to InducedSI. +BR significantly improved the performance by utilizing differences of bridges connecting different partitions. For example, GED computation time was reduced by 2.4 times on the AIDS dataset and 3.3 times on the PubChem dataset when $\tau = 4$. The significant improvement can be explained by the number of candidates requiring GED computation. Table 4 shows the results on the AIDS and PubChem datasets. As shown in the table, +BR substantially reduced the size of the candidates requiring GED computation.

Table 4: Bridge constraint (number of candidates)

GED threshold (τ)		1	2	3	4	5
AIDS	−BR	135	517	4,686	21,780	60,443
	+BR	125	253	1,086	6,902	30,565
PubChem	−BR	226	397	1,138	5,827	25,354
	+BR	219	369	838	3,675	16,907

Figure 9(b) and (e) show the effect of the partition rematching method on the AIDS and PubChem datasets, where +RM and -RM denotes the results with and without the partition rematching method, respectively. On the PubChem dataset,+RM significantly reduced the GED computation time. For example, the GED time of +RM was about 10, 6, 5, 6, and 3 times faster than -RM for $\tau \in [1, 5]$, respectively. Table 5 shows the number of candidates requiring GED computation with and without the rematching method. Interestingly, the number of candidates reduced by +RM was smaller than that of +BR, while +RM achieved a higher performance gain on GED computation. This is because, although -BR does not use the bridge constraint, the bridge errors are considered in our GED algorithm and those false positives having bridge errors are quickly pruned when computing GED. It can also be explained by the size of mismatching partitions. Since the rematching method reduces the size of mismatching partitions,

[5] For the PubChem dataset, we manually replaced a few queries because existing techniques did not evaluate those queries in a reasonable amount of time.

(b) Bridge method (AIDS)

(c) Reordering method (AIDS)

(d) Partial GED (PubChem)

(e) Bridge method (PubChem)

(f) Reordering method (PubChem)

Figure 10: Evaluating optimization methods in Inves GED computation

A* algorithm can identify more edit errors at higher levels of the state-space tree and prune false positives early. Table 6 shows average sizes of mismatching partitions on the PubChem dataset.

Table 5: Partition rematching (number of candidates)

GED threshold (τ)		1	2	3	4	5
AIDS	−RM	129	279	1,451	8,807	36,265
	+RM	125	253	1,086	6,902	30,565
PubChem	−RM	223	384	951	4,184	18,322
	+RM	219	369	838	3,675	16,907

Table 6: Average mismatching partition size (PubChem)

GED threshold (τ)	1	2	3	4	5
−RM	4.49	17.93	27.34	33.79	37.73
+RM	1.78	9.13	18.28	26.5	31.69

On the AIDS dataset, however, +RM slightly degraded the overall performance because the GED computation on the AIDS dataset is much faster than that on the PubChem dataset and the rematching overhead of +RM is greater than the performance gain on GED computation. From the experiments, we observed that the rematching method should be used for steady performance even though it increases the partitioning time.

Figure 9(c) and (f) show the effect of the tunable parameter α described in Algorithm 2 in Section 3.3. As shown in the figure, tiny connected components greatly degraded the partitioning performance. Without the worst-case prevention method, the partitioning was extremely slow on the PubChem dataset and it did not finish in a reasonable amount of time. For this reason, we omit the result for $\alpha = 0$ in Figure 9(f). Based on the experiment, we used $\alpha = 1$ for the AIDS dataset and $\alpha = 4$ for the PubChem dataset. We performed similar experiments on the PROTEIN dataset, and chose $\alpha = 1$.

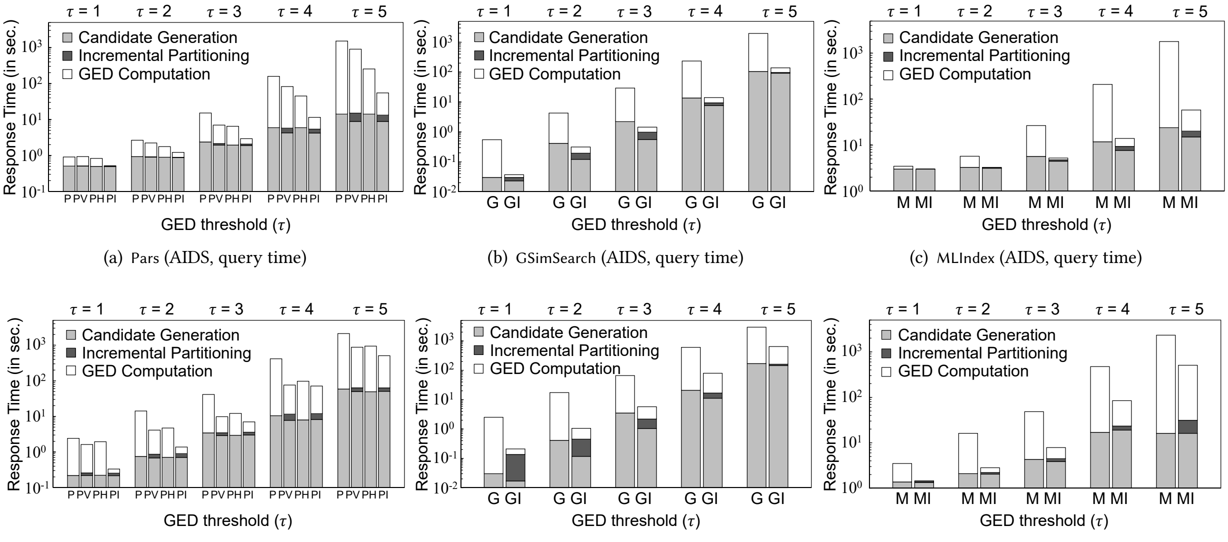
5.2.2 Methods in GED Computation. Evaluation results of the GED computation methods on the AIDS and PubChem datasets are shown in Figure 10. Figure 10(a) and (d) show the effect of the partial GED computation, where -PA and +PA denote InvesVerifier with and without this method, respectively. In our experiments, we observed that the tunable parameter β in InvesVerifier is relatively insensitive, and used $\beta = 0.7$ (we omit the results in the interest of space). +PA showed a good performance for low GED thresholds on both datasets. When a GED threshold was low, most candidates were answers, thus we had more chances to find an answer through a partial GED computation. As the threshold increased, however, most query time was spent on verifying false positives, and this method provided a marginal benefit only.

Figure 10(b) and (e) show the experimental results of our GED computation method with and without exploiting bridge errors, which are denoted by +BR and -BR, respectively. By precisely calculating edit errors in bridges, +BR reduced GED computation time up to 7 times on both datasets.

Figure 10(c) and (f) show the evaluation results of alternative vertex orderings. VO, PO, and CO denote the original vertex order, the vertex order considering vertices in mismatching partitions first, and the vertex order considering connectivity of vertices in Algorithm 5, respectively. PO significantly outperformed VO on both datasets. For example, PO is about 1.5 to 3 times faster than CO on the AIDS dataset. The performance on the PubChem dataset was extremely poor when VO was used. For example, VO was about 100 times slower than PO when $\tau = 3$. This is because the dataset contains graphs having repeating substructures, and thus the A* algorithm cannot efficiently prune the state-space tree without a proper vertex ordering. Considering the connectivity of vertices in different partitions, CO exhibited best performance for all the GED thresholds on both datasets.

5.3 Improving existing techniques

In this experiment, we evaluated how Inves can be adopted by existing techniques to improve their performance. We chose three representative techniques:



(a) Pars (AIDS, query time)

(b) GSimSearch (AIDS, query time)

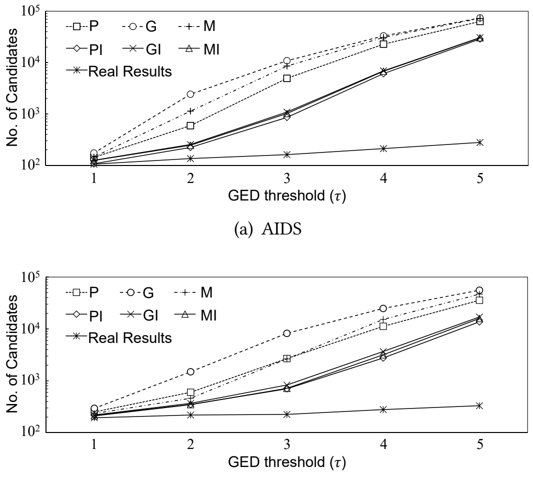
(c) MLIndex (AIDS, query time)

(d) Pars (PubChem, query time)

(e) GSimSearch (PubChem, query time)

(f) MLIndex (PubChem, query time)

Figure 11: Improvement of existing techniques



(a) AIDS

(b) PubChem

Figure 12: Number of candidates

(1) GSimSearch, labeled as G in figures, is a path-based q-gram approach proposed in [25, 26]. According to the results of [25], we used $q = 4$ for the AIDS dataset and $q = 3$ for the PROTEIN dataset. We conducted experiments on gram lengths for the PubChem dataset, and used $q = 4$ based on the results.

(2) Pars, labeled as P, is the state-of-the art partition-based approach [24]. For best performance, we improved Pars in the following ways. Since sequential scanning of indexed partitions was very slow, we implemented an index access method by modifying the SwiftIndex [16]. After we generated candidates using the index access method, we applied their recycling subgraph isomorphism test to each candidate. We also improved its verification process by using the local label filtering and the vertex ordering based on mismatching q-grams proposed in GSimSearch.

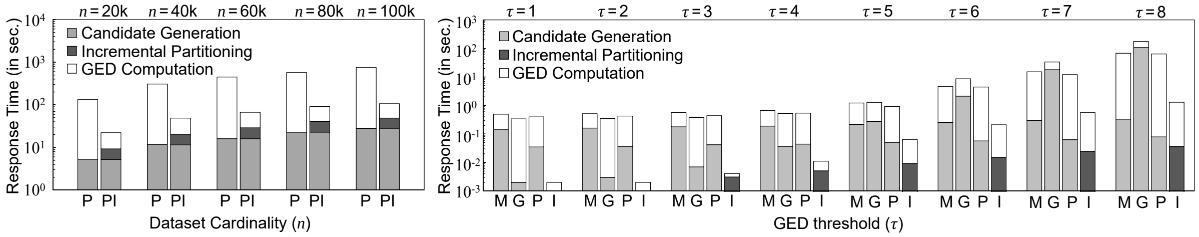
(3) MLIndex, labeled as M, is a multi-layered index technique proposed in [12]. We also improved MLIndex in the same way as Pars.

For each of the three implemented techniques, we adopted Inves in their verification phase. We labeled the corresponding improved techniques as PI, GI, and MI, respectively. We did not include other existing techniques such as c-star [22], SEGOS [20] and k-AT [19] since GSimSearch and Pars consistently outperformed these techniques [24–26]. We also excluded Mixed [27] because its performance results showed no significant differences with the performance of GSimSearch as reported in [3].

Figure 11 shows the results on the AIDS and PubChem datasets (see Figure 13(b) for the results of the PROTEIN dataset). In Figure 11(a) and (d), PV and PH denote Pars with the proposed verifier (without our GED computation methods), and Pars with the bridge method for GED (without the incremental partitioning), respectively. As shown in Figures 11, Inves improved the performance of all these three existing techniques by up to an order of magnitude. The significant improvement can be explained by the results of PV, PH, and PI in Figure 11(a) and (d). Both our partitioning and GED computation methods significantly reduced the total search time. When the incremental partitioning and GED computation methods are used together, the overall performance improvement was even more. In Figure 11(a), for example, when $\tau = 4$, PV was about 2 times faster than P, and PH was about 4 times faster than P. PI was about 25 times faster than P. Similar results were also observed on GSimSearch and MLIndex. Another important indicator of the improvement is the number of candidates requiring GED computation. As shown in Figures 12, Inves generated much smaller sets of candidates for the AIDS and PubChem datasets.

Scalability tests: We also evaluated the scalability of the proposed technique, on both the PROTEIN dataset and synthetic datasets generated by a graph generator[7]. The generator measured the graph size in terms of the number of edges ($|E|$), and

[7] GraphGen (http://www.cse.ust.hk/graphgen/) is a popular graph generator widely used in related work (e.g., [12, 24, 26]) for scalability tests.



(a) Dataset cardinality (Synthetic, $\tau = 3$)

(b) GED threshold (PROTEIN)

Figure 13: Evaluating scalability

the density of a graph defined as $d = 2|E|/|V|(|V| - 1)$. We used $|E| = 20$ and $d = 0.3$ for the experiments, which were default values of the generator. The cardinality of vertex and edge label domains were set to 2 and 1, respectively. Figure 13(a) shows the results. To evaluate the scalability, we generated five synthetic datasets consisting of 20k, 40k, 60k, 80k, and 100k graphs. In the experiments, 100 query graphs were randomly sampled from each dataset and the GED threshold was fixed as 3. The query time grew steadily and the growth ratios of query times were similar in P and PI.

Figure 13(b) shows the scalability results of the GED threshold. Because the PROTEIN dataset contains dense graphs, we chose the dataset to increase τ up to 8. Since the dataset contains 600 graphs only, we separately ran Inves, denoted by I in the figure, by scanning all the data graphs. As shown in the figure, Inves scaled best in terms of response time and outperformed existing techniques by up to about 65 times.

6 CONCLUSIONS

In this paper, we developed a novel technique called Inves for verifying if the graph edit distance (GED) between two graphs is within a threshold, an important and expensive step in graph similarity search. Its main idea is to judiciously and incrementally partition a candidate graph based on the query graph, and use the results to compute a lower bound of their distance. If a full GED computation is needed, Inves utilizes the collected information, and uses novel methods and an A* algorithm to search in the space of possible vertex mappings between the graphs to compute their GED efficiently. We presented a full specification of the technique, and conducted extensive experiments on both real and synthetic datasets. The results showed that the technique can significantly improve the performance of existing techniques [12, 24–26] by an order of magnitude.

ABSTRACT

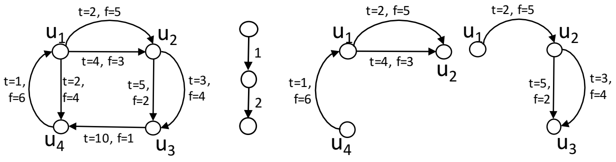
Many real-world phenomena are best represented as interaction networks with dynamic structures (e.g., transaction networks, social networks, traffic networks). Interaction networks capture flow of data which is transferred between their vertices along a timeline. Analyzing such networks is crucial toward comprehending processes in them. A typical analysis task is the finding of motifs, which are small subgraph patterns that repeat themselves in the network. In this paper, we introduce *network flow motifs*, a novel type of motifs that model significant flow transfer among a set of vertices within a constrained time window. We design an algorithm for identifying flow motif instances in a large graph. Our algorithm can be easily adapted to find the top-k instances of maximal flow. In addition, we design a dynamic programming module that finds the instance with the maximum flow. We evaluate the performance of the algorithm on three real datasets and identify flow motifs which are significant for these graphs. Our results show that our algorithm is scalable and that the real networks indeed include interesting motifs, which appear much more frequently than in randomly generated networks having similar characteristics.

1 INTRODUCTION

Interaction networks include a large number of highly connected components that dynamically exchange information. Examples of such graphs are neural networks, food webs, signal transfer pathways, the bitcoin network, social networks, and traffic networks. An interaction network captures *flow of data* (e.g., money, messages, passengers, etc.) which is transferred between its vertices along a timeline. In such a network, there could be multiple edges connecting the same pair of vertices, modeling data exchange between them at different times. Figure 1(a) shows a small example of an interaction network, where the vertices represent users who exchange money. The edges are annotated by timestamped interactions; e.g., edge u_1u_2 with label $t = 2, f = 5$ denotes that user u_1 sent 5 units of flow (money) to user u_2 at time 2.

Interaction networks are a powerful and versatile model, and as such they have been studied extensively in the literature [12, 23, 24]. In this paper, we consider the problem of finding small characteristic patterns in the networks, such as chains, triangles or cycles. These patterns are called *network motifs*. A motif is a subgraph that appears significantly more often in a real network than in a randomized network with similar characteristics [15]. Finding motifs is a method of identifying functional properties of a network. Previous work mainly focused on static motif patterns [15, 21]. Recently, there has been increasing interest in analyzing temporal networks [6, 8, 9, 17, 23, 24], where edges carry timestamps that signify the time of interaction between vertices. However, to the best of our knowledge, there is no previous work on motif search that considers the flow of data between connected nodes. Motivated by this, we define the concept of *flow motifs* in temporal interaction networks and study their identification.

Our definition of flow motifs extends a well-accepted definition of temporal motifs [17]. We define flow motifs as small graphs whose edges are ordered; the order defines how the data flows between the vertices. An instance of the motif is a subgraph of the interaction network, whose edges obey the total order specified by the edges of the motif. Moreover, the time difference between the temporally last and first edges should not exceed a pre-defined threshold δ which is a parameter of the motif. These requirements are the same as in the temporal motif definition of [17], which however disregards the data flow in interactions. The distinctive feature of our flow motifs is that, in a flow motif instance, multiple edges of the graph can instantiate a single edge of the motif, if they satisfy the order constraint with the edges that instantiate the motif's previous and next edges. The flow values in the edge-set that instantiates a motif edge are *aggregated* to a single value, which captures the *total flow* passing through the motif edge. The *minimum aggregated flow* at any motif edge defines the flow of the instance. In order for the instance to be valid, we require that its flow exceeds a threshold ϕ.



(a) multigraph (b) motif (c) instance 1 (d) instance 2

Figure 1: Example of graph, motif, and instances

Consider again the interaction network of Figure 1(a). Assuming that the motif of interest is a chain of three nodes (Figure 1(b)), where the labels in edges specify the flow order and that $\delta = 5$ and $\phi = 5$, the two subgraphs of Figures 1(c) and 1(d) are instances of the motif because the sets of edges mapped to each motif edge satisfy (i) the time order constraint of the motif and (ii) thresholds δ and ϕ. For example, in Figure 1(d), both edges that connect u_2 to u_3 are temporally after the edge that connects u_1 to u_2 and their aggregated flow is 6 ($\geq \phi$); in addition, the

Series ISSN: 2367-2005

10.5441/002/edbt.2019.22

time difference between the temporally first and last edges in the instance is $5 - 2 = 3$ ($\leq \delta$).

Overall, a valid flow motif instance should satisfy three requirements: (a) a *structural constraint*, defined by the graph structure of the motif; (b) a *temporal constraint* defined by the temporal window size δ; (c) a *flow constraint* defined by the minimum flow value ϕ.

Flow motifs correspond to frequently occurring sub-structures with high activity that appear in short time windows. Finding instances of flow motifs is of great importance in understanding interaction networks. For instance, in networks that model money transfers, flow motifs correspond to transaction patterns involving significant flow of money that appear more frequently than expected. Flow motif search is of particular interest to Financial intelligent units (FIUs); these are organizations which identify suspicious flow patterns that may suggest criminal behavior (e.g., money laundering). Belize FIU (fiubelize.org) and Hong Kong's JFIU (www.jfiu.gov.hk) indicate as suspicious patterns which include 'smurfing' (i.e., numerous small-volume transfers which aggregate to large amounts), cyclic transactions between parties, and chains of significant money transfers within limited time (e.g., payments out which are paid in on the same or on the previous day). In addition, bitcoin theft has been associated to flow patterns in [14]. In communication and social networks, flow motifs may reveal common patterns of influence [3, 11]. For example, the strength of the relationships between two social network users is correlated with the frequency of online interactions between them [22]. This implies that groups of users with frequent communication between them within a short period have high chance to influence each other.

Given a large interaction network, we propose an algorithm that takes as input a flow motif and efficiently finds its instances in the network. Our algorithm operates in two phases. First, the structural matches of the motif (disregarding temporal and flow information) are identified. Then, for each structural match, we find the motif instances which satisfy the temporal and flow constraints. This is achieved by sliding a time window of the same length as the duration constraint of the motif and systematically finding the combinations of edges that constitute motif instances. Compared to motif search algorithms from previous work, our algorithm is novel in that it considers the aggregated flow on multiple edges that connect the same pair of nodes in the network during the construction of the motif instances. Due to the large number of possible edge combinations, the problem is harder compared to finding instances of motifs, by disregarding flows and multiple edges. Our algorithm effectively uses the duration and flow constraints to prune the space. We also suggest a variant of the algorithm that identifies the top-k instances of an input flow motif with the highest flow. Finally, we propose a dynamic programming module for the algorithm, for the problem of finding the motif instance with the maximum flow.

We evaluate the performance of the algorithm on three real datasets of different nature (bitcoin user network, facebook network, and Passenger flow network). We compare the performance of our algorithm to a baseline method which builds up motif instances by joining their components and demonstrate the superiority of our approach against this alternative method. We also show that our tested flow motifs indeed appear more frequently in real networks than in randomized networks having the same characteristics as the real ones.

In summary, this paper makes the following contributions:

- We propose the novel concept of flow motif. To our knowledge, this is the first work that defines and studies the search of flow motifs in interaction networks.
- We propose an efficient algorithm for finding flow motif instances in large interaction networks and variants of it that identify the instances of a motif with the maximum flow.
- We evaluate our approach using three real datasets, and demonstrate that it scales well for large data.
- We investigate the significance of the tested motifs in the real networks.

The rest of the paper is organized as follows. Section 2 describes work related to network flow motifs, which are then formally defined in Section 3. Our motif search algorithm is presented in Section 4. Section 5 shows how to extend our algorithm to find the k instances of a given motif with the maximum flow. In Section 6, we experimentally evaluate our algorithm and the significance of the motifs by using a randomization approach. Finally, in Section 7, we conclude our paper and give directions for future work.

2 RELATED WORK

There has been a lot of research interest in motif search and mining in interaction networks [5, 20, 21]. In this section we summarize the most representative works in static and temporal networks.

Static Networks. Milo et al. [15] introduced the concept of motifs and studied their identification in large graphs. They defined a network motif as a *"pattern of interconnections occurring in complex networks at numbers that are significantly higher than those in randomized networks"*. They investigated motif discovery in directed networks, which do not carry temporal information (i.e., the motifs do not consider the time when the interactions took place).

FANMOD [21] is an efficient tool for finding network motifs in static networks, up to a size of eight vertices. Given a subgraph size, the tool either enumerates all subgraphs of that size or samples them uniformly. The identified subgraphs are grouped into classes based on their isomorphism. The significance of each class is finally measured by counting their frequencies in a number of random graphs (generated by swapping edges between vertices in the original network).

Temporal Networks. In *temporal networks*, the interactions between vertices are labeled by the time when they happen. Fundamental definitions, concepts, and problems on temporal networks are given in [6]. For instance, the concept of *time-respecting path* and its relation to network flows are defined and studied here.

Paranjape et al. [17] define motifs in temporal networks as small connected graphs, whose edges are temporally ordered. Instances of a motif are subgraphs that structurally match the motif and their edges obey the order. In addition, the time-difference between the temporally last and the first edges should not exceed a motif *duration* constraint δ. They propose a general algorithmic framework for computing the number of motif instances in a graph and fast algorithms that count certain classes of temporal motifs. Our network flow motifs are similar to the temporal motifs of [17], however, in our case (i) a motif edge can be instantiated by multiple edges of the graph and (ii) we introduce and consider a minimum flow requirement.

Another work that defines and studies the enumeration of temporal motifs is [8]. In the context of this work, the interactions between vertices are not instantaneous but they carry a duration interval. Motifs are again subgraphs whose edges are temporally ordered. As opposed to [17], there is no δ threshold between the last and the first edge in a motif instance. Instead, a maximum time-difference Δt between consecutive edges in a motif instance is allowed.

Rocha et al. [2] also define motifs that model the information spread in temporal networks. They study the impact of time ordering information by comparing the instances of the motifs by considering or not the temporal order. The flow motifs defined and used in [2] are different to ours, because in our case (i) we consider the flow on edges (ii) we define the flow in a motif differently and (iii) our input graph and the motif instances are multigraphs.

Communication motifs are suggested as a model for capturing the structure of human interaction in networks over time. Zhao et al. [23] studied the evolution of such behavioral patterns in social networks. For any two adjacent interactions, the term *maximum flow* is used to characterize those interactions that are the most probable to belong to the same information propagation path among any such adjacent interactions. On the other hand, in our context, flow refers to the data (e.g., money, messages, etc.) being transferred from one node along network paths. Another work that studies behavioral patterns in social networks by defining and mining communication motifs between people in social networks is [4]. A scalable mining technique (called COMMIT) for such communication motifs is proposed.

A recent work that studies the structure of social networks and the temporal relations between entities in them is [24]. Temporal pattern search is proposed as a tool in this direction. In order to facilitate the efficient retrieval of pattern instances, occurrences of small patterns are precomputed and indexed.

Flow can also be used to describe other concepts. In [9], the authors study the information propagation problem. They try to identify all time-respecting paths in temporal networks to model potential pathways for information spread. Our work is diffent in that (i) we are interested in specific motifs and (ii) we consider the flow on edges. The identification of time-respecting paths (as defined in [9]) that form cycles is studied in [10], where an efficient algorithm (2SCENT) is proposed.

Motif discovery in Heterogeneous Information Networks (HiNs) which carry temporal information was also recently studied [12]. In such graphs, some nodes are associated to events (which happened at a specific time). A motif is then defined by a graph and a maximum temporal difference between the events that instantiate its event nodes. As in the rest of previous work, any data flow on the edges of the network is disregarded in the definition and search of motifs.

3 DEFINITIONS

In this section, we formally define flow motifs and the graph wherein they are identified. Table 1 shows the notations used frequently in the paper.

The input to our problem is a directed multigraph $G(V, E)$, where each pair of nodes $u, v \in V$ can be connected by any number of edges in E. We denote by $E(u, v)$ the edge-set from $u \in V$ to $v \in V$. Each edge $e \in E$ is annotated by a unique *timestamp* $t(e)$ in a continuous time domain $\mathcal{T}$ and a positive real number $f(e)$, called *flow*.

Table 1: Table of notations

Notations	Description
$G_M(V_M, E_M)$	graph structure of motif M
δ	duration constraint of a motif
ϕ	flow constraint of a motif
$\ell(e)$	order of edge e in a motif M
SP_M	spanning path of motif M
e_i or $SP_M[i]$	i-th edge of motif M
$SP_M[i:j]$	subpath $e_i \dots e_j$ of SP_M
$G(V, E)$	input graph
$E(u, v)$	set of edges in G from u to v
$f(e)$	flow on edge e
$t(e)$	timestamp of edge e
$f(G_I)$	flow of motif instance G_I
$G_T(V, E_T)$	time-series graph equivalent to $G(V, E)$
(t, f)	flow interaction element on an edge of E_T
$R(u, v)$	time series on edge $(u, v) \in E_T$
$R(e_i)$	time series on edge of E_T mapped to e_i
S	set of structural matches of a motif
G_s	structural match of a motif

Figure 2 shows an example of an input graph G from a real application, where vertices correspond to users (addresses) of the bitcoin network and edges correspond to transactions between them. Each edge is annotated by the timestamp of the transaction followed by the transaction amount. For example, user u_1 at timestamps 13 and 15 sent 5 and 7 bitcoins, respectively, to u_2.

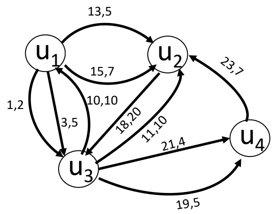


Figure 2: Example of an interaction graph (bitcoin user graph)

Definition 3.1 (Flow Motif). A network flow motif M is a triplet (G_M, δ, ϕ) consisting of (i) a directed graph $G_M(V_M, E_M)$ with $m = |E_M|$ edges, where each edge e is labeled by a unique number $\ell(e)$ in $[1, m]$; (ii) a value δ, which defines an upper-bound on the duration of the motif; and (iii) a value ϕ, which defines a lower bound on the flow of the motif.

The labels of the edges in the motif graph G_M define a total order of the edges that models the direction of the flow in G_M. For example, if G_M consists of two edges (u, v) and (v, w) and we have $\ell(u, v) = 1$ and $\ell(v, w) = 2$, this means that the flow in the graph originates from node u, it is first transferred to v, and then from v to w.

Figure 3 shows some examples of motifs (we only show the motif graphs G_M, but not the thresholds δ and ϕ). The numbers in the parentheses denote the number of nodes and edges in the motifs. For example, the motif labeled $M(3, 3)$ models a cyclic flow between three nodes.

We assume that the ordering of the edges according to their labels defines a *path* in the graph G_M. We refer to this path as the *spanning path* of the motif, and we denote it as SP_M. The spanning path is not necessarily a simple path, i.e., there may be repeated vertices in the path. We sometimes refer to a motif graph

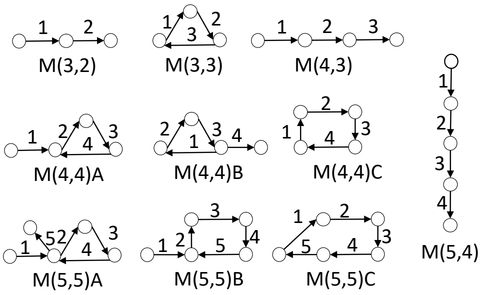

Figure 3: Examples of motifs.

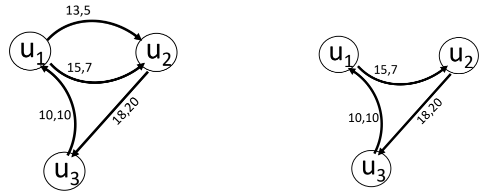


(a) maximal instance

(b) non-maximal instance

Figure 4: Examples of motif instances

G_M by its spanning path $SP_M = e_1e_2 \dots e_m$, i.e., the total order of its edges, where e_i denotes the edge with label i. For example, we may refer to motif $M(3,3)$ in Figure 3 by the sequence $SP_{M(3,3)} = e_1e_2e_3$ of its three edges. In addition, we use e_i or $SP_M[i]$ to denote the i-th edge of the motif, and $SP_M[i:j]$ to denote the subsequence of edges $e_i \dots e_j$ along the path. We now define motif instances as follows.

Definition 3.2 (Flow Motif Instance). An instance of a motif $M = (G_M, \delta, \phi)$ in the graph $G(V, E)$ is a subgraph, $G_I(V_I, E_I)$, $V_I \subseteq V$, $E_I \subseteq E$ of G with the following properties:

- There is a bijection $\mu : V_M \rightarrow V_I$ from the vertex set of the motif graph V_M to the instance vertex set V_I.
- For every edge $(u,v) \in E_M$ there is a non-empty set of edges $E_I(\mu(u), \mu(v))$ in G_I, such that $E_I(\mu(u), \mu(v)) \subseteq E(\mu(u), \mu(v))$. In addition, $E_I = \bigcup_{(u,v) \in E_M} E_I(\mu(u), \mu(v))$.
- The edge-sets in G_I are *time-respecting*: For every pair of edges (u,v) and (v,w) in E_M, if $l(u,v) < l(v,w)$, then for every pair of edges $e_i \in E_I(\mu(u), \mu(v))$, $e_j \in E_I(\mu(v), \mu(w))$, $t(e_i) < t(e_j)$.
- The maximum time difference between any two edges in E_I is at most δ.
- The sum of flows of any edge-set in E_I is at least ϕ.

The first two conditions express a structural requirement on the matching subgraph, the third and fourth conditions temporal constraints, and the last condition a minimum flow constraint. Figure 4(a) shows an instance of $M(3,3)$ in the graph of Figure 2, assuming that $\delta = 10$ and $\phi = 7$. u_3, u_1, and u_2 are mapped to the first, second, and third node of $M(3,3)$ according to the order of its edges. u_1 and u_2 in the instance are linked by two edges which are both temporally after the edge(s) that link u_3 to u_1 and before the edge(s) that link u_2 to u_3. The maximum time difference between any two edges is 8 ($\leq \delta$) and the aggregate flows on $E_I(u_3, u_1)$, $E_I(u_1, u_2)$, and $E_I(u_2, u_3)$ are 10, 12, and 20, respectively (i.e., each of them is at least ϕ). If we denote $M(3,3)$ by its spanning path $SP_{M(3,3)} = e_1e_2e_3$, we can express the instance of Figure 4(a) by $[e_1 \leftarrow \{(10,10)\}, e_2 \leftarrow \{(13,5),(15,7)\}, e_1 \leftarrow \{(18,20)\}]$.

For the ease of exposition, we define the flow $f(G_I)$ of an instance G_I of motif M as the minimum total flow among all edge-sets $E_I(\mu(u), \mu(v))$ which instantiate the edges (u,v) of M. Formally:

$$f(G_I) = \min_{(u,v) \in E_M} \sum_{e \in E_I(\mu(u), \mu(v))} f(e) \qquad (1)$$

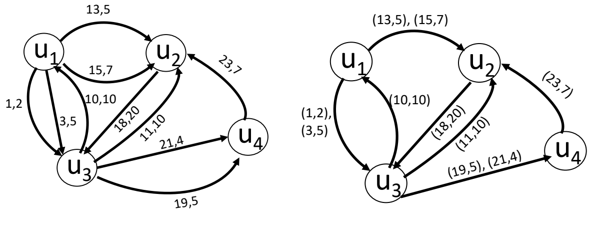
We now define the concept of motif instance maximality.

Definition 3.3 (Instance Maximality). An instance $G_I(V_I, E_I)$ of a motif $M = (G_M, \delta, \phi)$ is maximal iff, the addition of one more edge to any edge-set $E_I(\mu(u), \mu(v))$ of G_I from the corresponding edge-set $E(\mu(u), \mu(v))$ of G violates the duration or flow constraints of the motif.

For example, assuming that $\delta = 10$ and $\phi = 7$, Figure 4(b) shows an instance of $M(3,3)$ in the graph of Figure 2, which is not maximal. This is because the addition of edge (13,5) to $E_I(u_1, u_2)$ results in the valid instance of Figure 4(a). In this paper, we focus on finding maximal instances of motifs only, because non-maximal ones are redundant and considering them can mislead towards the importance of a motif. For example, if $\phi = 0$, all combinations of subsets of the edge-sets that form a valid motif instance are also valid (but not maximal) instances. Considering them would exponentially increase the total number of motif instances, potentially over-estimating its importance.

4 FINDING FLOW MOTIF INSTANCES

We now present an efficient algorithm for enumerating the maximal instances of a given motif $M(V_M, E_M)$ in an input graph $G(V, E)$. For the ease of presentation, we consider the input graph G not as a temporal multi-graph, but as a graph where all original edges from a vertex $u \in V$ to a vertex $v \in V$ are *merged* to a single edge. The single edge (u,v) is associated with an *interaction time-series* $R(u,v) = \{(t_1, f_1), (t_2, f_2), \dots\}$. Each pair (t_i, f_i) represents a *flow interaction* occurring at time t_i with flow transfer f_i from u to v. The interaction time series is ordered in time. Figure 5 shows an example of how the edges of a multigraph G are merged to time series. For example, the two edges from u_1 to u_2 are considered as a single edge; the two edges with timestamps 13 and 15 are now considered as a time series on a single edge (u_1, u_2). The conversion of the multigraph to a graph does not have to be explicitly performed; for each connected pair of vertices, it suffices to consider their multiple edges ordered by timestamp. We will use $G_T(V, E_T)$ to denote this graph and we will refer to it as the *time series graph.*



(a) multigraph

(b) time series graph

Figure 5: From a multigraph to a time series graph

Our algorithm takes as input the multigraph $G(V, E)$ and a motif $M = (G_M, \delta, \phi)$, and finds all instances of M in G. The algorithm operates on the time series graph G_T and works in two phases P1 and P2:

P1 Find the set S of all *structural matches* of graph G_M in graph G_T, disregarding the labels on the edges and constraints δ and ϕ.

P2 For each $G_s \in S$, using the time series of the edges in G_s, find all instances of M in G_s (which should satisfy the duration and flow constraints defined by δ and ϕ).

We now elaborate on the two phases.

Phase P1: To illustrate phase P1, as an example, consider the graph G_T of Figure 5(b) and the motif $M(3,3)$ shown in Figure 3. Figure 6 shows all six structural matches of $M(3,3)$ in G_T found in phase P1. The labels $\{e_1, e_2, e_3\}$ on the edges of the matches indicate the edges of the motif on which they are mapped. For example, edge (u_1, u_2) of the first match is mapped to the first edge e_1 of the motif.

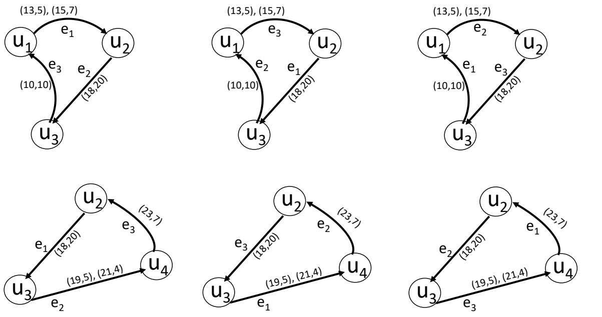


Figure 6: Structural matches of $M(3,3)$ (phase P1)

Algorithmically, for phase P1, any graph pattern matching algorithm for static graphs can be used (e.g., [21]). In our implementation, we exploit the fact that the ordering of the edges defines a path. Using a modified depth-first search algorithm on G_T, we can extract all paths of length $|E_M|$ that are structural matches of G_M in G_T. Specifically, in a loop, we map every node in G_T to the first node in G_M (i.e., the origin node of the first edge in G_M) and recursively find all paths that originate from that node and map them to the spanning path SP_M of G_M. For example, for motif $M(3,3)$, the depth-first search algorithm should make sure that the last vertex of the traversed path is the same as the first vertex of the path. Hence, the algorithm on the graph G of our running example would identify path $u_1u_2u_3u_1$ as a match of $M(3,3)$.

Phase P2: In phase P2, given the set of structural matches S, for each $G_s \in S$, we process the time series on the edges of G_s in order to find valid flow motif instances. In a nutshell, we slide a time window of length δ along the set of all (t_i, f_i) interactions on the edges of G_s; for all sets of interactions within δ time difference, we find all combinations thereof which constitute valid motif instances. Note that each structural match G_s from phase P1 may produce an arbitrary number of flow motif instances, as each time window position can generate different instances depending on the combinations of edge flows we use.

To illustrate, consider again $M(3,3)$ (for $\delta = 10$) and a possible structural match, shown in Figure 7. We will get different flow motif instances depending on whether we consider window $[10,20]$ or $[15,25]$. Furthermore, even for the specific time-window $[10,20]$, we can get different flow motif instances depending on how we combine the edges in this window. For example, one possible flow motif instance is $[e_1 \leftarrow \{(10,5)\}, e_2 \leftarrow \{(11,3),(16,3)\}, e_3 \leftarrow \{(19,6)\}]$, while another flow motif instance is $[e_1 \leftarrow \{(10,5)\}, e_2 \leftarrow \{(11,3)\}, e_3 \leftarrow \{(14,4),(19,6)\}]$. Note that the flow in the former case is 5, while in the latter is 3, meaning that the latter instance would be rejected for $\phi = 5$.

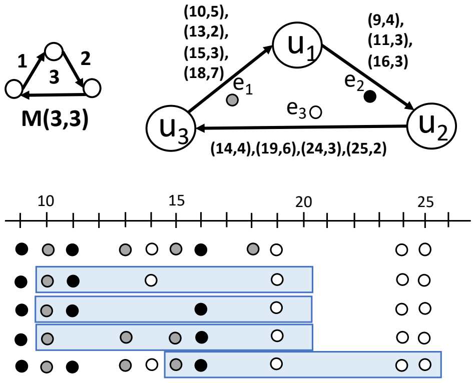

Figure 7: Example for Algorithm 1

Algorithm 1 is applied in phase P2 to find all instances of the motif M in a match G_s (found in phase P1). The algorithm slides a window T of length δ over the time domain, to find subsets of edges in G_s that satisfy the duration constraint δ and can generate maximal motif instances. Given a specific window T we run procedure FindInstances in order to generate all possible maximal flow-motif instances that satisfy the flow constraint ϕ. The procedure is recursive on the length m of the spanning path $SP_M = e_1e_2 \ldots e_m$ of the motif.

FindInstances takes as input the graph instance G_s, a spanning path SP, a time-window T and the threshold ϕ. Let $R(e_i)$ be the interaction time series on the edge of G_s which is mapped to edge e_i of the motif. If the spanning path consists of a single edge e_1, then the procedure finds the set $R_T(e_1) \subseteq R(e_1)$ of all elements in $R(e_1)$, which are within the time-window T, and aggregates their flow. If the total flow $f(R_T(e_i))$ of these elements satisfies the flow constraint ϕ, the edge-set of G corresponding to $R_T(e_i)$ becomes an instance of SP and it is returned. For longer spanning paths, the procedure considers again the first edge $e_1 = SP[1]$. For every prefix T_p of the window T that contains instances of the edge e_1, it computes the set $R_{T_p}(e_1) \subseteq R(e_1)$ of all (t, f) interaction elements in $R(e_1)$ for which $t \in T_p$. If $R_{T_p}(e_1)$ is non-empty and satisfies the flow constraint, then FindInstances is recursively called on the rest of the spanning path $SP_{next} = SP[2:m]$, with time window $T_{next} = T - T_p$. This recursive call will return the set of valid instances within time-window T_{next} for the sub-motif defined by SP_{next}. Each of these instances is *concatenated* to $R_{T_p}(e_1)$ to create a new valid instance for SP.

The condition at line 16 of the algorithm helps us to find invalid prefixes of the motif instances early. In other words, if a sub-series $R_{T_p}(e_1)$ which is candidate for instantiating a motif edge does not qualify ϕ, we do not consider the possible instances that include the elements of $R_{T_p}(e_1)$ as an instance of e_1. Hence, the search space is effectively pruned.

Figure 7 illustrates the functionality of Algorithm 1. On top, the figure shows motif $M(3,3)$ and a structural match G_s of it, where each edge is labeled by the time series of flows between the corresponding nodes (e.g., at time 10, u_2 sent to u_1 a flow of 5). The elements on the edges of G_s are illustrated (as sequences of dots ordered by time) at the bottom of the figure, colored by

Algorithm 1 Instance finding module

```
Require: $\delta$, $\phi$, time window $T$, structural match $G_s$
$\mathcal{I} \leftarrow \emptyset$                                  ▷ set of instances of $G_s$ in $T$
for each maximal time window $T$ that satisfies $\delta$ do
    $\mathcal{I} \leftarrow \mathcal{I} \cup$ FindInstances($G_s$, $SP_M$, $T$, $\phi$)
end for
return $\mathcal{I}$

procedure FindInstances($G_s$, $SP$, $T$, $\phi$)
    $\mathcal{I} \leftarrow \emptyset$                              ▷ set of instances of $G_s$ in $T$
    if $length(SP) = 1$ then
        $R_T(e_1) \leftarrow$ all $(t, f)$ elements of $R(e_1)$ in $T$
        if $f(R_T(e_1)) \geq \phi$ then                      ▷ $\phi$ condition check
            add $R_T(e_1)$ to $\mathcal{I}$
        end if
    else
        for each prefix $T_p$ of time window $T$ do
            $R_{T_p}(e_1) \leftarrow$ all $(t, f)$ elements of $R(e_1)$ in $T_p$
            if $f(R_{T_p}(e_1)) \geq \phi$ then              ▷ $\phi$ condition check
                $SP_{next} \leftarrow SP[2:m]$                  ▷ suffix of $SP$
                $T_{next} \leftarrow T - T_p$                    ▷ suffix of $T$
                $\mathcal{I}_{next} \leftarrow$ FindInstances($G_s$, $SP_{next}$, $T_{next}$, $\phi$)
                for each $I \in \mathcal{I}_{next}$ do
                    add $R_{T_p}(e_1) \circ I$ to $\mathcal{I}$
                end for
            end if
        end for
    end if
    return $\mathcal{I}$
end procedure
```

the edge they belong to (e.g., black for e_2). The first row of dots includes all (t, f) elements, i.e., the first black dot corresponds to element $(9, 4)$ on edge (u_1, u_2), which is mapped to the second edge e_2 of $M(3, 3)$. To find the motif instances that comprise of nodes and edges in G_s, we slide a window of length δ along the timeline. Assuming that $\delta = 10$, the first position of the sliding window is $[10, 20]$. The algorithm finds all prefixes of elements in $R(e_1)$ that fall in this window and for each such prefix, it generates recursively the combinations of elements from other edges that form valid instances (according to δ). For example, for the prefix $T_p = [10, 10]$, which includes just the first element $(10, 5)$ from e_1, the 2nd and the 3rd line of dots in the figure show the valid instances formed. Specifically, these instances are $[e_1 \leftarrow \{(10, 5)\}, e_2 \leftarrow \{(11, 3)\}, e_3 \leftarrow \{(14, 4), (19, 6)\}]$ and $[e_1 \leftarrow \{(10, 5)\}, e_2 \leftarrow \{(11, 3), (16, 3)\}, e_3 \leftarrow \{(19, 6)\}]$. Note that the ϕ constraint is applied at every prefix in order to prune the search space if it is violated (e.g., if $\phi = 5$, any instance $[e_1 \leftarrow \{(10, 5)\}, e_2 \leftarrow \{(11, 3)\}, \dots]$ would be rejected. Note also that there is no instance which contains just the first two elements of e_1 but not the third one, because there is no element from e_2 which is temporally between $(13, 2)$ and $(15, 3)$. Finally, note that the next position of the sliding window is $[15, 25]$ because the position $[13, 23]$ which starts from the 2nd element of e_1 does not include any new elements from e_3 compared to the previous window position $[10, 20]$; hence, considering window position $[13, 23]$ would result in redundant (i.e., non-maximal) instances and this position is skipped.

We have not explained yet how window positions are skipped in Algorithm 1. First, only window positions which start at elements of $R(e_1)$ are considered; in-between positions (e.g., window $[11, 21]$ in Figure 7) would result in redundant (non-maximal) instances because there will be a subsequent position for which $R(e_1)$ (and the other sets) can only expand (e.g., window $[13, 23]$ in Figure 7). Second, from those window positions that are considered, we skip those, where $R(e_m)$ (i.e., the interaction time series, which is mapped to the last edge e_m of the motif) is not expanded with new elements, compared to the previous valid window position. In our example, $[13, 23]$ is skipped because no element is added to $R(e_3)$, compared to position $[10, 20]$. If we used window position $[13, 23]$, we would generate instances that would not be maximal because we could add to each of them element $(10, 5)$ of e_1 without violating the δ constraint. In summary, in consecutive window positions where module FindInstances is applied, the first elements of $R(e_1)$ should be different and the last elements of $R(e_m)$ should also be different.

Algorithm 1 does not miss any maximal instances because it systematically explores the combinations of edge-sets which are time-respecting and maximal within a window. Moreover, the windows have maximal lengths and in each of them the produced instances essentially include the temporally first (t_i, f_i) element that maps to e_1 and the temporally last (t_i, f_i) element that maps to e_m. At least one of these pairs changes in the next window position; therefore, instances produced at different windows do not violate the maximality condition.

Complexity Analysis. In the worst case, for each G_s and each time window, we should consider all combinations of edges in G that instantiate the edges of the motif. For example, when $\phi = 0$, prefix-based pruning cannot be applied. In the worst case, $G_s = G$ and the edges in G ordered by timestamp are assigned to the sequence of motif edges in a round-robin fashion. That is, the temporally first edge of G is mapped to e_1, the second to e_2, etc. In this case, assuming the loosest possible constraints $\delta = \infty, \phi = 0$, the number of combinations of pairs to be considered (which all form valid motif instances) is $O(|E|/m)^m$, i.e., exponential to the number of edges m in the motif. In addition, the number of structural matches is also exponential to m. In practice, G_T is sparse (or V is small) and the constraints δ and ϕ help in pruning combinations of edges that do not form instances early, which renders the algorithm scalable, as we will show in the experimental evaluation.

5 TOP-K FLOW MOTIF SEARCH

Setting an appropriate value for the parameters δ and ϕ could be hard for non-experts of the domain. Parameter δ is intuitively easier to be set to a time constraint that makes sense to the application (for example, the analyst could be interested in patterns of bitcoin transactions which happen within an hour or day). On the other hand, ϕ is less intuitive, as too large values could result in too few or zero instances, whereas too small values could result in thousands of instances which may overwhelm the user. One solution to this problem is to replace the ϕ constraint by a ranking of the motif instances G_I with respect to their flow (see Equation 1). In other words, we may opt to search for the k instances G_I of the motif (with $\phi = 0$) that satisfy δ, which have the maximum flow $f(G_I)$.

To solve this top-k flow motif search problem, we can use our algorithm with a small number of modifications. Phase P1 is identical; we should still find the set S of all structural matches. Then, for each $G_s \in S$, we apply phase P2, by making the following changes to Algorithm 1. First, we keep track in a priority queue (heap) the top-k instances in terms of their minimum flow so far. Second, in place of ϕ, we use the flow $f(G_I^k)$ of the k-th instance G_I^k so far as a dynamic (floating) threshold.

5.1 Finding the top motif instance

For the special case, where k=1, the top-1 motif instance search problem can potentially be solved faster with the help of a dynamic programming (DP) algorithmic module. Recall that the objective of procedure FindInstances in Algorithm 1 is to find the motif instances in a structural match G_s, within a time window T, which qualify ϕ. We can replace this module by a dynamic programming algorithm that finds the instance of maximum flow within T. This DP module can be described by Algorithm 2.

Algorithm 2 DP module for top-1 instance search

```
Require: $\delta$, time window $T$, structural match $G_s$
maxflow ← 0        ▷ keeps track of max flow found at any instance
for each maximal time window $T$ that satisfies $\delta$ do
    for all timestamps $t_i$ in $T$ do
        compute $Flow([t_1, t_i], 1) = flow([t_1, t_i], 1)$
    end for
    for $\kappa$ = 2 to $n$ do
        for all timestamps $t_i$ in $T$ do
            compute $Flow([t_1, t_i], \kappa)$ by Eq. 2
        end for
    end for
    maxflow = max (maxflow, $Flow([t_1, t_\tau, m])$)
end for
return maxflow
```

Specifically, let $[t_1, t_2, \ldots, t_\tau]$ be the sequence of timestamps in T for which there is a (t, f) interaction element in G_s. Let M_κ be the prefix of M which includes its fist κ edges only and $Flow([t_1, t_i], \kappa)$ be the flow of the top-1 motif instance of M_κ in the time window $[t_1, t_i]$. Then, $Flow([t_1, t_i], \kappa)$ can be recursively computed as follows:

$$Flow([t_1, t_i], \kappa) = \max_{1<j\leq i}\{\min(Flow([t_1, t_{j-1}], \kappa-1), flow([t_j, t_i], \kappa))\}, \quad (2)$$

where $flow([t_j, t_i], \kappa)$ is the total flow of all (t, f) elements of the time series $R(e_\kappa)$ on the κ-th edge of G_s, whose timestamps are in the time interval $[t_j, t_i]$. The $Flow([t_1, t_i], 1)$ array is initialized by scanning the elements of the first edge of G_s in T. Then, for each $\kappa > 1$, $Flow([t_1, t_i], \kappa)$ is computed using array $Flow([t_1, t_i], \kappa-1)$. Finally, $Flow([t_1, t_\tau], m)$ corresponds to the top-1 flow of any motif instance in G_s within time window T. By applying this algorithm for every window T, we can find the top instance in G_s. Repeating this for each G_s gives us the top-1 instance of M in G.

Table 2 shows the steps of the DP module in the course of finding the top-1 instance in time window $[10, 20]$ (assuming that δ=10) for the structural match of $M(3, 3)$ shown in Figure 7. The first row shows the values of $Flow([t_1, t_i], 1)$ for the first edge of the motif and for all values of t_i (i.e., columns of the table). (Recall that the starting timestamp t_1 of the time window is 10.) The second row shows, for the first two edges of the motif, the value of $Flow([t_1, t_i], 2)$ for all values of t_i, as well as the value of t_j, which determines $Flow([t_1, t_i], 2)$. For all t_i, the value of t_j that maximizes the flow is 11 and for $t_i \geq 16$ the flow becomes $min(5, 3 + 3) = 5$. Finally, the last row shows the maximum flow for the best arrangement of (t, f) pairs to all three edges of the motif, for all prefixes of the time window. Note that the last value corresponds to the entire window and contains the flow of the best instance of the entire motif in $[10, 20]$, which is 5. The cells of the matrix in bold show how the top-1 instance, i.e., $[e_1 \leftarrow \{(10, 5)\}, e_2 \leftarrow \{(11, 3), (16, 3)\}, e_3 \leftarrow \{(19, 6)\}]$, can be identified.

Table 2: Example of the DP module

t_i	10	11	13	14	15	16	18	19
κ=1	**5**	5	7	7	7	7	10	10
κ=2		3 (t_j=11)	3 (t_j=11)	3 (t_j=11)	3 (t_j=11)	5 (t_j=11)	**5 (t_j=11)**	5 (t_j=11)
κ=3			0 (t_j=13)	4 (t_j=14)	4 (t_j=14)	4 (t_j=14)	4 (t_j=14)	**5 (t_j=19)**

Complexity Analysis. For each G_s and each time window, we should consider all binary splits of the window at each iteration (i.e., for each edge in M). Hence the time complexity is $O(\tau^2|E|)$, where τ is the number of timestamps in T for which there is an (t_i, f_i) element in G_s. The space complexity is $O(\tau \cdot |E|)$ because we only need all $Flow([t_1, t_i], \kappa-1)$ for $\kappa-1$ when we process the κ-th edge. The overall time complexity per structural match in S is $O(|S|\delta\tau^2|E|)$, since the number of windows to be considered is $O(\delta)$. The number of structural matches $|S|$ is exponential to m, as discussed in our previous analysis.

Extensibility. The DP module can be used to solve top-1 problems at a finer granularity. In particular, it can be used to find the top-1 instance for each structural match G_s. This may be desirable if we want to compare the sets of entities that constitute the structural instances (e.g., groups of bitcoin users) based on their max-flow interactions. In addition, we might be interested in finding the top-1 instance for each position of the sliding time window T. This can be part of analysis tasks that compare the volume of interactions (according to the motif structure) at different periods of time.

6 EXPERIMENTAL EVALUATION

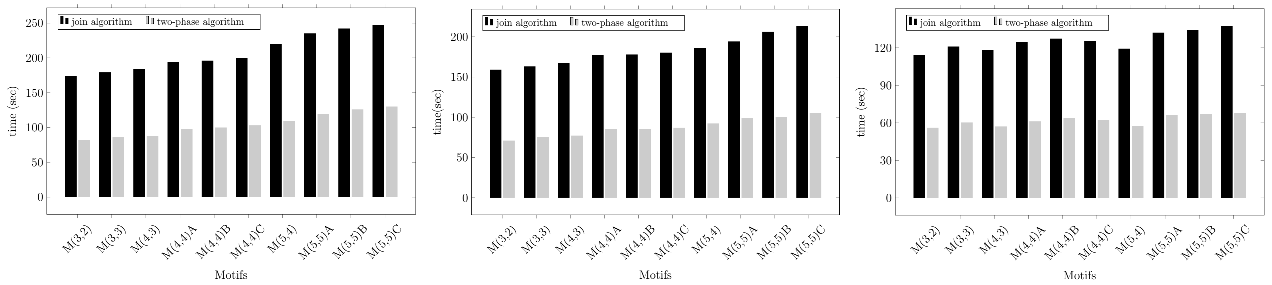
The goal of our experimental evaluation is twofold: test the performance and scalability of our algorithms and study the significance of flow motifs. We implemented the algorithm presented in Section 4 and its two variants proposed in Section 5 (top-k instance search, dynamic programming module for top-1 search). As a baseline, we also implemented an alternative motif instance finding method based on finding and joining instances of motif components in a hierarchical manner.

We evaluate the performance of all these methods on three real networks, to be described in Section 6.1. We measure the efficiency and scalability of the tested methods as a function of the problem parameters δ and ϕ on the motif structures shown in Figure 3. These graphs model representative flows of interaction that could be of interest to data analysts (e.g., $M(3, 3)$ corresponds to cyclic transactions in a money-exchange network, $M(4, 3)$ corresponds to paths of region-to-region movements in a passenger flow network). We also assess the statistical significance of the tested motifs in three real graphs. All algorithms were implemented in Python3 and we ran all the experiments on a machine with an Intel Xeon CPU E5-2620 prossesor running Ubuntu 18.04.1 LTS.

6.1 Dataset Description

We used three datasets extracted from real interaction networks: the **Bitcoin** network, the **Facebook** network and a **Passenger** flow network. Table 3 shows statistics of the datasets. The third column is the distinct number of node pairs $(u, v) \in V$, for which there is at least one edge (i.e., interaction) from u to v. This number equals to the number $|E_T|$ of edges in the corresponding time-series graph G_T. We now provide more details about them.

Bitcoin network. We downloaded all transactions in the bitcoin blockchain [16] in the period February 1st 2014 to November



(a) Bitcoin Network

(b) Facebook Network

(c) Passenger Network

Figure 8: Our two-phase algorithm vs. the join algorithm

Table 3: Statistics of Datasets

Dataset	#nodes	#connected node pairs	#edges	Avg. flow per edge
Bitcoin	24.6M	88.9M	123M	4.845
Facebook	45800	264000	856000	3.014
Passenger	289	77896	215175	1.933

30 2014 and converted them to a bitcoin *user graph*.[1] Nodes correspond to users and for each transaction of f bitcoins in the blockchain from user u to user v at time t, we added an edge from u to v with label (t, f). Since the same bitcoin user may control and use multiple addresses, we applied a well-known heuristic [1, 7] to *merge* addresses that are considered to belong to the same user to a single network node. Specifically, we merged addresses that appear together as input in the same transaction. We did not take into account insignificant transactions with amounts under 0.0001 BTC. Bitcoin is a relatively sparse graph and the cases of two nodes being connected by multiple edges is rare. Finding motif instances in the Bitcoin network can help towards understanding complex interactions between users and can possibly help toward identifying suspicious transactions like money laundering and bitcoin theft [14].

Facebook network: We consider Facebook as an interaction network between users. We divide the time into 30-second intervals $[t_s, t_e)$ and for each pair of users u and v we aggregate all interactions from u to v and add an edge from u to v with label (t_s, f), where f is the total number of interactions from u to v in this interval. We consider as interactions the posts of likes by u targeting v or the messages sent from u to v. We created the Facebook user network using data from April 2015 to October 2015; the same dataset is used in [19]. The Facebook network is relatively sparse and each pair of connected nodes have about four edges on average. Motif search on this graph can help in analyzing influence [3, 11] and finding important interactions among users [13].

Passenger flow network: We processed trips of yellow taxis in NYC in January 2018.[2]. Each record includes the pick-up and drop-off taxi zones (regions) the date/time of the pick-up and drop-off, and the number of passengers inside the taxi. Using these records, we created an interaction network where the nodes are the taxi zones; for each record, we generate an edge that links the corresponding nodes and carries the timestamp of the activity (i.e., the pickup time) and the corresponding flow (i.e., the number of passengers). This Passenger flow network is dense; in addition, each pair of connected nodes have about three edges on average. Motif instances found in this passenger flow graph can help in understanding the flow of movement between different regions.

6.2 Efficiency and Scalability

In this section, we evaluate the efficiency and scalability of our algorithm when applied to find the instances of the motifs depicted in Figure 3. The default values for the duration constraint δ are 600 sec., 600 sec., and 900 sec. on Bitcoin, Facebook, and Passenger, respectively. These value represent realistic time intervals for the corresponding applications. The corresponding default values for ϕ are 5, 3, and 2, respectively.

6.2.1 Comparison to a competitor. In our first set of experiments, we compare our algorithm with an alternative motif instance finding algorithm which is based on progressively finding and joining instances of motif subgraphs.

Specifically, this *join algorithm* starts by accessing each edge (u, v) of the time series graph G_T and finding all time-intervals of length at most δ and their aggregated flows. For each such interval $[t_s, t_e]$ a quintuple (u, v, t_s, t_e, f) is generated. These tuples are kept in two tables; C_1 sorts them by starting vertex u and C_2 sorts them by ending vertex v. In the next step, C_2 and C_1 are merge-joined to find all pairs (c_2, c_1) having $c_2.u = c_1.v$ and also satisfying $c_1.t_e - c_2.t_s \leq \delta$. The set P of all these tuple pairs constitute results of all sub-motifs of M which include two consecutive edges. In the next step, P is self-joined again to produce instances of sub-motifs of M with three consecutive edges. This is done by finding pairs $\{(c_2, c_1), (c_2', c_1')\}$ of couples in P for which $c_1 = c_2'$ and $c_1'.t_e - c_2.t_s \leq \delta$. The next steps are applied in a similar manner until the instances of the entire motif M are constructed. Note that for each motif or sub-motif that closes a cycle (e.g., $M(3, 3)$), we check the additional condition that the starting vertex of the first motif edge in the instance is the same as the target vertex of the last edge. At each step, we apply a merge join for the production of sub-motif instances, after having sorted the tuples produced in the previous step accordingly.

Figure 8 compares the runtime cost of the join algorithm with that of our two-phase algorithm presented in Section 4. For all motifs, we used the default values for δ and ϕ. Our two-phase algorithm is typically twice as fast as the join algorithm. This is due to the fact that the join algorithm produces a large number of intermediate results (i.e., sub-motif instances), which are avoided by our method. Many of these sub-motif instances do not end up as components of any instance of the complete motif, so their generation is redundant. In the rest of this section, we do not include additional comparisons with the join algorithm since it was always found to be slower than our approach.

Figure 10: Number of instances and time for different values of ϕ

6.2.2 Sensitivity to δ and ϕ. The next set of experiments evaluate the performance of our algorithm on the different datasets and motifs, for various values of the constraints δ and ϕ. Table 4 shows the number of structural matches found and the time spent by the algorithm just for its first phase, which is independent of the δ and ϕ values (since these constraints are not used when searching for the structural matches). This cost constitutes a lower bound for our algorithm. Naturally, more complex motifs require more time but they also have fewer structural matches.

Figures 9 and 10 show the number of instances and total runtime of our algorithm for different values of δ (in seconds) and ϕ. When we vary δ, we set ϕ to its default value and vice versa. As expected, in all cases, when δ increases the number of instances and the runtime increases. The algorithm scales well as its cost increases at a lower pace compared to the results found.

When comparing the different motifs, note that the simpler ones (e.g., $M(3,2)$ and $M(3,3)$) naturally have more instances and are cheaper to search compared to the more complex ones (e.g., $M(5,5)A$). The relative order between the motifs is similar in the Bitcoin and Facebook networks. In both networks, cyclic flow is quite common; i.e., motifs containing cycles have a similar number of instances as motifs without cycles having the same number of edges. On the other hand, in the Passenger network, acyclic motifs dominate in terms of number of instances. This is expected, as it is relatively rare that passengers move between regions on a map forming cycles compared to moving along a chain of different regions.

The behavior is also consistent to our expectation when ϕ varies; the number of instances and the runtime drop when ϕ increases. The algorithm becomes faster because partial motif instances that do not qualify ϕ are pruned early.

6.2.3 Top-k flow motif instance search. We now evaluate the results and the performance of top-k motif search on the three datasets, when using the default values of δ. In the first experiment, we run the version of our algorithm which finds the top-k motif instances that have the maximum flow. For each run, we record the flow of the k-th instance in Figure 11. As expected, the flow of the k-th instance drops as k increases; the drop rate decreases when k becomes large (note that the x-axis is not linear). In the second experiment, we compare the runtime of the general top-k algorithm with its version that employs the dynamic programming module proposed in Section 5.1. The barcharts show that the second phase of the algorithm benefits from the use of dynamic programming (the runtime drops 20% to 40%). The improvement is better on the Passenger network.

6.2.4 Scalability to the dataset size. In the next experiment, we test the performance of our algorithm on samples of the original datasets having different sizes. For each of the three datasets, we take samples defined by prefixes of the total period covered by the timestamps of the edges included in the sample. Specifically, for the Bitcoin network we define 5 samples: B1, B2, B3, B4, B5. B1 includes all transactions happened in the first month of the 9-month period of the complete dataset. B2, B3, B4, and B5 cover the first 2, 4, 6, and 9 months, respectively. Similarly, F1, F2, F3, F4, and F5 cover the first 1, 2, 3, 4, and 6 months of the entire dataset, respectively. Lastly, T1, T2, T3, and T4 cover the first 8, 16, 24, and 31 days of January 2018, respectively. Figure 13 shows the growth in the number of instances and in the runtime of the algorithm for the different motifs. Observe that the algorithm scales well as its cost grows at a slower pace compared to the number of instances and the size of the input data.

6.3 Significance of Motifs

In the last experiment, we assess the significance of the different flow motifs in our networks. Following the standard practice [18], we generated randomized versions of our datasets, we computed the number of instances of each motif in each of these datasets, and we compared it against the same number for the real dataset. A large divergence between real and randomized numbers indicates a significant motif.

Specifically, from each dataset (e.g.. Bitcoin network) we generated random datasets by keeping the structure of the corresponding graph fixed, and permuting the flows on the edges. Recall that in the original input multigraph $G = (V, E)$ each edge e is associated with a timestamp $t(e)$ and a flow value $f(e)$. A pair of nodes (u, v) is connected by a set of edges $E(u, v)$. Given the entire set of flow values $\{f(e) : e \in E\}$, we compute a random permutation π of the flow values and reassign them to the graph edges in this order. This generates a randomized dataset $G_r(V, E)$ with the same set of nodes and the same set of edges; each edge e has the same timestamp $t(e)$, and flow value $\pi(f(e))$. Hence, G_r is derived from G by "shuffling" the flow values on the edges.

The random graph G_r has the same structure as G and the edges in the graph appear at the same timestamps. Therefore, all structural matches of the motifs in G will also appear in G_r. In addition, putting aside the flow constraint ϕ, the motif instances in the two graphs will be the same, when considering only δ. What changes is the flow value of each motif instance, which will result in a different number of flow motif instances in G_r compared to G, for non-zero values of ϕ. Our goal is to see whether the motif instances that satisfy the ϕ constraint in the real data are significantly more than those in the randomized data.

We generated 20 different random graphs for each real network according to the procedure we described above. We found the instances of each motif in all these random datasets. In addition, we computed the mean and standard deviation of the number of motif instances in all 20 random graphs per real dataset. To assess the significance of a motif in the real data, we compared the number of instances in the real data with those in the random data. Figure 14 shows, for each dataset and motif, the distribution of the numbers of instances for all random graphs in a box plot, and the corresponding number in the real graph (marked by a diamond). Each real value is also associated with the *z-score* (shown above the corresponding diamond), which is computed as follows. For some motif M, let r_M denote the number of instances of the motif in the real data, let μ_M denote the mean number of motif instances in the randomized data, and let σ_M denote the standard deviation. The z-score z_M of the motif is computed as

$$z_M = \frac{r_M - \mu_M}{\sigma_M}$$

The higher the z-score, the further the value r_M from μ_M.

The first observation is that the number of instances in all random graphs is much lower compared to that in the corresponding real network and these values do not deviate much from their mean. The empirical p-value (the fraction of random datasets with number of instances greater than that of the real data) is zero, indicating statistical significance of the motif occurrences in all cases. This is consistent with the intuition that the flow is not arbitrarily generated or consumed at the vertices of the network, but it is transferred from one node to another. To discriminate between the different motifs we look at the z-scores. We observe that for the Bitcoin network, two out of the three top z-scores are

for motifs that contain cycles, indicating that large flow movements that close a cycle are statistically over-represented in the bitcoin network. A similar observation holds for the Passenger flow network, where three out of the top-three motifs contain a cycle. A different pattern emerges in the Facebook dataset, where two out of the three highest z-scores are for chains of nodes. We conjecture that this due to propagation trees of information in the Facebook network, which result in chains with significantly

Figure 14: Number of instances in random networks (box plots), in real networks (diamonds), and z-scores

high flow movement. It is interesting that the significance of the discovered motifs varies in the different types of interaction networks, indicating differences in the way flow is distributed.

7 CONCLUSION

In this paper, we introduced the novel concept of *network flow motifs*. To the best of our knowledge we are the first to define and study motifs in interaction networks, which consider both the temporal and flow information of the interactions. We proposed an efficient algorithm for enumerating flow motif instances in large graphs and variants of that find the top-k instances of maximal flow. We evaluated our algorithm on three real datasets and demonstrated its scalability. In addition, we compared it to a baseline motif instance finding method based on joining instances of motif components and showed its superiority. Finally, we studied the statistical significance of a wide range of representative motifs on the real graphs and showed that they indeed appear more frequently than in random networks with the same characteristics. This indicates that the flow is transferred from one node to another (as opposed to being arbitrarily consumed or generated) and that there are subgraphs in the network where significant flow is transferred at certain periods of time.

In the future, we plan to investigate in more detail the distribution of motif instances in the real networks. For example, we can group the motif instances per structural match, in order to identify the structural matches (i.e., sets of vertices in the graph G) with the largest activity and how this activity is spread along the timeline. Another direction is to improve the efficiency of the algorithm, by processing multiple structural instances together in phase P2. Since two or more structural matches may share the same prefix, we can compute the flow instances of their common prefix simultaneously before expanding these instances to complete ones for the different motifs. In addition, we will work towards a version of the algorithm which focuses on counting instances of (possibly multiple) motifs without constructing them (along the direction of previous work [17]). Finally, we will generalize the definition of flow motifs to capture other graph structures besides paths (e.g., directed acyclic graphs with forks and joins) and study their search in large networks.

ABSTRACT

Functional dependencies (FDs) support various tasks for the management of relational data, such as schema normalization, data cleaning, and query optimization. However, while existing FD discovery algorithms regard only static datasets, many real-world datasets are constantly changing – and with them their FDs. Unfortunately, the computational hardness of FD discovery prohibits a continuous re-execution of those existing algorithms with every change of the data.

To this end, we propose DynFD, the first algorithm to discover and maintain functional dependencies in dynamic datasets. Whenever the inspected dataset changes, DynFD *evolves* its FDs rather than recalculating them. For this to work efficiently, we propose indexed data structures along with novel and efficient update operations. Our experiments compare DynFD's incremental mode of operation to the repeated re-execution of existing, static algorithms. They show that DynFD can maintain the FDs of dynamic datasets over an order of magnitude faster than its static counter-parts.

1 FUNCTIONAL DEPENDENCIES

Traditional data profiling algorithms solve the problem of *discovering* all metadata of type X in dataset Y. However, once those algorithms finish, the dataset usually keeps evolving, thereby rendering the discovered metadata outdated. An *incremental* data profiling algorithm, on the contrary, acknowledges the dynamic nature of data by *maintaining* all metadata of some type. It takes as input the data and its (statically profiled) metadata and, then, updates the metadata with every change, i. e., insert, update, and delete of the data. In this paper, we propose such an incremental algorithm for functional dependencies.

For an instance r of a relation R, a functional dependency (FD) $X \longrightarrow A$ holds iff all records with the same values for the set of attributes $X \subseteq R$ also share the same value for attribute $A \in R$ [5]. We say that X *functionally determines* A.

Definition 1.1. The *functional dependency* $X \longrightarrow A$ with $X \subseteq R$ and $A \in R$ is *valid* for instance r of R, iff $\forall t_i, t_j \in r\colon t_i[X] = t_j[X] \Rightarrow t_i[A] = t_j[A]$. We call X the left-hand side (LHS) and A the right-hand side (RHS), respectively.

FDs often arise from real-world relationships. Consider, for example, a relation with information about people including their *ZIP code* and *city* name. In such a dataset, the ZIP codes functionally determine the city names of the records, because ZIP codes are a more fine-grained localization. The presence or absence of certain dependencies, in general, helps to understand complex semantic relationships in data exploration scenarios. Being able to track the validity of certain dependencies over time provides even deeper insights. In a product database, for instance, the FD *num_sales* ⟶ *num_shipments* might hold only overnight, because shipments are delayed in daily business. Or the FD *product* ⟶ *price* in a pricing database was temporarily violated at the time of a system migration. Apart from data exploration, further applications for functional dependencies include schema normalization [4], query optimization [14], data integration [11], data cleansing [2], and data translation [3]. Given that the functional dependencies are not only known for a snapshot of the data but over a longer period of time, it is for any of these use cases easier to identify *robust* dependencies. Continuous *change patterns* for non-robust dependencies, on the other hand, can be of interest themselves; and *sudden changes* of thus far robust FDs might signal data quality issues, i. e., erroneous updates.

The most interesting FDs for all such applications are *minimal, non-trivial* FDs. An FD $X \longrightarrow A$ is non-trivial if $A \notin X$, otherwise it would hold on any instance r of R and, hence, would not characterize r. An FD is minimal if no *generalization*, i. e., no subset of the FD's LHS also describes a valid FD. More formally, an FD $X' \longrightarrow A$ is a generalization of another FD $X \longrightarrow A$ if $X' \subset X$. On the other hand, an FD $X'' \longrightarrow A$ is a *specialization* of an FD $X \longrightarrow A$ if $X \subset X''$, i. e., if its LHS is a superset of the other FD's LHS. Any valid, minimal FD implies that all of its specializations are valid as well, which makes them particularly interesting. As a result, given the *complete* set of minimal FDs, all other FDs can be inferred from it. For this reason, it suffices to discover and maintain only minimal, non-trivial FDs.

Series ISSN: 2367-2005

10.5441/002/edbt.2019.23

Despite the restriction to minimal FDs, the discovery of all such dependencies is still expensive: Liu et al. have shown that, when using nested loops for the dependency validations, the complexity of the discovery is in $O\left(n^2 \left(\frac{m}{2}\right)^2 2^m\right)$ for relations with m attributes and n records [10]. More sophisticated, index-based algorithms, such as [8] or [13], avoid the quadratic complexity of the candidate validations (n^2), but the algorithms' complexity w. r. t. the number of attributes stays exponential (2^m). This is inevitable due to the potentially exponential number of discovered FDs. The discovery problem becomes even harder when taking data changes into account. As mentioned above, all state-of-the-art FD discovery algorithms operate only on *static datasets* and one needs to re-execute them after every change of the data to maintain the FDs on *dynamic datasets*. Unfortunately, this is computationally far too expensive in practical situations: It is not unusual for those algorithms to take minutes or even hours to complete.

However, the following two observations suggest that this problem can be solved with a novel, *incremental* algorithm: First, most changes affect only a small subset of records and only these small deltas need to be investigated for causing metadata changes – the majority of records still support the same FDs as before. Second, most changes in the FDs are minor, meaning that a close specialization or generalization of a former minimal FD becomes a new minimal FD.

On the face of this opportunity, we propose DynFD, the first algorithm that maintains the complete and exact set of minimal, non-trivial FDs on dynamic data. The algorithm monitors data changes, i. e., inserts, updates, and deletes, and calculates their effect on the metadata. The changes are grouped into batches of configurable size so that a user can specify timeliness of the metadata (at the cost of performance). So rather than frequently re-computing all FDs, DynFD continuously deduces FD changes from the previous set of FDs and the batch of change operations. In detail, our contributions are the following:

(1) *FD maintenance algorithm.* We present DynFD, an algorithm that incorporates data changes, i. e., inserts, updates, and deletes, as batches into sets of minimal functional dependencies. While updates are simply handled as a combination of insert and delete, the algorithm offers specialized handling strategies for inserts and deletes (Section 2).

(2) *FD maintenance data structures.* To update the dependencies efficiently, our DynFD algorithm needs to maintain several data structures, such as position list indexes, dictionary-encoded records, and FD prefix trees, over time. We explain these data structures and how they need to change w. r. t. newly inserted or deleted tuples. We also propose a novel cover inversion algorithm to deduce an FD negative cover from an FD positive cover (Section 3).

(3) *FD maintenance pruning rules and techniques.* We devise novel pruning rules and techniques for insert and delete operations that allow DynFD to optimize or even skip certain validations. For validations that cannot be skipped, we propose efficient validation methods that exploit the incremental nature of the data changes (Section 4 and Section 5).

(4) *Evaluation.* We provide an exhaustive evaluation of DynFD w. r. t. scalability and speed-up. We investigate the effectiveness of our pruning and maintenance strategies and compare DynFD to HyFD, the state-of-the-art FD discovery algorithm for static data (Section 6).

2 OVERVIEW OF DYNFD

Before we discuss implementation details, we give an overview of our proposed algorithm DynFD. This algorithm operates on a single relation, such as the one exemplified in Table 1, which may or may not contain an initial set of tuples (here: tuples 1–4). The relation is then subject to a series of batches of changes. Each batch inserts and/or deletes tuples from the relation. For instance, Table 1 shows a batch that removes tuple 3 and inserts tuples 5 and 6. Note that tuple updates can be expressed by a delete and an insert operation. Also, note that the size of the batches is at the discretion of users and their use cases and allows for a trade-off between granularity and performance of the FD maintenance process.

As explained in Section 1, each batch *can* change the set of minimal FDs in a relation. For instance, while the FD $z \longrightarrow c$ continues to be a minimal FD in Table 1 before and after the batch has been applied, $f \longrightarrow c$ becomes a new minimal FD and $fc \longrightarrow z$ ceases to be a (minimal) FD.

To discover these changes, DynFD comprises three principal components as can be seen in Figure 1: (i) the *data structures*, which are position list indexes and dictionary-encoded records, concisely model all relevant features of the relation to determine the currently valid FDs; (ii) the *positive cover* indexes all minimal FDs and allows to reason on the effect of insert operations; and (iii) the *negative cover* with all maximal non-FDs allows to process delete operations analogously. If the profiled relation contains initial tuples, we employ the static algorithm HyFD [13] to bootstrap the data structures and the positive cover. The negative cover can then be derived from the positive cover via a *cover inversion* as we describe in Section 3.2.

Having initialized all necessary data structures, DynFD begins to monitor changes of the profiled relation. These changes arrive as a stream that is first transformed and then processed in batches, i. e., non-overlapping groups of insert, update, and delete operations. The batches can be, e. g., equally sized groups of change operations or, alternatively, all operations from within a tumbling time window. Each batch is processed according to the following observation: According to Definition 1.1, insert operations can introduce violations to existing FDs, but never remove them. As a result, those FDs become invalid. We can efficiently retrace these changes by operating on the positive cover, i. e., on the existing minimal FDs. Delete operations constitute the opposite case: Exiting violations may be removed, thereby introducing new FDs – or in other words, existing non-FDs may become valid. Here, the negative cover is more appropriate to efficiently reason on delete operations. For this reason, we handle insert and delete operations separately, yet with the same basic principles.

Figure 1: Processing one batch of insert and delete operations with DynFD.

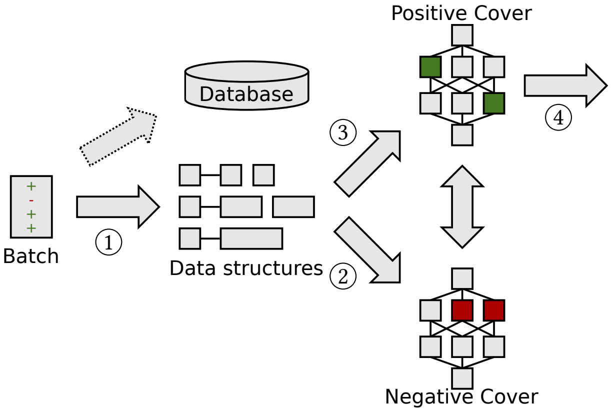

Figure 1 depicts the processing pipeline in more detail. In Step (1) of this process, DynFD efficiently updates its data structures according to the changes in the batch (see Section 3.1). In doing so, DynFD does not need to perform potentially expensive read operations on the database. Not accessing the database is particularly important, also because reads would lead to race conditions with the changes applied by the database itself, i. e., a change that is being processed by DynFD might not have been (fully) applied by the database, yet, or the database may have already applied a subsequent change that DynFD has not yet seen. In Step (2), DynFD processes all deletes in the batch by checking whether they resolve any maximal non-FD in the negative cover (see Section 5); if a non-FD becomes a valid FD, this change is also propagated to the positive cover. Then, in Step (3), the algorithm processes all inserts by checking whether they introduce a violation to any minimal FD in the positive cover (see Section 4); in case they do, the positive cover is updated and the changes are propagated to the negative cover. Hence, due to the change propagation, Steps (2) and (3) may both affect both covers. In Step (4), DynFD finally signals all changed FDs to the user and is then ready to process the next batch.

The attentive reader may have noticed that we choose to process deletes before inserts, although the other way around is also possible. The decision on which type of operation to process first is particularly important for the special but common case of tuple updates, which we split into an insert and a delete. By processing the delete first, we avoid operating on an intermediate relation that contains both the old and the new version of the updated tuple. Such an almost duplicate tuple would violate many dependencies, in particular key dependencies, for the time of its existence. Hence, many FDs would change only to change back when the (almost) duplicate is removed again. So in short, processing deletes first significantly reduces the number of temporarily changing FDs.

3 DATA STRUCTURES

Rather than recalculating the FDs of a relation after each batch of changes, DynFD creates and maintains several data structures from which to derive the FDs. For that matter, we discern two types of data structures, namely those that represent the relation in a compact format that is suitable to efficiently check the validity of FD candidates; and the positive and negative cover, which we use to evolve the set of minimal FDs and maximal non-FDs, respectively. In the following, we briefly describe those data structures and how to update them in incremental scenarios.

3.1 Representing relations compactly

When validating FD candidates against a relation, the actual values within that relation are irrelevant. Instead, we merely need to know, which tuple pairs have identical values for which attributes. Therefore, it is sufficient for DynFD to represent the relation as *compressed records* [13]. Consider the example in Table 2, which represents the initial state of Table 1, i. e., before the change. Essentially, the compressed records replace all values of the original relation with a number that uniquely identifies that value within its column. For instance, the city name "Potsdam" is replaced by the value 0 and the city name "Berlin" is replaced by the value 1. This replacement not only has a small memory footprint but also allows for more efficient equality comparisons. This scheme is further optimized by replacing unique values with the value "−1". If DynFD encounters a "−1", it can skip all comparisons, as by definition all other tuples must have distinct values for the affected column.

Table 2: The dictionary-encoded example of Table 1.

ID	f	l	z	c
1	0	0	0	0
2	0	−1	0	0
3	0	0	−1	1
4	−1	−1	−1	1

While compressed records are well-suited to compare individual tuple pairs to quickly detect FD violations and rule out some FD candidates, they are not suitable to validate FD candidates as a whole. Therefore, DynFD complements the compressed records with *position list indexes* (Plis) [13], also known as stripped partitions [8]. In few words, a Pli lists the *clusters* of tuple IDs that have the same values for a certain attribute. For our example data from Table 1, we therefore obtain the Plis $\pi_f = \{\{1, 2, 3\}, \{4\}\}$ for firstname, $\pi_l = \{\{1, 3\}, \{2\}, \{4\}\}$ for lastname, $\pi_z = \{\{1, 2\}, \{3\}, \{4\}\}$ for zip, and $\pi_c = \{\{1, 2\}, \{3, 4\}\}$ for city. The Pli π_X for a set of attributes X can be computed via Pli intersection, i. e., by intersecting all pairs of overlapping clusters in the Plis π_Y and π_Z with $Y \cup Z = X$. Hence, $\pi_X = \pi_Y \cap \pi_Z$ and, for example, $\pi_{fc} = \pi_f \cap \pi_c = \{\{1, 2\}, \{3\}, \{4\}\}$. A functional dependency $X \longrightarrow A$ holds iff $\pi_X \cap \pi_A = \pi_X$, i. e., π_A does not split any cluster in π_X so that all records with equal values in X have also equal values in A [8]. Calculating $\pi_X \cap \pi_A$ can be done efficiently by using the compressed records: The (well-known) FD validation algorithm uses the Pli for some attribute $A \in X$ as an index to sets of tuples in the compressed records that are, then, grouped by same X values and checked against their A values. For more details and optimizations of this validation algorithm, we refer the interested reader to [13].

Compressed records and Plis synergize well in validating FD candidates, which has already been shown for static FD discovery. In a static setup, however, both data structures identify each record by its row number, i. e., position in the relational table. These row numbers, change in the dynamic setting, because the table grows and shrinks. For this reason, we assign a continuous number as a surrogate key to each record to identify it. The main challenge for using compressed records and Plis in the dynamic case is that we need to update these data structures with every batch of changes. For this, we propose the following:

Insert. A newly inserted record adds an entry to both data structures: We first add its identifier to all Plis. For every attribute, we read the attribute's value from the new record and fetch the attribute's Pli from the list of Plis. We then need to find the cluster in the Pli that corresponds to the said value and add the record's identifier to it. To find that cluster, the algorithm needs to remember the value of each cluster. It does so by storing and maintaining an additional *inverted index* on top of the Plis, i. e., the inverted index points each value to the Pli cluster in which it occurs. Following this mapping, it is easy to find the clusters were DynFD needs to add an identifier; if some value has no cluster in a Pli yet, it creates a new cluster. Given the cluster numbers of all attributes for the new record, updating the dictionary-encoded records is done by simply appending the array of these cluster numbers to the list of dictionary-encoded records.

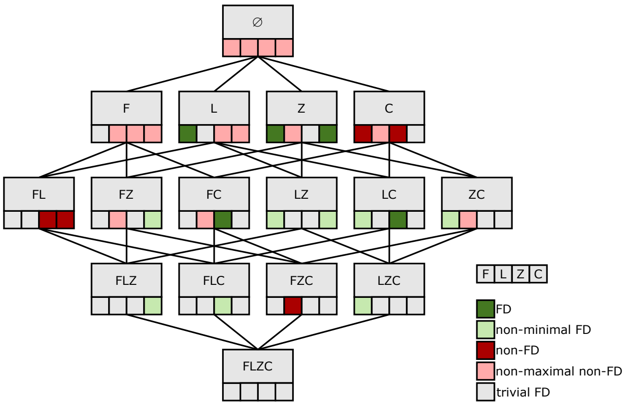
Delete. To delete a record from the data structures, we follow a similar, quick look-up strategy: For every attribute, DynFD first retrieves the Pli cluster that corresponds to the attribute's value in the deleted record. Then, it removes the identifier of the deleted record from these clusters; if a cluster becomes empty, the algorithm deletes the cluster from the Pli entirely. After the Pli update, DynFD also removes the record's compressed representation from the list of dictionary-encoded records. To find the record, we use another additional index, the *hash index*, that points the identifiers to their dictionary-encoded records. Alternatively, one could also find the record via binary search on the list of dictionary-encoded records, but the hash index has an infinitesimally small memory footprint in comparison to the other data structures and offers better performance than binary search. Once the compressed record is determined, DynFD deletes it from the list and the hash index.

3.2 Organizing functional dependencies

Let us now describe how DynFD organizes its discovered FDs and non-FDs. The FD search space is usually modeled as a *powerset lattice*, which is a graph representation of all possible attribute combinations. Due to the partial order of the power set, every two elements have a unique supremum and a unique infimum so that the graph can connect each node $X \subseteq R$ to its direct subsets $X \setminus A$ and direct supersets $X \cup \{B\}$ (with $A \in X$, $B \in R \backslash X$). Every node in the lattice represents one Lhs attribute combination for a set of FD candidates; each such FD candidate is defined by its Rhs attribute, which can bee seen as annotations at every node. In this way, all $2^m \cdot m$ possible FDs are covered by the lattice. During FD discovery, we classify each annotation and, hence, the respective Lhs $\longrightarrow$ Rhs candidate as either valid or invalid FD.

Figure 2 depicts the lattice of FD candidates for the initial state of our example relation from Table 1 (tuples 1 to 4). The five minimal FDs $l \longrightarrow f$, $z \longrightarrow f$, $z \longrightarrow c$, $fc \longrightarrow z$, and $lc \longrightarrow z$ have been discovered with a static profiling algorithm and we can infer all non-minimal and invalid FDs from them. To show how valid and invalid FDs are located in this search space visualization, all annotations have been color coded: Green cells represent valid FDs whereas red cells represent invalid FDs or short *non-FDs*. Stronger colors denote minimality for FDs and maximality for non-FDs. Note that a non-FD is maximal if no specialization of it is also a non-FD. Trivial FDs are shown in grey, because they are not of interest. So for example, we find the valid, minimal FD $fc \longrightarrow z$ as the dark green annotation for Rhs attribute Z in Lhs node *FC*.

Figure 2: FD lattice for the data shown in Table 1.



The complete set of minimal FDs is called the *positive cover*, because all non-minimal FDs can be derived from it. The complete set of maximal non-FDs, in contrast, is called *negative cover*, because it defines all existing non-FDs.

DynFD stores both the negative and the positive cover as *FD prefix trees*, which are technically prefix trees with annotations: Each node in the tree represents a Lhs attribute, any path starting from the root node represents a Lhs, and annotations on the nodes indicate valid Rhs attributes for the respective paths [6]. FD prefix trees are not only a compact data structure for storing FDs, they also offer efficient look-up functions for FD generalizations and specializations – functions that are called frequently by DynFD.

The positive cover, the Plis, and the dictionary compressed records represent the initial input for DynFD. By running the static FD discovery algorithm HyFD first, we can simply obtain all three data structures directly from that algorithm; otherwise, if only the set of minimal FDs is given, it is trivial to construct them in a preprocessing step. What is not trivial is the calculation of the negative cover, i. e., all maximal non-FDs, from the given FDs. The process of calculating the positive from the negative cover is known as *cover inversion* [6] or *dependency induction* [13], but its inverse, the calculation of the negative from the positive cover, has not been studied before. With Algorithm 1, we hence present the first inversion algorithm for this step.

We start with an empty FD prefix tree *nonFds* (line 1). For every attribute A of a relation R, the algorithm then adds the most specific non-FD, which states that all other attributes do not functionally determine A (lines 2-4). Initialized in this way, the negative cover invalidates all possible FDs and basically states that there are no FDs in the data. This initialization is probably not true, but serves as a starting point for successive refinement. Hence, the algorithm then checks for every valid FD whether it covers some non-FD by looking up all specializations of that FD in the negative cover (lines 5-6). This look-up is implemented as a simple depth-first search in the FD prefix tree. If a non-FD has been found to be a specialization of a valid FD, it must in fact be valid. For this reason, Algorithm 1 removes it from the negative cover (line 8). Then, we need to check all direct generalizations of the removed non-FD for being maximal non-FDs. The inversion algorithm creates each of these generalizations by removing one Lhs attribute from the current non-FD's Lhs (lines 9-11). If such a created non-FD is maximal, i. e., if it has no specialization in the cover, it is added to the negative cover (lines 12-13); otherwise, if

Algorithm 1: Cover inversion

```
Data: relation $R$, positive cover $fds$
Result: negative cover $nonFds$
$nonFds \leftarrow \emptyset$;
for $A \in R$ do
    $initialLhs \leftarrow R \setminus \{A\}$;
    $nonFds \leftarrow nonFds \cup \{initialLhs \rightarrow A\}$;
for $fd \in fds$ do
    $violated \leftarrow nonFds.getSpecializations(fd)$;
    for $nonFd \in violated$ do
        $nonFds \leftarrow nonFds \setminus \{nonFd\}$;
        for $l \in fd.getLhs()$ do
            $newLhs \leftarrow nonFd.getLhs() \setminus \{l\}$;
            $gen \leftarrow (newLhs \rightarrow nonFd.getRhs())$;
            if $\neg nonFds.containsSpecialization(gen)$ then
                $nonFds \leftarrow nonFds \cup \{gen\}$;
return $nonFds$
```

it is not maximal, it is simply discarded. Repeating this for every valid, minimal FD creates the negative cover.

Applied to the example data shown in Table 1, we start with the assumption that $flz \rightarrow c$, $flc \rightarrow z$, $fzc \rightarrow l$, and $lzc \rightarrow f$ are maximal non-FDs. Because the non-FD $lzc \rightarrow f$ is a specialization of the minimal FD $l \rightarrow f$, it needs to be removed as a non-FD. We then generalize it to $zc \rightarrow f$ as a new maximal non-FD candidate. This non-FD is a specialization of the minimal FD $z \rightarrow f$ (that we check next) so we generalize it once more, to $c \rightarrow f$. After also applying the remaining three minimal FDs to the negative cover, the inversion algorithms yields the final maximal non-FDs $fzc \rightarrow l$, $fl \rightarrow z$, $fl \rightarrow c$, $c \rightarrow f$, and $c \rightarrow z$.

4 HANDLING INSERTS

Having discussed DynFD's principal workflow along with its basic data structures, we now present a mechanism to maintain FDs in the light of insert operations (delete operations are discussed in the following section). Inserts can only render previously valid FDs invalid. Because the minimal FDs in the positive cover imply all valid FDs, they are the starting point for our validations. To process a batch of inserts, we validate all known minimal FDs and specialize them in case they became invalid. To ensure minimality for newly created specializations, we validate the minimal FDs from most general to most specific. In this way, we can check for each new specialization, if there is a valid generalization in the positive cover; the specialization would then not be minimal, because its generalization has already been determined to be true (minimality pruning). We discuss this main validation process, which is basically a *lattice traversal* type FD discovery approach, in Section 4.1.

To identify invalid FDs more quickly, we add an optimization to the validation process that, if the process becomes inefficient, progressively searches for FD violations. If a certain amount of FDs has been found invalid, the lattice traversal starts creating and checking many new candidates – most of which are usually invalid. For this situation, related work proposed *dependency induction* and sampling techniques that find most such violations faster than validating all candidates individually [13]. In Section 4.3, we propose an adapted version of these techniques for our dynamic setup.

Algorithm 2: Lattice-based FD validation

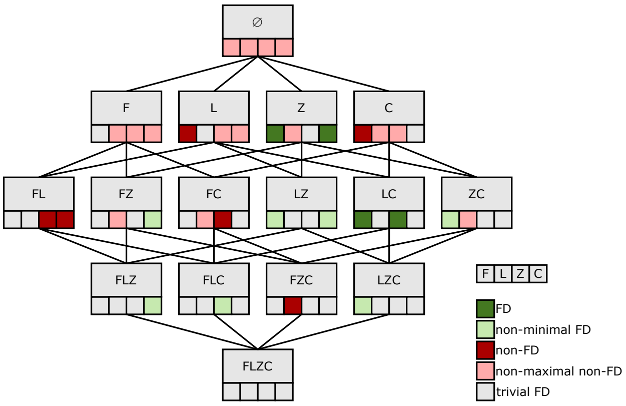
```
Data: relational schema $R$, positive cover $fds$, negative
      cover $nonFds$
Result: updated $fds$, $nonFds$
1  for $level \in 0...|R|$ do
2      $invalidFds \leftarrow \emptyset$;
3      for $fd \in fds.getLevel(level)$ do
4          if $\neg isValid(fd)$ then
5              $invalidFds \leftarrow invalidFds \cup \{fd\}$;
6      for $nonFd \in invalidFds$ do
7          $fds \leftarrow fds \setminus \{nonFd\}$;
8          $nonFds.removeGeneralizations(nonFd)$;
9          $nonFds \leftarrow nonFds \cup \{nonFd\}$;
10         $rhs \leftarrow nonFd.getRhs()$;
11         for $r \in R \setminus (nonFd.getLhs() \cup \{rhs\})$ do
12             $newLhs \leftarrow nonFd.getLhs() \cup \{r\}$;
13             $spec \leftarrow \langle newLhs \rightarrow rhs \rangle$;
14             if $\neg fds.containsGeneralization(spec)$ then
15                 $fds \leftarrow fds \cup \{spec\}$;
16     if $|invalidFds| \;/\; |fds.getLevel(level)| > 0.1$ then
17         $progressiveViolationSearch(fds, nonFds)$
18 return $fds$, $nonFds$
```

Note that whenever either of the two validation strategies, i. e., the lattice traversal or the dependency induction, discovers a non-FD, this non-FD must also be added to the negative cover. The process for updating the negative cover with a new non-FD covers two simple steps: First, remove all generalizations of the new non-FD from the cover (they are not maximal any more); then, add the new non-FD to the negative cover (without a check for specializations, because the non-FD used to be a valid FD before and is, therefore, inevitably maximal).

4.1 Incremental FD validation process

Algorithm 2 shows the lattice traversal-based FD validation algorithm that is executed for every batch in the dynamic setting. We start with the most general FDs in the positive cover and proceed to ever larger FDs (line 1). On each level of the lattice, the algorithm validates all minimal FDs and stores the invalid ones (lines 2-5). The validation function *isValid()* implements an optimized version of the Pli intersection technique that we touched on in Section 3.1; we discuss the optimization in Section 4.2. Iterating over all found non-FDs (line 6), the algorithm first removes each non-FD from the positive cover (line 7). As stated before, these non-FDs must also be maximal and are, therefore, added to the negative cover (lines 8-9). Afterwards, Algorithm 2 generates and adds all specializations of the current non-FD to the positive cover that are minimal w. r. t. the existing FDs (lines 10-15): To generate the specializations, we first add each attribute that is not already part of the Lhs or Rhs to the new Lhs (lines 11-13); each specialization is checked for generalizations in the positive cover before it is finally added to the cover (lines 14-15). On the next level, Algorithm 2 automatically validates these specializations. However, before moving to the next level, we check which fraction of validations in the current level has led to non-FDs (line 16). If this fraction is greater than 10% (see [13] for why this is a good threshold), then we consider the lattice traversal to be

Figure 3: Lattice after handling inserts in Table 1.



inefficient and start a progressive search for violations (line 17). When the search returns, it might yield updated versions of the positive and negative cover. Algorithm 2 then proceeds to the next lattice level until all minimal FDs have been checked.

Applying this to our example, we have the initial candidates $z \longrightarrow c$, $z \longrightarrow f$, $l \longrightarrow f$, $lc \longrightarrow z$, and $fc \longrightarrow z$. They are represented by the dark green cells in Figure 2. We start at the top of the lattice and work our way to the bottom. When validating the most general FDs, we find that $l \longrightarrow f$ is not valid anymore and, hence, a candidate for a maximal non-FD. The only new candidate is $lc \longrightarrow f$, since $lz \longrightarrow f$ is not minimal. Validating the now most general candidates shows that $fc \longrightarrow z$ is also invalid. There are no new candidates to be added. It also follows that $c \longrightarrow z$ is no maximal non-FD anymore and needs to be removed from the negative cover. Because no candidates are left, we are done and found the minimal FDs holding after inserting the new records. The corresponding lattice is shown in Figure 3.

4.2 Cluster pruning

To validate the minimal FDs in the positive cover, we build on the Pli-based validation algorithm presented in [13]: This algorithm uses the single-column Plis and dictionary-encoded records to dynamically calculate the Pli intersection of all Lhs attributes; at the same time, the algorithm checks the resulting clusters against the Rhs attribute clusters. If a check fails, i. e., if it reveals an FD violation, the algorithm terminates the validation process early. Furthermore, it performs this check for all FD candidates with the same Lhs simultaneously.

Our DynFD algorithm enhances this validation strategy: Instead of validating the FD against the entire dataset, we validate it against only the newly added and a few related records. Recall from Definition 1.1 that an FD is invalidated by a pair of records with equal values in the Lhs attributes but different values in the Rhs attribute. Because for inserts we validate only previously valid FDs, all pairs of *old* records still satisfy the FD. Only pairs of records containing at least one new record might introduce violations. Thus, the validation step for inserts needs to check such pairs only.

We integrate this optimization into our validation algorithm as follows: Given a fixed ordering of attributes by their respective Pli sizes, the validation starts by iterating the clusters of the Pli of the first Lhs attribute. For each cluster, the algorithm dynamically calculates the intersection with all other Lhs clusters to check the result against the Rhs clusters. At this point, which is, before calculating the intersections, DynFD first checks if the current cluster of the first Lhs attribute contains an identifier of a new record. This check is very simple, because the identifier numbers are assigned monotonically increasing (see Section 3.1) and the identifiers in each cluster are sorted. Hence, DynFD simply checks whether the last entry in the cluster is less than the identifier of the first insert-record in the current batch: If so, the cluster can be ignored; otherwise, the cluster contains at least one new record and needs to be checked via dynamically intersecting the Lhs attributes and probing the result against the Rhs attribute clusters.

As a result, DynFD's validation function *isValid()* (Algorithm 2 line 4) checks only the delta of the current batch for changing an FD and not the entire dataset. This optimization significantly improves the efficiency of the validation step, as many unnecessary comparisons are saved.

4.3 Violation search

If the lattice traversal becomes inefficient (Algorithm 2 line 16-17), DynFD switches to a strategy that we call *violation search*. This strategy is a best effort approach to find violations for formerly valid FDs via comparing records: Given two records r_i and r_j with their dictionary-encoded signature, we can easily compute the set of attributes X, in which r_i and r_j hold same values, and the set of attributes Y, in which r_i and r_j hold different values. It follows that $X \longrightarrow Y$ are all non-FDs.

Any newly inserted record can cause violations only with those partner records that have at least one value with the inserted record in common; records that do not share any value with the inserted record need not be considered. With DynFD's Plis, we can easily retrieve all those partner records by simply collecting all Pli clusters of the inserted record. Comparing the inserted record to all records in these clusters would, in fact, reveal all new violations, but the comparison costs are quadratic in the number of records, which is usually too expensive. For this reason, DynFD compares an inserted or changed record only to a small, promising subset of partner records.

Related work has shown that record pairs with possibly many overlapping values are promising candidates for finding new violations [13]. A sorting approach was demonstrated that moves pairs with high overlap closer together so that near neighborhoods become promising candidates. These neighborhoods are then progressively explored by moving ever larger windows over the sortings. If the violation search becomes inefficient, which is when less than 10% of the comparisons reveal new violations, the search ends. DynFD implements the exact same progressive search, but it compares only those record pairs that include at least one inserted (or updated) record.

For every discovered non-FD, DynFD needs to update both the positive and the negative cover. Algorithm 3 shows the necessary steps: It first updates the positive cover (lines 1-9) and then the negative cover (lines 10-13). To update the positive cover, the algorithm collects all invalidated FDs and removes them from the cover (lines 1-3). For each of these invalidated FDs, it also generates all direct specializations adding the minimal ones to the positive cover (lines 4-9). To update the negative cover, Algorithm 3 first checks if it contains a specialization (line 10); only if there is no specialization, the current non-FD is maximal and we add it to the negative cover (lines 11-12).

Algorithm 3: Dependency induction from a non-FD

```
Data: relational schema $R$, nonFd, positive cover fds,
      negative cover nonFds
Result: updated fds, nonFds
invalid ← fds.getGeneralizations(nonFd);
for fd ∈ invalid do
    fds ← fds \ {fd};
    rhs ← fd.getRhs();
    for $r \in R \setminus$ (nonFd.getLhs() ∪ {rhs}) do
        newLhs ← fd.getLhs() ∪ {r};
        spec ← (newLhs → rhs);
        if ¬fds.containsGeneralization(spec) then
            fds ← fds ∪ {spec};
if ¬nonFds.containsSpecialization(nonFd) then
    nonFds.removeGeneralizations(nonFd);
    nonFds ← nonFds ∪ {nonFd};
return fds, nonFds
```

5 HANDLING DELETES

To handle deletes, we propose a lattice traversal approach that validates the non-FDs in the negative cover level-wise starting with the most specific non-FDs and successively proceeding to more general ones. Because the maximal non-FDs imply all other non-FDs, the validation algorithm checks and, if necessary, generalizes only maximal non-FDs. Due to the level-wise iteration of the lattice, we can test any newly derived generalization for specializations in the negative cover to ensure that only maximal non-FDs are added back into the negative cover (maximality pruning). We describe this main validation process of the negative cover in more detail in Section 5.1 and its optimizations in Section 5.2 and Section 5.3.

5.1 Incremental non-FD validation process

Algorithm 4 shows the lattice traversal-based *non-FD* validation algorithm. This algorithm basically inverts the lattice traversal algorithm for inserts (see Algorithm 2): It operates on the negative cover instead of the positive cover (line 3), it traverses the cover from the most special non-FDs to the most general non-FDs instead of from most general to most special FDs (line 1), it transfers updates to the positive cover instead of to the negative cover (lines 8-9), and it generalizes de-facto-valid non-FDs instead specializing de-facto-invalid FDs (lines 10-14).

The validation function *isValid()* (line 4) is the same validation function that we already introduced for the validation of FDs in the insert scenario, but we now expect the outcomes to be mostly non-FDs. For non-FDs, DynFD adds an additional pruning technique to the validation that we explain in Section 5.2.

One major difference to the insert scenario, though, is that deleted records *resolve* violations and do not *introduce* them. For this reason, the progressive violation search, which compares promising record pairs in the quest for new non-FDs, makes no sense due to the lack of new non-FDs. Instead, we propose optimistic *depth-first searches* if the number of valid FDs exceeds 10% of all validated non-FDs in a current level (lines 15-16). We explain these optimistic depth-first searches in Section 5.3.

Applying the algorithm to our example, we start with the initial candidates for maximal non-FDs $fzc \rightarrow l$, $fl \rightarrow z$, $fl \rightarrow c$, $fc \rightarrow z$, $l \rightarrow f$, and $c \rightarrow f$. They are the dark red cells in Figure 3 and we traverse the lattice from bottom to top. Starting with the most specific candidate, nothing changes. In the next step, it turns out that both $fl \rightarrow z$ and $fl \rightarrow c$ become valid. Thus, they are both candidates for new minimal FDs. Furthermore, we need to add the generalizations $f \rightarrow c$, $l \rightarrow z$, and $l \rightarrow c$ to the negative cover. $f \rightarrow z$ is not maximal and therefore not a new candidate. Validating the remaining five candidates shows that also $f \rightarrow c$ is valid and thus a candidate for a new minimal FD. $fl \rightarrow c$ is not a minimal FD anymore. There are no new candidates for maximal non-FDs and we end up with six minimal FDs. The corresponding lattice is shown in Figure 4.

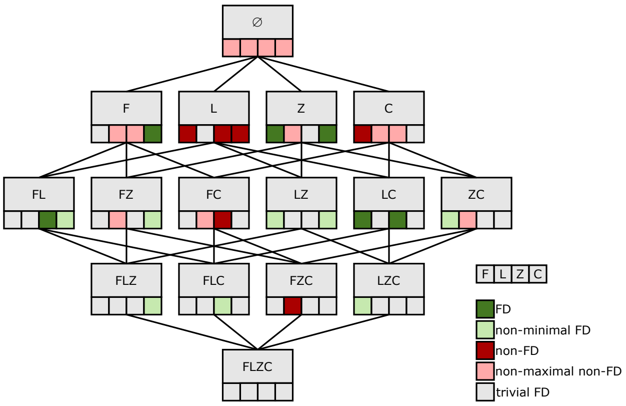
Algorithm 4: Lattice-based non-FD validation

```
Data: relational schema $R$, positive cover fds, negative
      cover nonFds
Result: updated fds, nonFds
1  for level ∈ |R|...0 do
2      validFds ← ∅;
3      for nonFd ∈ nonFds.getLevel(level) do
4          if needsValidation(nonFd) ∧ isValid(nonFd) then
5              validFds ← validFds ∪ {nonFd};
6      for fd ∈ validFds do
7          nonFds ← nonFds \ {fd};
8          fds.removeSpecializations(fd);
9          fds ← fds ∪ {fd};
10         for r ∈ fd.getLhs() do
11             newLhs ← fd.getLhs() \ {r};
12             gen ← (newLhs → fd.getRhs());
13             if ¬nonFds.containsSpecialization(gen) then
14                 nonFds ← nonFds ∪ {gen};
15     if |validFds| / |nonFds.getLevel(level)| > 0.1 then
16         depthFirstSearch(validFds, fds, nonFds)
17 return fds, nonFds
```

5.2 Validation pruning

Most FD candidates that we validate in the delete scenario are non-FDs and the purpose of validation is to confirm that there is still at least one violation to each candidate. Although the validation algorithm terminates as soon as it finds the first violation to a candidate, in many cases it still checks a lot of matching

Figure 4: Lattice after validating non-FDs



Algorithm 5: Depth first search for FDs

```
Data: fd, positive cover fds, negative cover nonFds
Result: updated fds, nonFds
1  for r ∈ fd.getLhs() do
2      newLhs ← fd.getLhs() \ {r};
3      newFd ← (newLhs → rhs);
4      if fds.containsGeneralization(newFD) ∨ isValid(newFd) then
5          depthFirst(newFd, fds, nonFds);
6  deduceNonFds(fd, fds, nonFds);
7  return fds, nonFds
```

value combinations, which is expensive. To avoid many of these checks, DynFD stores a violating record pair, which is a pair of two identifiers whose records contradict the FD, as a *surrogate violation* for every maximal non-FD in the negative cover. As long as these two records exist in the data, the algorithm does not need to check the corresponding non-FD.

So what DynFD does is the following: Whenever the algorithm creates a non-FD, it also attaches the record pair that made the FD invalid to the respective non-FD lattice node. When this lattice node needs to be validated (see Algorithm 4 line 4), the algorithm first calls the function *needsValidation()* to check whether one of its two attached records was deleted in the current batch. In case both records are still present, which is usually true, no validation is needed; otherwise, the algorithm has to run the validation to, depending on the result, either attach a new violating record pair or remove the non-FD.

In order to consistently attach violating record pairs to all non-FDs in the negative cover throughout the dynamic discovery process, we need to consider two procedures in DynFD that identify new non-FDs: the candidate validation (*isValid()* function) and the sampling (Section 4.3). Both procedures know a violating record pair whenever an FD candidate is invalidated so that they can simply attach this record pair to a new non-FD. Conversely, if records are deleted, they need to be consistently removed from the non-FDs. For this purpose, we index all non-FD annotations (*recordID* → *nonFD*) and, for every batch of deletes, remove from the negative cover all record identifiers (and their respective partner record identifiers) if a batch deletes them. The initial non-FD annotations in the negative cover are calculated on the fly with the first batch, because whenever a maximal non-FD lacks a violation annotation, Algorithm 4 validates it anyway.

5.3 Depth-first searches

If a prior non-FD becomes valid, we successively check all its generalizations. These checks can continue for many levels in the lattice and stretch out to an exponential number of candidates (exponential in the number of attributes); this makes the validation very expensive. The new non-FDs are, however, often covered by only a few maximal non-FDs. Hence, we propose optimistic depth-first searches that target maximal non-FDs of small Lhs-arity; these non-FDs prune many candidate non-FDs from the lattice.

If more than 10% of the non-FDs in one level of the negative cover became true FDs (Algorithm 4 line 15), we start the optimistic depth-first search. This subroutine takes the *validFds*, which are the former non-FDs that have been found valid, as input. For a sample of 10% of these *seed FDs*, DynFD aggressively searches their generalizations for new maximal non-FDs. We consider only a sample of the seed FDs, because the depth-first searches are an optimistic optimization attempt and should not change the search strategy entirely – most FDs still change only a bit making breath-first search in general more effective. The 10% efficiency threshold and the 10% seed sample are hard-coded parameters that have shown to be efficient settings for most datasets. The non-FDs discovered in the depth-first searches might be new overall maximal non-FDs and are, hence, used to update both the negative cover *nonFds* and the positive cover *fds*.

Algorithm 6: Dependency induction from a FD

```
Data: fd, positive cover fds, negative cover nonFds
Result: updated fds, nonFds
1  valid ← nonFds.getSpecializations(fd);
2  for nonFd ∈ valid do
3      nonFds ← nonFds \ {nonFd};
4      rhs ← nonFd.getRhs();
5      for r ∈ fd.getLhs() do
6          newLhs ← nonFd.getLhs() \ {r};
7          gen ← (newLhs → rhs);
8          if ¬nonFds.containsSpecialization(gen) then
9              nonFds ← nonFds ∪ {gen};
10 if ¬fds.containsGeneralization(fd) then
11     fds.removeSpecializations(fd);
12     fds ← fds ∪ {fd};
13 return fds, nonFds
```

The algorithm that performs an optimistic depth-first search for one seed FD is depicted in Algorithm 5. It implements a recursive depth-first traversal of the positive cover starting with the seed FD *fd*. Given a valid FD, Algorithm 5 first generates all its direct generalizations by gradually removing each attribute from the Lhs (lines 1-3). For each generalization, the algorithm then checks if it has an own generalization in the positive cover. In that case, the generalization is true and it must not be validated; otherwise, Algorithm 5 validates the generalization (line 4). For every valid generalization, we continue the depth-first search (line 5). After handling all generalizations, the current FD is used to deduce new non-FDs in the negative cover (line 6). This step is done at last, because the deduction is expensive and, if some more general FDs have already been used for deduction in some recursion, there is less to be deduced for the current FD.

The function *deduceNonFds()* updates both negative and positive cover with a new, true FD. It is basically an exact inversion of the deduction Algorithm 3 for non-FDs as we now specialize the negative cover and generalize the positive cover accordingly. Technically, we switch negative and positive cover, and generalization and specialization, which yields Algorithm 6. This algorithm starts by retrieving all non-FD specializations of the known FD from the negative cover (line 1). All these FDs are valid now. Hence, it then removes each such FD from the negative cover (lines 2-3). To generalize the new valid FDs into possibly true non-FDs, the algorithm removes each attribute of the valid FD's Lhs once (lines 5-7). If such a generalization is maximal, it is added to the negative cover (lines 8-9). After updating the negative cover, Algorithm 6 also updates the positive cover with the known FD by adding the FD to the positive cover and removing all its specializations (lines 10-12).

6 EVALUATION

We now evaluate the performance of our FD maintenance algorithm DynFD on multiple real-world datasets. The evaluation covers a detailed analysis of our proposed pruning rules and techniques and compares DynFD to the repeated execution of HyFD, the state-of-the-art FD discovery algorithm for static setups.

To evaluate DynFD, we need some datasets with a change history and a special experimental setup. That is what we discuss first. We then evaluate DynFD's batch processing times and its throughput. Afterwards, we analyze the algorithm's performance w. r. t. different batch sizes and, then, compare the batch times to HyFD's batch times. As a final set of experiments, we evaluate our four main pruning strategies: *cluster pruning*, *violation search*, *validation pruning*, and *depth-first searches.*

6.1 Datasets and experimental setup

Datasets. For our experiments, we use six real-world datasets and their change history: The *artist* relation from the MusicBrainz database [9], the *claims* relation from the airport baggage claims dataset published by Homeland Security [15], and the Wikipedia infobox relations *cpu*, *disease*, *actor*, and *single* put together by Google [7]. The six datasets and their characteristics, i. e., number of columns, rows, changes, and FDs, are listed in Table 3. The insert, delete, and update percentage columns refer to the number of changes that we have for these datasets. For each dataset, we highlight the characteristics that make the dataset interesting: The selection contains wide (*actor*) and long (*artist*) relations, ones with insert (*single*), and update (*cpu*) heavy changes, and a dataset with particularly many changes (*claims* and *disease*). Hence, it fairly represents real-world data in general.

Changes. The six datasets are given as a series of dataset dumps in different versions. Because DynFD requires the individual change operations that transformed one version into its successor version, we extracted all inserts, deletes, and updates from the change history of each dataset. The first version in each history serves as the initial dataset and the sequence of changes broken down into fixed-sized batches constitutes the dynamic input for the FD maintenance task. In practice, the size of the batches depends on the change rate, the size of the data, and use case specific currentness requirements; in our experiments, we test different batch sizes and their impact on the FD maintenance performance.

Experiments. Given the initial dataset and the batched sequence of changes, all experiments process the entire sequence of batches as fast as possible. This gives us an upper bound for the throughput performance: If the actual change rate is higher, the maintenance would apply back-pressure and throttle the database. The research question is, though, what throughput we can achieve.

Hardware. All experiments have been executed on a Dell PowerEdge R620 with two Intel Xeon E5-2650 2.00 GHz CPUs and 128 GB RAM. This server runs on CentOS 6.4 and uses OpenJDK 64-Bit 1.8.0_111 as Java environment.

6.2 Batch processing performance

In this first experiment, we evaluate the batch processing performance of DynFD on all datasets by fixing the batch size to 100 and measuring the processing time of each such batch. We run up to 100 batches of each change history, which corresponds to 10,000 changes per dataset; for *cpu* and *actor*, we process only 1,463 and 5,647 changes respectively, because this is their entire change history length. The results are shown in Table 4.

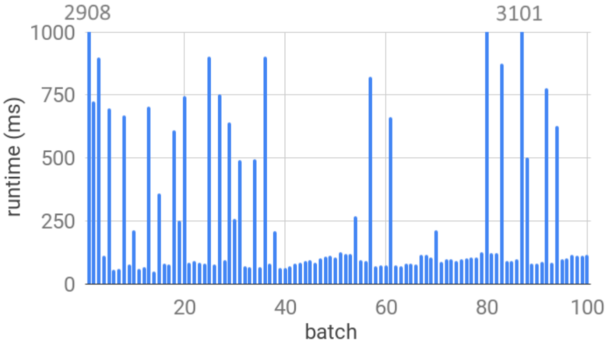


Figure 5: Runtime per batch (size 100) on *single*.

The measurements show that both the accumulated *runtime* and the *throughput* are affected by the width (#Column) and the length (#Rows) of the data: Although *single* has about three times more rows than *actor*, *actor*'s three times more columns result in almost half the throughput performance; if the number of rows is, however, significantly larger as for the *artist* dataset, the throughput also drops significantly, i. e., to only 17 changes per second. Considering the complexity of FD discovery, which is also the complexity of processing each batch, this observation is no surprise. Note that the comparably low throughput for *cpu* is due to the fact that the dataset is very short (62 rows) so that every batch (100 changes) basically rewrites the entire dataset.

The *average batch times* together with the *percentile* times show that the batch times have many outliers, i. e., runtime spikes that differ greatly from the average runtime of a batch. For most batches, the set of minimal FDs does not change much and our maintenance strategies do a good job skipping through these batches; for some batches, however, the FDs do change, sometimes even significantly. Then, DynFD needs to evolve FDs and invest some additional effort, which we tried to minimize with our pruning strategies.

Figure 5 supports this observation by plotting the individual batch times for the *single* dataset: The majority of batches is processed very quickly while some batches take orders of magnitude longer. This plot looks similar for the other datasets, namely a default batch processing time with occasional runtime spikes.

6.3 Batch size scalability

In the previous experiment, we fixed the batch size to 100 changes per batch. To see the impact of the batch size, we now scale it from 10 to 1,000 changes per batch. Figure 6 shows the average runtime of DynFD per batch w. r. t. the different batch sizes. The average in this experiment is calculated over the first 10,000 changes per dataset and both axes of the chart are in log-scale.

Most batch processing costs, such as the costs for updating the data structure and for checking whether the deletes resolved any violations, scale linearly with the size of the batch. The experimental results in Figure 6, however, show that 100 times more changes in a batch cause only about 10 times longer batch times on all datasets. This means that increasing the batch size also increases the throughput, as the processing costs per change decrease. This is because some batch activities, such as the expensive validation of the positive cover, constitute constant costs per batch regardless of its size (if no FD changes). The number of

Table 3: Characteristics of the datasets used in our evaluation.

Dataset	#Columns	#Rows (initial)	#Changes	#FDs (initial)	#FDs (final)	%Inserts	%Deletes	%Updates
cpu	15	62	1,463	209	327	4.3	0.2	**95.5**

claims	1.8	5,602.2	17.9	89.6	56.2	44.1

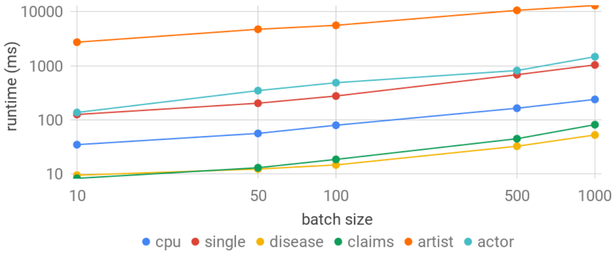

Figure 6: Average runtime for different batch sizes.

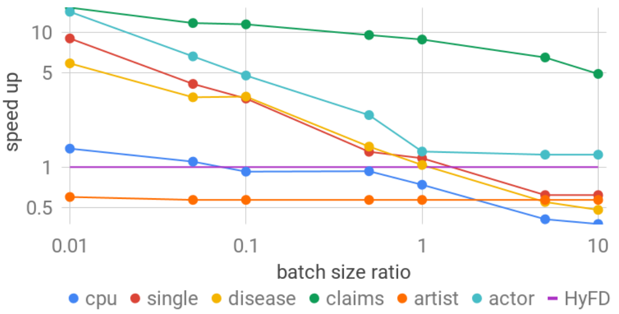

Figure 7: Speedup of DynFD relative to the runtime of HyFD.

changing FDs per batch does also not increase linearly with the batch size: Intuitively, if we look at the data less often, we probably overlook some changes, e. g., if $A \longrightarrow B$ changes to $AC \longrightarrow B$ and then to $ACD \longrightarrow B$, we might *observe* only the change of $A \longrightarrow B$ to $ACD \longrightarrow B$. Hence, we observe that the average batch processing time increases sub-linearly when increasing the batch size in DynFD. It is, furthermore, remarkable that the runtime increase is similar for all datasets although they differ greatly in size and change patterns.

6.4 Competitive evaluation

Our next experiment compares the batch processing performance of DynFD to repeated executions of the static profiling algorithm HyFD. For this comparison, it is especially interesting to see for which batch sizes our dynamic algorithm exhibits superior performance compared to a static profiling approach. For this purpose, we now scale it up from small to excessively large. We also now define the batch size relative to the initial dataset size, to make the measurements comparable across differently sized datasets: We start with a batch size containing as many changes as 1% of the initial dataset length, i. e., 1% of #Rows, and increase the batch size to 1000% of initial dataset size. Then, we plot the runtime of DynFD relative to the runtime of HyFD for each dataset, e. g., a speedup of 5 indicates that DynFD was 5 times faster than HyFD with a particular batch size ratio on a particular dataset; 1 is equally fast and speedups smaller than 1 are slower than HyFD.

The results depicted in Figure 7 show that DynFD is more than an order of magnitude faster than HyFD for small and medium batch sizes. This superiority decreases as we increase the batch size – until HyFD becomes faster for most datasets. DynFD's poor performance on *artist* is due to the fact that a batch size of 1% initial dataset size already covers 11,228 changes – about half of the entire change history. The first batch in each experiment is also more expensive than later batches, because this is when DynFD collects the initial violation annotations for the negative cover. Because 10% batch size ratio already covers the entire change history for *artist*, the performance does not change after that measurement. For *cpu*, we observe the opposite effect: The dataset is so tiny that simply re-profiling it with every batch is the best option anyway.

According to the measurements for *disease*, *single*, and *actor*, the inflection point at which static profiling (with HyFD) tends to overtake dynamic profiling (with DynFD) is at about 100% batch size ratio, i. e., when a batch basically re-writes the entire dataset.

6.5 In-depth performance analysis

DynFD proposes an FD maintenance algorithm with four major pruning strategies. The basic algorithm performs the incremental data structure updates and the level-wise valuations of the positive and negative cover; it basically enables the dynamic evolution of FDs. The four pruning strategies, which are *cluster pruning* (see Section 4.2), *violation search* (see Section 4.3), *validation pruning* (see Section 5.2), and *depth-first searches* (see Section 5.3), aim to reduce the maintenance effort as much as possible. Let us now evaluate how effective each individual strategy is and what the performance implications are.

In this final set of experiments, we execute DynFD with different sets of pruning strategies on all datasets. Because the *violation search* is so important for the algorithm, i. e., the performance drops significantly without any form of this strategy, we let the baseline algorithm run a naive sampling that compares changed records only to their direct neighbors w. r. t. some sorting. For each combination of strategies and dataset, we measure the processing time for all batches of fixed size 1,000 (Figure 8) and relative size 10% (Figure 9), respectively.

The measurements for both batch sizes show that the composition of all pruning strategies performs best in general. It is not the optimal composition of pruning strategies for all datasets, but the performance is reliably good throughout all our datasets. With a few exceptions, every strategy tends to improve the performance a bit. One exception is the *violation search* (4.3) on the *disease* dataset, because a naive version of this strategy is already in use by the baseline; and the optimized version, which is the version that runs progressively increasing windows, does not improve upon this naive strategy. The second exception is the *validation pruning* (5.2) that performs poorly on *claims*, *single*, and *artist*: On *claims*, the batches simply do not contain any deletes so that the strategy introduces the overhead of labeling non-FDs with violations without ever needing them. On *single* and *artist*, the annotations did not effectively prevent violations, because many of the annotated violations did vanish, i. e., the violations in these datasets are simply not stable enough to prevent enough violations that could balance the overhead of maintaining the violations.

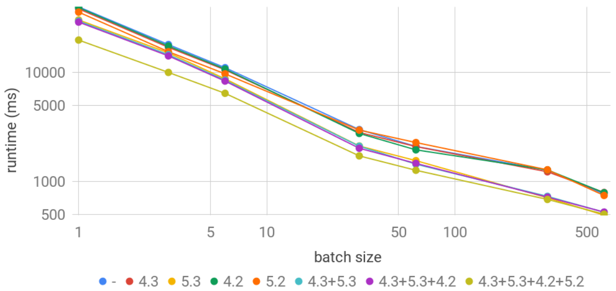

Figure 10: Runtime on *cpu* with different sets of pruning strategies and different batch sizes.

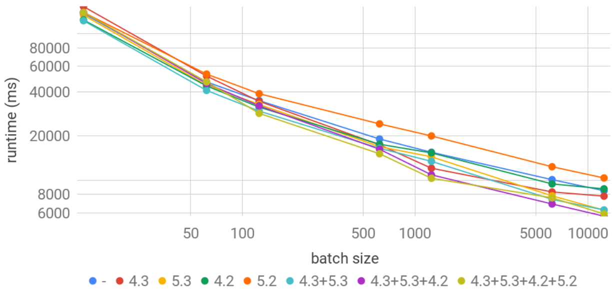

Figure 11: Runtime on *single* with different sets of pruning strategies and different batch sizes.

The measurements in Figure 10 and Figure 11 present the runtimes of the different strategy compositions for different batch sizes. The lines show that the composition of *all* pruning strategies also performs reliably well, i. e., best or close to best, regardless of the batch size.

7 RELATED WORK

DynFD is the first algorithm to maintain FDs under inserts, updates, and deletes in dynamic data. Nonetheless, we identify two categories of related work, namely (i) the discovery of FDs in static data and (ii) the maintenance of metadata in dynamic data in general.

7.1 Discovering FDs in static data

Research has brought up many FD discovery algorithms for static data, which can be classified into *column-based*, *row-based*, and *hybrid* algorithms [12]. In the following, we briefly describe one popular representative of each class.

One of the earliest FD discovery algorithms is the column-based algorithm Tane that models the search space, i. e., the set of all candidate FDs, as a powerset lattice of attribute combinations [8]. It traverses this lattice in a level-wise bottom-up fashion until it arrives at the non-trivial, minimal FDs. Although, DynFD adopts the lattice-shaped search space, it traverses it both bottom-up and top-down in response to data changes. For the candidate validation, Tane proposed *stripped partitions* (also: *position list indexes*, Plis) that we also use in DynFD.

The row-based FDEP algorithm proposes a fundamentally different strategy [6]: It compares all pairs of records in the input relation to deduce the complete *negative cover*, i. e., all candidate FDs that are violated by some tuple pair. The non-trivial, minimal FDs are derived from the negative cover via cover inversion. DYNFD also maintains a negative cover, but for the purpose of processing tuple deletions and not to infer the positive cover.

The hybrid algorithm HYFD combines column- and row-based techniques to avoid possibly many ineffective candidate validations and tuple comparisons [13]. By interleaving the two discovery principles and by having them exchange intermediate results, HYFD significantly outperforms all non-hybrid competitors. In DYNFD, we tailor the hybrid discovery approach to work on dynamic data. Our experiments show that the proposed extensions and adjustments have a great, positive impact on the performance of the approach.

7.2 Maintaining metadata in dynamic data

Arguably, maintaining metadata in dynamic data has received much less attention than static data profiling. Therefore, this section widens its scope to maintaining *any* kind of metadata, not only FDs.

To the best of our knowledge, the only existing FD maintenance algorithm was proposed by Wang et al. in [17]. The algorithm deals only with tuple deletions and neither inserts nor updates. Similar to DYNFD, the algorithm uses bottom-up and top-down approaches as well as indexes to evolve the FDs. Unlike DYNFD, however, it does not maintain a negative cover of non-FDs that significantly improves and distinguishes the handling of deletes from the static case.

The SWAN algorithm by Abedjan et al. is an incremental discovery algorithm for unique column combinations (UCCs), i. e., key candidates in dynamic datasets [1]. Starting from a pre-calculated set of UCCs, SWAN actively applies all insertions and deletions to the current metadata set. The algorithm groups change operations into batches and uses various indexes to optimize the change calculations – two principles that are also used by DYNFD. In contrast to SWAN, however, DYNFD operates on both a positive and a negative cover representation of the metadata, which enable additional pruning strategies.

Lastly, Shaabani and Meinel proposed an incremental algorithm to maintain inclusion dependencies (INDs) in dynamic data [16]. The algorithm uses a concept called *attribute clustering* that can be used in an incremental setup to evolve INDs w. r. t. sets of data changes. Besides the fact that this algorithm also handles both inserts and updates in batches, it has little in common with DYNFD, because IND discovery is very different from FD discovery.

8 CONCLUSION

In this paper, we introduced DYNFD, a novel algorithm that maintains the functional dependencies of dynamic datasets. To evolve the set of FDs with every batch of inserts, updates, and deletes, the algorithm continuously adapts its validation structures as well as a negative and a positive cover of FDs. With DYNFD, we proposed a new cover inversion algorithm and four pruning strategies that stabilize the maintenance performance. Our evaluation shows that, if the batch size is small, the dynamic algorithm is more than an order of magnitude faster than repeated executions of a state-of-the-art, static profiling algorithm.

Because profiling static data is already a challenging task, profiling dynamic data is a research direction that has not been studied much thus far. With DYNFD, we made a first approach to solve this task for functional dependencies. Our experiments show that this algorithm greatly improves upon using static data profiling algorithms in dynamic scenarios, but it leaves several interesting research questions open:

(1) *Devising a measure for interestingness* could serve to track only interesting and, hence, fewer dependencies; this would greatly improve the maintenance performance.

(2) *Incorporating knowledge about existing database constraints* into the maintenance process could help to prune further validations; FDs with a key constraint on their LHS, for instance, cannot invalidate.

(3) *Exploiting the specifics of update operations*, such as the fact that most updates do not alter all attribute values but only a few, could help to devise further pruning rules.

ABSTRACT

Effective data analytics on data collected from the real world usually begins with a notoriously expensive pre-processing step of data transformation and wrangling. Programming By Example (PBE) systems have been proposed to automatically infer transformations using simple examples that users provide as hints. However, an important usability issue—**verification**—limits the effective use of such PBE data transformation systems, since the verification process is often effort-consuming and unreliable.

We propose a data transformation paradigm design CLX (pronounced "clicks") with a focus on facilitating verification for end users in a PBE-like data transformation. CLX performs pattern clustering in both input and output data, which allows the user to verify at the pattern level, rather than the data instance level, without having to write any regular expressions, thereby significantly reducing user verification effort. Thereafter, CLX automatically generates transformation programs as regular-expression replace operations that are easy for average users to verify.

We experimentally compared the CLX prototype with both FlashFill, a state-of-the-art PBE data transformation tool, and Trifacta, an influential system supporting interactive data transformation. The results show improvements over the state of the art tools in saving user verification effort, without loss of efficiency or expressive power. In a user study on data sets of various sizes, when the data size grew by a factor of 30, the user verification time required by the CLX prototype grew by 1.3× whereas that required by FlashFill grew by 11.4×. In another user study assessing the users' understanding of the transformation logic — a key ingredient in effective verification — CLX users achieved a success rate about twice that of FlashFill users.

1 INTRODUCTION

Data transformation, or data wrangling, is a critical pre-processing step essential to effective data analytics on real-world data and is widely known to be human-intensive as it usually requires professionals to write ad-hoc scripts that are difficult to understand and maintain. A *human-in-the-loop* Programming By Example (PBE) approach has been shown to reduce the burden for the end user: in projects such as FlashFill [6], BlinkFill [24], and Foofah [11], the system synthesizes data transformation programs using simple examples the user provides.

Problems — Most of existing research in PBE data transformation tools has focused on the "system" part — improving the efficiency and expressivity of the program synthesis techniques. Although these systems have demonstrated some success in efficiently generating high-quality data transformation programs for real-world data sets, **verification**, as an indispensable interaction procedure in PBE, remains a major bottleneck within existing PBE data transformation system designs. The high labor cost, may deter the user from confidently using these tools.

Any reasonable user who needs to perform data transformation should certainly care about the "correctness" of the inferred transformation logic. In fact, a user will typically go through rounds of "verify-and-specify" cycles when using a PBE system. In each interaction, a user has to verify the correctness of the current inferred transformation logic by validating the transformed data instance by instance until she identifies a data instance mistakenly transformed; then she has to provide a new example for correction. **Given a potentially large and varied input data set, such a verification process is like "finding a needle in a haystack" which can be extremely time-consuming and tedious.**

A naïve way to simplify the cumbersome verification process is to add explanations to the transformed data so that the user does not have to read them in their raw form. For example, if we can somehow know the desired data pattern, we can write a checking function to automatically check if the post-transformed data satisfies the desired pattern, and highlight data entries that are not correctly transformed.

However, a *data explanation* procedure alone can not solve the entire verification issue; the undisclosed transformation logic remains untrustworthy to the end user. Users can at best verify that existing data are converted into the right form, but **the logic is not guaranteed to be correct and may function unexpectedly on new input** (see Section 2 for an example). Without good insight into the transformation logic, PBE system users cannot tell if the inferred transformation logic is correct, or when there are errors in the logic, they may not be able to debug it. **If the user of a traditional PBE system lacks good understanding of the synthesize program's logic, she can only verify it by spending large amounts of time testing the synthesized program on ever-larger datasets**.

Naïvely, previous PBE systems can support *program explanation* by presenting the inferred programs to end users. However, these data transformation systems usually design their own Domain Specific Languages (DSLs), which are usually sophisticated. The steep learning curve makes it unrealistic for most users to quickly understand the actual logic behind the inferred programs. Thus, besides more explainable data, a desirable PBE system should be able to present the transformation logic in a way that most people are already familiar with.

Insight — Regular expressions (regexp) have been known to most programmers of various expertise and regexp replace operations have been commonly applied in data transformations. The influential data transformation system, Wrangler (later as Trifacta), proposes simplified natural-language-like regular expressions which can be understood and used even by non-technical data analysts. This makes regexp replace operations a good choice for an *explainable transformation language*. The challenge then is how to automatically synthesize regexp replace operations as the desired transformation logic in a PBE system.

A regexp replace operation takes in two parameters: an *input pattern* and a *replacement function*. Suppose an input data set is given, and the desired data pattern can be known, the challenge is to determine a suitable input pattern and the replacement function to convert all input data into the desired pattern. Moreover, if the input data set is heterogeneous with many formats, we need to find out an unknown set of such input-pattern-and-replace-function pairs.

Pattern profiling can be used to discover clusters of data patterns within a data set that are are useful to generate regular replace operations. Moreover, it can also serve as a data explanation approach helping the user quickly understand the pre- and post-transformation data which reduces the verification challenge users face in PBE systems.

Proposed Solution — In this project, we propose a new data transformation paradigm, CLX, to address the two specific problems within our claimed verification issue. The CLX paradigm has three components: two algorithmic components—*clustering* and *transformation*—with an intervening component of *labeling*. In this paper, we present an instantiation of the CLX paradigm. We present (1) an efficient pattern clustering algorithm that groups data with similar structures into small clusters, (2) a DSL for data transformation, that can be interpreted as a set of regular expression replace operations, (3) a program synthesis algorithm to infer desirable transformation logic in the proposed DSL.

Through the above means, we are able to greatly ameliorate the usability issue in verification within PBE data transformation systems. Our experimental results show improvements over the state of the art in saving user verification effort, along with increasing users' comprehension of the inferred transformations. Increasing comprehension is highly relevant to reducing the verification effort. In one user study on a large data set, when the data size grew by a factor of 30, the CLX prototype cost 1.3× more verification time whereas FlashFill cost 11.4× more verification time. In a separate user study accessing the users' understanding of the transformation logic, CLX users achieved a success rate about twice that of FlashFill users. Other experiments also suggest that the expressive power of the CLX prototype and its efficiency on small data are comparable to those of FlashFill.

Organization — After motivating our problem with an example in Section 2, we discuss the following contributions:

- We define the data transformation problem and present the PBE-like CLX framework solving this problem. (Section 3)
- We present a data pattern profiling algorithm to hierarchically cluster the raw data based on patterns. (Section 4)
- We present a new DSL for data pattern transformation in the CLX paradigm. (Section 5)
- We develop algorithms synthesizing data transformation programs, which can transform any given input pattern to the desired standard pattern. (Section 6)
- We experimentally evaluate the CLX prototype and other baseline systems through user studies and simulations. (Section 7)

We explore the related work in Section 8 and finish with a discussion of future work in Section 9.

2 MOTIVATING EXAMPLE

Bob is a technical support employee at the customer service department. He wanted to have a set of 10,000 phone numbers in various formats (as in Figure 1) in a unified format of "(xxx) xxx-xxxx". Given the volume and the heterogeneity of the data, neither manually fixing them or hard-coding a transformation script was convenient for Bob. He decided to see if there was an automated solution to this problem.

Figure 4: Suggested data transformation operations

Bob found that Excel 2013 had a new feature named FlashFill that could transform data patterns. He loaded the data set into Excel and performed FlashFill on them.

Example 2.1. Initially, Bob thought using FlashFill would be straightforward: he would simply need to provide an example of the transformed form of each ill-formatted data entry in the input and copy the exact value of each data entry already in the correct format. However, in practice, it turned out not to be so easy. First, Bob needed to carefully check each phone number entry deciding whether it is ill-formatted or not. After obtaining a new input-output example pair, FlashFill would update the transformation results for the entire input data, and Bob had to carefully examine again if any of the transformation results were incorrect. This was tedious given the large volume of heterogeneous data **(verification at string level is challenging)**. After rounds of repairing and verifying, Bob was finally sure that FlashFill successfully transformed all existing phone numbers in the data set, and he thought the transformation inferred by FlashFill was impeccable. Yet, when he used it to transform another data set, a phone number "+1 724-285-5210" was mistakenly transformed as "(1) 724-285", which suggested that the transformation logic may fail anytime **(unexplainable transformation logic functions unexpectedly)**. Customer phone numbers were critical information for Bob's company and it was important not to damage them during the transformation. With little insight from FlashFill regarding the transformation program generated, Bob was not sure if the transformation was reliable and had to do more testing **(lack of understanding increases verification effort)**.

Bob heard about CLX and decided to give it a try.

Example 2.2. He loaded his data into CLX and it immediately presented a list of distinct string patterns for phone numbers in the input data (Figure 3), which helped Bob quickly tell which part of the data were ill-formatted. After Bob selected the desired pattern, CLX immediately transformed all the data and showed a new list of string patterns as Figure 2. **So far, verifying the transformation result was straightforward.** The inferred program is presented as a set of Replace operations on raw patterns in Figure 3, each with a picture visualizing the transformation effect. Bob was not a regular expressions guru, but

Notation	Description
$\mathcal{S} = \{s_1, s_2, \ldots\}$	A set of ad hoc strings $s_1, s_2, \ldots$ to be transformed.
$\mathcal{P} = \{p_1, p_2, \ldots\}$	A set of string patterns derived from $\mathcal{S}$.
$p_i = \{t_1, t_2, \ldots\}$	Pattern made from a sequence of tokens t_i
$\mathcal{T}$	The desired target pattern that all strings in $\mathcal{S}$ needed to be transformed into.
$\mathcal{L} = \{(p_1, f_1), (p_2, f_2), \ldots\}$	Program synthesized in CLX transforming data the patterns of $\mathcal{P}$ into $\mathcal{T}$.
$\mathcal{E}$	The expression $\mathcal{E}$ in $\mathcal{L}$, which is a concatenation of Extract and/or ConstStr operations. It is a transformation plan for a source pattern. We also refer to it as an *Atomic Transformation Plan* in the paper.
$Q(\widetilde{\mathrm{t}}, p)$	Frequency of token $\widetilde{\mathrm{t}}$ in pattern p
$\mathcal{G}$	Potential expressions represented in Directed Acyclic Graph.

Table 1: Frequently used notations

Token Class	Regular Expression	Example	Notation
digit	`[0-9]`	"12"	$\langle D \rangle$
lower	`[a-z]`	"car"	$\langle L \rangle$
upper	`[A-Z]`	"IBM"	$\langle U \rangle$
alpha	`[a-zA-Z]`	"Excel"	$\langle A \rangle$
alpha-numeric	`[a-zA-Z0-9_-]`	"Excel2013"	$\langle AN \rangle$

Table 2: Token classes and their descriptions

these operations seemed simple to understand and verify. Like many users in our User Study (Section 7.3), **Bob had a deeper understanding of the inferred transformation logic with** CLX **than with** FlashFill**, and hence, he knew well when and how the program may fail, which saved him from the effort of more blind testing.**

3 OVERVIEW

3.1 Patterns and Data Transformation Problem

A data pattern, or string pattern, is a "high-level" description of the attribute value's string. A natural way to describe a pattern could be a regular expression over the characters that constitute the string. In data transformation, we find that groups of contiguous characters are often transformed together as a group. Further, these groups of characters are meaningful in themselves. For example, in a date string "11/02/2017", it is useful to cluster "2017" into a single group, because these four digits are likely to be manipulated together. We call such meaningful groups of characters as *tokens*.

Table 2 presents all *token classes* we currently support in our instantiation of CLX, including their class names, regular expressions, and notation. In addition, we also support tokens of constant values (e.g., ",", ":"). In the rest of the paper, we represent and handle these tokens of constant values differently from the 5 token classes defined in Table 2. For convenience of presentation, we denote such tokens with constant values as ***literal tokens*** and tokens of 5 token classes defined in Table 2 as ***base tokens***.

A pattern is written as a sequence of tokens, each followed by a quantifier indicating the number of occurrences of the preceding token. A quantifier is either a single natural number or "+", indicating that the token appears at least once. In the rest of the paper, to be succinct, a token will be denoted as "$\langle\widetilde{\mathrm{t}}\rangle\mathfrak{q}$" if $\mathfrak{q}$ is a number (e.g., $\langle D\rangle 3$) or "$\langle\widetilde{\mathrm{t}}\rangle+$" otherwise (e.g., $\langle D\rangle+$). If $\widetilde{\mathrm{t}}$ is a literal token, it will be surrounded by a single quotation mark, like ':'. When a pattern is shown to the end user, it is presented as a *natural-language-like regular expression* proposed by Wrangler [13] (see regexps in Fig 4).

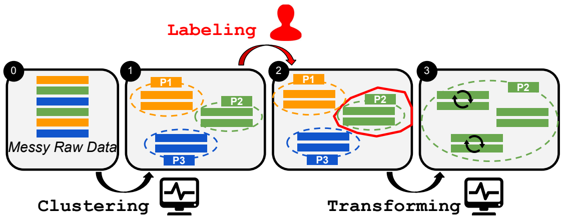

Figure 5: "CLX" Model: Cluster–Label–Transform

With the above definition of data patterns, we hereby formally define the problem we tackle using the CLX framework—data transformation. Data transformation or wrangling is a broad concept. Our focus in this paper is to apply the CLX paradigm to transform a data set of heterogeneous patterns into a desired pattern. A formal definition of the problem is as follows:

Definition 3.1 (Data (Pattern) Transformation). *Given a set of strings $\mathcal{S} = \{s_1, \ldots, s_n\}$, generate a program $\mathcal{L}$ that transforms each string in $\mathcal{S}$ to an equivalent string matching the user-specified desired target pattern $\mathcal{T}$.*

$\mathcal{L} = \{(p_1, f_1), (p_2, f_2), \ldots\}$ is the program we synthesize in the transforming phase of CLX. It is represented as a set regexp replace operations, Replace(p, f)[1], that many people are familiar with (e.g., Fig 4).

With above definitions of patterns and data transformations, we present the CLX framework for data transformation.

3.2 CLX Data Transformation Paradigm

We propose a data transformation paradigm called Cluster-Label-Transform (CLX, pronounced "clicks"). Figure 5 visualizes the interaction model in this framework.

Clustering — The clustering component groups the raw input data into clusters based on their data patterns/formats. Compared to raw strings, data patterns is a more abstract representation. The number of patterns is fewer than raw strings, and hence, it can make the user understand the data and verify the transformation more quickly. Patterns discovered during clustering is also useful information for the downstream program synthesis algorithm to determine the number of regexp replace operations, as well as the desirable input patterns and transformation functions.

Labeling — Labeling is to specify the desired data pattern that every data instance is supposed to be transformed into. Presumably, labeling can be achieved by having the user choose among the set of patterns we derive in the clustering process assuming some of the raw data already exist in the desired format. If no input data matches the target pattern, the user could alternatively choose to manually specify the target data form.

Transforming — After the desired data pattern is labeled, the system automatically synthesizes data transformation logic that transforms all undesired data into the desired form and also proactively helps the user understand the transformation logic.

In this paper, we present an instantiation of the CLX paradigm for *data pattern transformation.* Details about the clustering component and the transformation component are discussed in Section 4 and 6. In Section 5, we show the domain-specific-language (DSL) we use to represent the program $\mathcal{L}$ as the outcome of program synthesis, which can be then presented as the regexp replace operations. The paradigm has been designed to allow new

[1] p is the regular expression, and f is the replacement string indicating the operation on the string matching the pattern p.

algorithms and DSLs for transformation problems other than data pattern transformation; we will pursue other instantiations in future work.

4 CLUSTERING DATA ON PATTERNS

In CLX, we first cluster data into meaningful groups based on their structure and obtain the pattern information, which helps the user quickly understand the data. To minimize user effort, this clustering process should ideally not require user intervention.

LearnPADS [4] is an influential project that also targets string pattern discovery. However, LearnPADS is orthogonal to our effort in that their goal is mainly to find a comprehensive and unified description for the entire data set whereas we seek to partition the data into clusters, each cluster with a single data pattern. Also, the PADS language [3] itself is known to be hard for a non-expert to read [29]. Our interest is to derive simple patterns that are comprehensible. Besides the explainability, efficiency is another important aspect of the clustering algorithm we must consider, because input data can be huge and the real-time clustering must be interactive.

To that end, we propose an automated means to hierarchically cluster data based on data patterns given a set of strings. The data is clustered through a two-phase profiling: (1) tokenization: tokenize the given set of strings of ad hoc data and cluster based on these initial patterns, (2) agglomerative refinement: recursively merge pattern clusters to formulate a ***pattern cluster hierarchy*** that allows the end user to view/understand the pattern structure information in a simpler and more systematic way, and also helps CLX generate a simple transformation program.

4.1 Initial Clustering Through Tokenization

Tokenization is a common process in string processing when string data needs to be manipulated in chunks larger than single characters. A simple parser can do the job.

Below are the rules we follow in the tokenization phase.

- Non-alphanumeric characters carry important hints about the string structure. Each such character is identified as an individual literal token.
- We always choose the most precise base type to describe a token. For example, a token with string content “cat” can be categorized as “lower”, “alphabet” or “alphanumeric” tokens. We choose “lower” as the token type for this token.
- The quantifiers are always natural numbers.

Here is an example of the token description of a string data record discovered in tokenization phase.

Example 4.1. Suppose the string “Bob123@gmail.com” is to be tokenized. The result of tokenization becomes [$\langle U\rangle$, $\langle L\rangle$2, $\langle D\rangle$3, ‘@’, $\langle L\rangle$5, ‘.’, $\langle L\rangle$3].

After tokenization, each string corresponds to a data pattern composed of tokens. We create the initial set of pattern clusters by clustering the strings sharing the same patterns. Each cluster uses its pattern as a label which will later be used for refinement, transformation, and user understanding.

Find Constant Tokens — Some of the tokens in the discovered patterns have constant values. Discovering such constant values and representing them using the actual values rather than base tokens helps improve the quality of the program synthesized. For example, if most entities in a faculty name list contain “Dr.”, it is better to represent a pattern as [‘Dr.’,‘\ ’, ‘$\langle U\rangle$’, ‘$\langle L\rangle$+’] than [‘$\langle U\rangle$’, ‘$\langle L\rangle$’, ‘.’, ‘\ ’, ‘$\langle U\rangle$’, ‘$\langle L\rangle$+’]. Similar to [4], we find tokens with constant values using the statistics over tokenized strings in the data set.

Algorithm 1: Refine Pattern Representations

```
Data: Pattern set $\mathcal{P}$, generalization strategy $\tilde{g}$
Result: Set of more generic patterns $\mathcal{P}_{final}$
1  $\mathcal{P}_{final}, \mathcal{P}_{raw} \leftarrow \emptyset$;
2  $C_{raw} \leftarrow \{\}$;
3  for $p_i \in \mathcal{P}$ do
4      $p_{parent} \leftarrow getParent(p_i, \tilde{g})$;
5      add $p_{parent}$ to $\mathcal{P}_{raw}$;
6      $C_{raw}[p_{parent}] = C_{raw}[p_{parent}] + 1$;
7  for $p_{parent} \in \mathcal{P}_{raw}$ ranked by $C_{raw}$ from high to low do
8      $p_{parent}.child \leftarrow \{p_j | \forall p_j \in \mathcal{P}, p_j.isChild(p_{parent})\}$;
9      add $p_{parent}$ to $\mathcal{P}_{final}$;
10     remove $p_{parent}.child$ from $\mathcal{P}$;
11 Return $\mathcal{P}_{final}$;
```

4.2 Agglomerative Pattern Cluster Refinement

In the initial clustering step, we distinguish different patterns by token classes, token positions, and quantifiers, the actual number of pattern clusters discovered in the ad hoc data in tokenization phase could be huge. User comprehension is inversely related to the number of patterns. It is not very helpful to present too many very specific pattern clusters all at once to the user. Plus, it can be unacceptably expensive to develop data pattern transformation programs separately for each pattern.

To mitigate the problem, we build *pattern cluster hierarchy*, i.e., a hierarchical pattern cluster representation with the leaf nodes being the patterns discovered through tokenization, and every internal node being a *parent pattern*. With this hierarchical pattern description, the user can understand the pattern information at a high level without being overwhelmed by many details, and the system can generate simpler programs. Plus, we do not lose any pattern discovered previously.

From bottom-up, we recursively cluster the patterns at each level to obtain *parent patterns*, i.e., more generic patterns, formulating the new layer in the hierarchy. To build a new layer, Algorithm 1 takes in different generalization strategy $\tilde{g}$ and the child pattern set $\mathcal{P}$ from the last layer. Line 3-5 clusters the current set of pattern clusters to get parent pattern clusters using the generalization strategy $\tilde{g}$. The generated set of parent patterns may be identical to others or might have overlapping expressive power. Keeping all these parent patterns in the same layer of the cluster hierarchy is unnecessary and increases the complexity of the hierarchy generated. Therefore, we only keep a small subset of the parent patterns initially discovered and make sure they together can cover any child pattern in $\mathcal{P}$. To do so, we use a counter C_{raw} counting the frequencies of the obtained parent patterns (line 6). Then, we iteratively add the parent pattern that covers the most patterns in $\mathcal{P}$ into the set of more generic patterns to be returned (line 7-10). The returned set covers all patterns in $\mathcal{P}$ (line 11). Overall, the complexity is $O(n \log n)$, where n is the number of patterns in $\mathcal{P}$, and hence, the algorithm itself can quickly converge.

In this paper, we perform three rounds of refinement to construct the new layer in the hierarchy, each with a particular generalization strategy:

(1) natural number quantifier to ‘+’

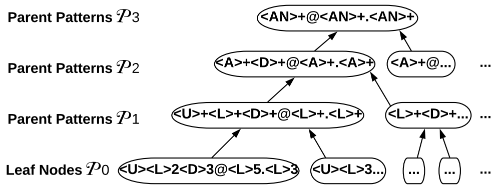

Figure 6: Hierarchical clusters of data patterns

(2) $\langle L \rangle$, $\langle U \rangle$ tokens to $\langle A \rangle$
(3) $\langle A \rangle$, $\langle N \rangle$, ’-’, ‘_’ tokens to $\langle AN \rangle$

Example 4.2. Given the pattern we obtained in Example 4.1, we successively apply Algorithm 1 with Strategy 1, 2 and 3 to generalize parent patterns $\mathcal{P}_1$, $\mathcal{P}_2$ and $\mathcal{P}_3$ and construct the pattern cluster hierarchy as in Figure 6.

4.3 Limitations

The pattern hierarchy constructed can succinctly profile the pattern information for many data. However, the technique itself may be weak in two situations. First, as the scope of this paper is limited to addressing the syntactic transformation problem (Section 5), the pattern discovery process we propose only considers syntactic features, but no semantic features. This may introduce the issue of “misclustering”. For example, a date of format “MM/DD/YYYY” and a date of format “DD/MM/YYYY” may be grouped into the same cluster of “$\langle N \rangle 2/\langle N \rangle 2/\langle N \rangle 4$”, and hence, transforming from the former format into the latter format is impossible in our case. Addressing this problem requires the support for semantic information discovery and transformation, which will be in our future work. Another possible weakness of “fail to cluster” is also mainly affected by the semantics issue: we may fail to cluster semantically-same but very messy data. E.g., we may not cluster the local-part (everything before ‘@’) of a very weird email address “Mike'John.Smith@gmail.com” (token $\langle AN \rangle$ cannot capture ‘'’ or ‘.’). Yet, this issue can be easily resolved by adding additional regexp-based token classes (e.g., emails). Adding more token classes is beyond the interest of our work.

5 DATA PATTERN TRANSFORMATION PROGRAM

As motivated in Section 1 and Section 3, our proposed data transformation framework is to synthesize a set of regexp replace operations that people are familiar with as the desired transformation logic. However, representing the logic as regexp strings will make the program synthesis difficult. Instead, to simplify the program synthesis, we propose a new language, UniFi, as a representation of the transformation logic internal to CLX. The grammar of UniFi is shown in Figure 7. We then discuss how to explain a inferred UniFi program as regexp replace operations.

The top-level of any UniFi program is a Switch statement that conditionally maps strings to a transformation. Match checks whether a string s is an *exact match* of a certain pattern p we discover previously. Once a string matches this pattern, it will be processed by an *atomic transformation plan* (expression $\mathcal{E}$ in UniFi) defined below.

Definition 5.1 (Atomic Transformation Plan). *Atomic transformation plan is a sequence of parameterized string operators that converts a given source pattern into the target pattern.*

The available string operators include ConstStr and Extract. $\mathsf{ConstStr}(\widetilde{s})$ denotes a constant string $\widetilde{s}$. $\mathsf{Extract}(\widetilde{\mathfrak{t}_i},\widetilde{\mathfrak{t}_j})$ extracts from the i^{th} token to the j^{th} token in a pattern. In the rest of the paper, we express an Extract operation as Extract(i,j), or Extract(i) if $i = j$. A token $\mathfrak{t}$ is represented as $(\widetilde{\mathfrak{t}}, \mathfrak{r}, \mathfrak{q}, i)$: $\widetilde{\mathfrak{t}}$ is the token class in Table 2; $\mathfrak{r}$ represents the corresponding regular expression of this token; $\mathfrak{q}$ is the quantifier of the token expression; i denotes the index (one-based) of this token in the source pattern.

$$\begin{aligned}
\text{Program } \mathcal{L} &:= \mathsf{Switch}((b_1, \mathcal{E}_1), \ldots, (b_n, \mathcal{E}_n)) \\
\text{Predicate } b &:= \mathsf{Match}(s, p) \\
\text{Expression } \mathcal{E} &:= \mathsf{Concat}(f_1, \ldots, f_n) \\
\text{String Expression } f &:= \mathsf{ConstStr}(\widetilde{s}) \mid \mathsf{Extract}(\widetilde{\mathfrak{t}_i}, \widetilde{\mathfrak{t}_j}) \\
\text{Token Expression } \mathfrak{t}_i &:= (\widetilde{\mathfrak{t}}, \mathfrak{r}, \mathfrak{q}, i)
\end{aligned}$$

Figure 7: UniFi Language Definition

As with FlashFill [6] and BlinkFill [24], we only focus on syntactic transformation, where strings are manipulated as a sequence of characters and no external knowledge is accessible, in this instantiation design. *Semantic transformation* (e.g., converting “March” to “03”) is a subject for future work. Further–again like BlinkFill [24]–our proposed data pattern transformation language UniFi does not support loops. Without the support for loops, UniFi may not be able to describe transformations on an unknown number of occurrences of a given pattern structure.

We use the following two examples used by FlashFill [6] and BlinkFill [24] to briefly demonstrate the expressive power of UniFi, and the more detailed expressive power of UniFi would be examined in the experiments in Section 7.4. For simplicity, Match(s, p) is shortened as Match(p) as the input string s is fixed for a given task.

Example 5.1. This problem is modified from test case “**Example 3**” in BlinkFill. The goal is to transform all messy values in the medical billing codes into the correct form “[CPT-XXXX]” as in Table 3.

Raw data	Transformed data
CPT-00350	[CPT-00350]
[CPT-00340	[CPT-00340]
[CPT-11536]	[CPT-11536]
CPT115	[CPT-115]

Table 3: Normalizing messy medical billing codes

The UniFi program for this standardization task is

```
Switch((Match("\[<U>+\-<D>+"),
     (Concat(Extract(1,4),ConstStr(']')))),
   (Match("<U>+\-<D>+"),
     (Concat(ConstStr('['),Extract(1,3),
       ConstStr(']'))))
   (Match("<U>+<D>+"),
     (Concat(ConstStr('['),Extract(1),
     ConstStr('-'),Extract(2),ConstStr(']')))))
```

Example 5.2. This problem is borrowed from “**Example 9**” in FlashFill. The goal is to transform all names into a unified format as in Table 4.

Raw data	Transformed data
Dr. Eran Yahav	Yahav, E.
Fisher, K.	Fisher, K.
Bill Gates, Sr.	Gates, B.
Oege de Moor	Moor, O.

Table 4: Normalizing messy employee names

A UniFi program for this task is

```
Switch((Match("<U><L>+\.\ <U><L>+\ <U><L>+"),
    Concat(Extract(8,9),ConstStr(','),
        ConstStr(' '),Extract(5))),
    (Match("<U><L>+\ <U><L>+\,\ <U><L>+\."),
     Concat(Extract(4,5),ConstStr(','),
        ConstStr(' '),Extract(1))),
    (Match("<U><L>+\ <U>+\ <U><L>+"),
     Concat(Extract(6,7),ConstStr(','),
        ConstStr(' '),Extract(1))))
```

Program Explanation — Given a UniFi program L, we want to present it as a set of regexp replace operations, Replace, parameterized by *natural-language-like regexps* used by Wrangler [13] (e.g., Figure 4), which are straightforward to even non-expert users. Each component of $(b, \mathcal{E})$, within the Switch statement of L, will be explained as a Replace operation. The replacement string f in the Replace operation is created from p and the transformation plan $\mathcal{E}$ for the condition b. In f, a ConstStr($\tilde{s}$) operation will remain as $\tilde{s}$, whereas a Extract($\tilde{t_i}, \tilde{t_j}$) operation will be interpreted as $\$\tilde{t_i} \dots \$\tilde{t_j}$. The pattern p in the predicate $b = \mathsf{Match}(s, p)$ in UniFi naturally becomes the regular expression p in Replace with each tokens to be extracted surrounded by a pair of parentheses indicating that it can be extracted. Note that if multiple consecutive tokens are extracted in p, we merge them as one component to be extracted in p and change the f accordingly for convenience of presentation. Figure 4 is an example of the transformation logic finally shown to the user.

In fact, these Replace operations can be further explained using visualization techniques. For example, we could add a *Preview Table* (e.g., Figure 8) to visualize the transformation effect in our prototype in a sample of the input data. The user study in Section 7.3 demonstrates that our effort of outputting an explainable transformation program helps the user understand the transformation logic generated by the system.

6 PROGRAM SYNTHESIS

We now discuss how to find the desired transformation logic as a UniFi program using the pattern cluster hierarchy obtained. Algorithm 2 shows our synthesis framework.

Given a pattern hierarchy, we do not need to create an *atomic transformation plan* (Definition 5.1) for every pattern cluster in the hierarchy. We traverse the pattern cluster hierarchy top-down to find valid *candidate source patterns* (line 6, see Section 6.1). Once a source candidate is identified, we discover all *token matches* between this source pattern in Q_{solved} and the target pattern (line 7, see Section 6.2). With the generated token match information, we synthesize the data pattern normalization program including an atomic transformation plan for every source pattern (line 11, see Section 6.3).

6.1 Identify Source Candidates

Before synthesizing a transformation for a source pattern, we want to quickly check whether it can be a *candidate source pattern* (or source candidate), i.e., it is possible to find a transformation from this pattern into the target pattern, through `validate`. **If we can immediately disqualify some patterns, we do not need to go through more expensive data transformation synthesis process for them.** There are a few reasons why some pattern in the hierarchy may not be qualified as a candidate source pattern:

(1) The input data set may be ad hoc and a pattern in this data set can be a description of noise values. For example, a data set of phone numbers may contain "N/A" as a data record because the customer refused to reveal this information. In this case, it is meaningless to generate transformations.

Algorithm 2: Synthesize UniFi Program

```
   Data: Pattern cluster hierarchy root $\mathcal{P}_R$, target pattern $\mathcal{T}$
   Result: Synthesized program $\mathcal{L}$
1  $Q_{unsolved}, Q_{solved} \leftarrow [\,]$;
2  $\mathcal{L} \leftarrow \emptyset$;
3  push $\mathcal{P}_R$ to $Q_{unsolved}$;
4  while $Q_{unsolved} \neq \emptyset$ do
5      $p \leftarrow$ pop $Q_{unsolved}$;
6      if validate($p, \mathcal{T}$) = $\top$ then
7          $\mathcal{G} \leftarrow$ findTokenAlignment($p, \mathcal{T}$);
8          push $\{p, \mathcal{G}\}$ to $Q_{solved}$;
9      else
10         push $p$.children to $Q_{unsolved}$;
11 $\mathcal{L} \leftarrow$ createProgs($Q_{solved}$);
12 Return $\mathcal{L}$
```

(2) We may be fundamentally not able to support some transformations (e.g., semantic transformations are not supported as in our case). Hence, we should filter out certain patterns which we think semantic transformation is unavoidable, because it is impossible to transform them into the desired pattern without the help from the user.

(3) Some patterns are too general; it can be hard to determine how to transform these patterns into the target pattern. We can ignore them and create transformation plans for their children. For instance, if a pattern is "$\langle AN\rangle$+,$\langle AN\rangle$+", it is hard to tell if or how it could be transformed into the desired pattern of "$\langle U\rangle\langle L\rangle$+ : $\langle D\rangle$+". By comparison, its child pattern "$\langle U\rangle\langle L\rangle$+, $\langle D\rangle$+" seems to be a better fit as the candidate source.

Any input data matching no candidate source pattern is left unchanged and flagged for additional review, which could involve replacing values with NULL or default values or manually overriding values.

Since the goal here is simply to quickly prune those patterns that are not good source patterns, the checking process should be able to find unqualified source patterns with *high precision* but not necessarily *high recall*. Here, we use a simple heuristic of *frequency count* that can effectively reject unqualified source patterns with high confidence: examining if there are sufficient base tokens of each class in the source pattern matching the base tokens in the target tokens. The intuition is that any source pattern with fewer base tokens than the target is unlikely to be transformable into the target pattern without external knowledge; base tokens usually carry semantic meanings and hence are likely to be hard to invent *de novo*.

To apply frequency count on the source pattern p_1 and the target pattern p_2, `validate` (denoted as $\mathcal{V}$) compares the *token frequency* for every class of base tokens in p_1 and p_2. The token frequency Q of a token class $\widetilde{\langle t\rangle}$ in p is defined as

$$Q(\widetilde{\langle t\rangle}, p) = \sum_{i=1}^{n} \{t_i.\mathrm{q} \mid t.name = \widetilde{\langle t\rangle}\}, p = \{t_1, \dots, t_n\} \qquad (1)$$

If a quantifier is not a natural number but "+", we treat it as 1 in computing Q.

Suppose $\mathfrak{T}$ is the set of all token classes (in our case, $\mathfrak{T} = [\langle D\rangle, \langle L\rangle, \langle U\rangle, \langle A\rangle, \langle AN\rangle]$), $\mathcal{V}$ is then defined as

$$\mathcal{V}(p_1, p_2) = \begin{cases} \text{true} & \text{if } Q(\widetilde{\langle t\rangle}, p_1) \geq Q(\widetilde{\langle t\rangle}, p_2), \forall \widetilde{\langle t\rangle} \in \mathfrak{T} \\ \text{false} & \text{otherwise} \end{cases} \qquad (2)$$

3      for $t'_j \in \mathcal{P}_{cand}$ do
4          if SyntacticallySimilar($t_i, t'_j$) = ⊤ then
5              $e \leftarrow$ Extract($t'_j$);
6              add $e$ to $\xi_{(i-1,i)}$;
7      if $t_i.type$ = 'literal' then
8          $e \leftarrow$ ConstStr($t_i.name$);
9          add $e$ to $\xi_{(i-1,i)}$;
10 for $i \in \{1, \dots, n-1\}$ do
11     $\xi_{in} \leftarrow \{\forall e_p \in \xi_{(i-1,i)}, e_p$ is an Extract operation$\}$;
12     $\xi_{out} \leftarrow \{\forall e_q \in \xi_{(i,i+1)}, e_q$ is an Extract operation$\}$;
13     for $e_p \in \xi_{in}$ do
14         for $e_q \in \xi_{out}$ do
15             if $e_p.srcIdx + 1 = e_q.srcIdx$ then
16                 $e \leftarrow$ Extract($e_p.t_i, e_q.t_j$);
17                 add $e$ to $\xi_{(i-1,i+1)}$;
18 $\mathcal{G} \leftarrow Dag(\widetilde{\eta}, \eta^s, \eta^t, \xi)$;
19 Return $\mathcal{G}$
```

Example 6.1. Suppose the target pattern $\mathcal{T}$ in Example 5.1 is ['[', $\langle U\rangle$+, '-', $\langle D\rangle$+, ']'], we know

$$Q(\langle D\rangle, \mathcal{T}) = Q(\langle U\rangle, \mathcal{T}) = 1$$

A pattern ['[', $\langle U\rangle$3, '-', $\langle D\rangle$5] derived from data record "[CPT-00350" will be identified as a source candidate by `validate`, because

$$Q(\langle D\rangle, p) = 5 > Q(\langle D\rangle, \mathcal{T}) \wedge$$
$$Q(\langle U\rangle, p) = 3 > Q(\langle U\rangle, \mathcal{T})$$

Another pattern ['[', $\langle U\rangle$3, '-'] derived from data record "[CPT-" will be rejected because

$$Q(\langle D\rangle, p) = 0 < Q(\langle D\rangle, \mathcal{T})$$

6.2 Token Alignment

Once a source pattern is identified as a source candidate in Section 6.1, we need to synthesize an atomic transformation plan between this source pattern and the target pattern, which explains how to obtain the target pattern using the source pattern. To do this, we need to find the token matches for each token in the target pattern: discover all possible operations that yield a token. This process is called *token alignment.*

For each token in the target pattern, there might be multiple different token matches. Inspired by [6], we store the results of the token alignment in Directed Acyclic Graph (DAG) represented as a $DAG(\widetilde{\eta}, \eta^s, \eta^t, \xi)$. $\widetilde{\eta}$ denotes all the nodes in DAG with η^s as the source node and η^t as the target node. Each node corresponds to a position in the pattern. ξ are the edges between the nodes in $\widetilde{\eta}$ storing the source information, which yield the token(s) between the starting node and the ending node of the edge. Our proposed solution to token alignment in a DAG is presented in Algorithm 3.

Align Individual Tokens to Sources — To discover sources, given the target pattern $\mathcal{T}$ and the candidate source pattern $\mathcal{P}_{cand}$, we iterate through each token t_i in $\mathcal{T}$ and compare t_i with all the tokens in $\mathcal{P}_{cand}$.

For any source token t'_j in $\mathcal{P}_{cand}$ that is *syntactically similar* (defined in Definition 6.1) to the target token t_i in $\mathcal{T}$, we create a token match between t'_j and t_i with an Extract operation on an edge from t_{i-1} to t_i (line 2-9).

Definition 6.1 (Syntactically Similar). *Two tokens t_i and t_j are syntactically similar if: 1) they have the same class, 2) their quantifiers are identical natural numbers or one of them is '+' and the other is a natural number.*

When t_i is a literal token, it is either a symbolic character or a constant value. To build such a token, we can simply use a ConstStr operation (line 7-9), instead of extracting it from the source pattern. This does not violate our previous assumption of not introducing any external knowledge during the transformation.

Example 6.2. Let the candidate source pattern be [$\langle D\rangle$3, '.', $\langle D\rangle$3, '.', $\langle D\rangle$4] and the target pattern be ['(', $\langle D\rangle$3, ')', ' ', $\langle D\rangle$3, '-', $\langle D\rangle$4]. Token alignment result for the source pattern $\mathcal{P}_{cand}$ and the target pattern $\mathcal{T}$, generated by Algorithm 3 is shown in Figure 9. In Figure 9, a dashed line is a token match, indicating the token(s) in the source pattern that can formulate a token in the target pattern. A solid line embeds the actual operation in UniFi rendering this token match.

Combine Sequential Extracts — The Extract operator in our proposed language UniFi is designed to extract one or more tokens sequentially from the source pattern. Line 4-9 only discovers sources composed of an Extract operation generating an individual token. *Sequential extracts* (Extract operations extracting multiple consecutive tokens from the source) are not discovered, and this token alignment solution is not complete. We need to find the *sequential extracts.*

Fortunately, discovering sequential extracts is not independent of the previous token alignment process; sequential extracts are combinations of individual extracts. With the alignment results ξ generated previously, we iterate each state and combine every pair of Extracts on an incoming edge and an outgoing edge that extract two consecutive tokens in the source pattern (line 10-17). The Extracts are then added back to ξ. Figure 10 visualizes combining two sequential Extracts. The first half of the figure (titled "Before Combining") shows a transformation plan that generates a target pattern pattern $\langle U\rangle\langle D\rangle$+ with two operations—Extract(1) and Extract(2). The second half of the figure (titled "After Combining") showcases merging the incoming edge and the outgoing edge (representing the previous two operations) and formulate a new operation (red arrow), Extract(1,2), as a combined operation of the two.

A benefit of discovering sequential extracts is it helps yield a "simple" program, as described in Section 6.3.

Correctness — Algorithm 3 is *sound* and *complete*, which is proved in Appendix A in the technical report [12].

6.3 Program Synthesis using Token Alignment Result

As we represent all token matches for a source pattern as a DAG (Algorithm 3), finding a transformation plan is to find a path from the initial state 0 to the final state l, where l is the length of the target pattern $\mathcal{T}$.

The Breadth First Traversal algorithm can find all possible atomic transformation plans for this DAG. However, not all of these plans are equally likely to be correct and desired by the end user. The hope is to prioritize the correct plan. The Occam's razor principle suggests that the simplest explanation is usually correct. Here, we apply **Minimum Description Length** (MDL) [23], a formalization of Occam's razor principle, to gauge the *simplicity* of each possible program.

Suppose $\mathcal{M}$ is the set of models. In this case, it is the set of atomic transformation plans found given the source pattern $\mathcal{P}_{cand}$ and the target pattern $\mathcal{T}$. $\mathcal{E} = f_1 f_2 \ldots f_n \in \mathcal{M}$ is an atomic transformation plan, where f is a string expression. Inspired by [21], we define *Description length* (DL) as follows:

$$L(\mathcal{E}, \mathcal{T}) = L(\mathcal{E}) + L(\mathcal{T}|\mathcal{E}) \tag{3}$$

$L(\mathcal{E})$ is the *model description length*, which is the length required to encode the model, and in this case, $\mathcal{E}$. Hence,

$$L(\mathcal{E}) = |\mathcal{E}| \log m \tag{4}$$

where m is the number of distinct types of operations.

$L(\mathcal{T}|\mathcal{E})$ is the *data description length*, which is the sum of the length required to encode $\mathcal{T}$ using the atomic transformation plan $\mathcal{E}$. Thus,

$$L(\mathcal{T}|\mathcal{E}) = \sum_{f_i \in \mathcal{E}} \log L(f_i) \tag{5}$$

where $L(f_i)$ the length to encode the parameters for a single expression. For a Extract(i) or Extract(i,j) operation, $L(f) = \log |\mathcal{P}_{cand}|^2$ (recall Extract(i) is short for Extract(i,i)). For a ConstStr($\widetilde{s}$), $L(f) = \log c^{|\widetilde{s}|}$, where c is the size of printable character set ($c = 95$).

With the concept of description length described, we define the minimum description length as

$$L_{min}(\mathcal{T}, \mathcal{M}) = \min_{\mathcal{E} \in \mathcal{M}} \Big[L(\mathcal{E}) + L(\mathcal{T}|\mathcal{E}) \Big] \tag{6}$$

In the end, we present the atomic transformation plan $\mathcal{E}$ with the minimum description length as the default transformation plan for the source pattern. Also, we list the other k transformation plans with lowest description lengths.

Example 6.3. Suppose the source pattern is "$\langle D \rangle 2 / \langle D \rangle 2 / \langle D \rangle 4$ ", the target pattern $\mathcal{T}$ is "$\langle D \rangle 2 / \langle D \rangle 2$". The description length of a transformation plan $\mathcal{E}_1$ = Concat(Extract(1,3)) is $L(\mathcal{E}_1, \mathcal{T}) = 1 \log 1 + 2 \log 3$. In comparison, the description length of another transformation plan $\mathcal{E}_2$ = Concat(Extract(1), ConstStr('/'),Extract(3)) is $L(\mathcal{E}_2, \mathcal{T}) = 3 \log 2 + \log 3^2 + \log 95 + \log 3^2 > L(\mathcal{E}_1, \mathcal{T})$. Hence, we prefer $\mathcal{E}_1$, a clearly simpler and better plan than $\mathcal{E}_2$.

6.4 Limitations and Program Repair

The target pattern $\mathcal{T}$ as the sole user input so far is more ambiguous compared to input-output example pairs used in most other PBE systems. Also, we currently do not support "semantic transformation". We may face the issue of "semantic ambiguity"—mismatching syntactically similar tokens with different semantic meanings. For example, if the goals is to transform a date of pattern "DD/MM/YYYY" into the pattern "MM-DD-YYYY" (our clustering algorithm works in this case). Our token alignment algorithm may create a match from "DD" in the first pattern to "MM" in the second pattern because they have the same pattern of $\langle D \rangle 2$. The atomic transformation plan we *initially* select for each source pattern can be a transformation that mistakenly converts "DD/MM/YYYY" into "DD-MM-YYYY". Although our algorithm described in Section 6.3 often makes good guesses about the right matches, the system still infers an imperfect transformation about 50% of the time (Appendix E in the technical report [12]).

Fortunately, as our token alignment algorithm is complete and the program synthesis algorithm can discover all possible transformations and rank them in a smart way, the user can quickly find the correct transformation through *program repair*: replace the initial atomic transformation plan with another atomic transformation plans among the ones Section 6.3 suggests for a given source pattern.

To make the repair even simpler for the user, we deduplicate equivalent atomic transformation plans defined below before the repair phase.

Definition 6.2 (Equivalent Plans). *Two Transformation Plans are* equivalent *if, given the same source pattern, they always yield the same transformation result for any matching string.*

For instance, suppose the source pattern is [$\langle D \rangle 2$, '/', $\langle D \rangle 2$]. Two transformation plans $\mathcal{E}_1$ = [Extract(3), Const('/'), Extract(1)] and $\mathcal{E}_2$ = [Extract(3), Extract(2), Extract(1)] will yield exactly the same output because the first and third operations are identical and the second operation will always generate a '/' in both plans. If two plans are *equivalent*, presenting both rather than one of them will only increase the user effort. Hence, we only pick the simplest plan in the same equivalence class and prune the rest. The methodology detecting the equivalent plans is elaborated in Appendix B in the technical report [12].

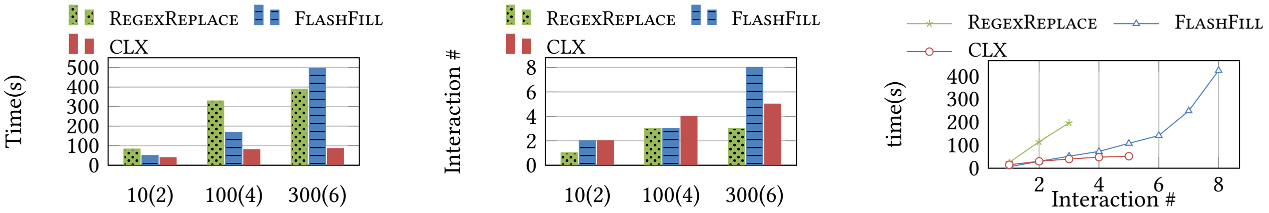
Overall, the repair process does not significantly increase the user effort. In those cases where the initial program is imperfect, 75% of the time the user made just a single repair (Appendix E in the technical report [12]).

7 EXPERIMENTS

We make three broad sets of experimental claims. First, we show that as the input data becomes larger and messier, CLX tends to be less work to use than FlashFill because verification is less challenging (Section 7.2). Second, we show that CLX programs are easier for users to understand than FlashFill programs (Section 7.3). Third, we show that CLX's expressive power is similar to that of baseline systems, as is the required effort for non-verification portions of the PBE process (Section 7.4).

7.1 Experimental Setup

We implemented a prototype of CLX and compared it against the state-of-the-art PBE system FlashFill. For ease of explanation, in this section, we refer this prototype as "CLX". Additionally, to make the experimental study more complete, we



(a) Overall completion time

(b) Rounds of interactions

(c) Interaction timestamps for 300(6)

Figure 11: Scalability of the system usability as data volume and heterogeneity increases (shorter bars are better)

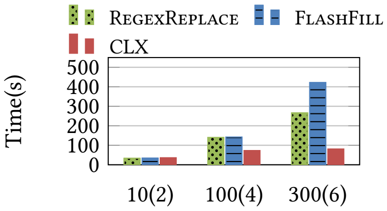


Figure 12: Verification time (shorter bars are better)

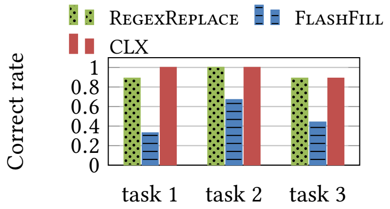

Figure 13: User comprehension test (taller bars are better)

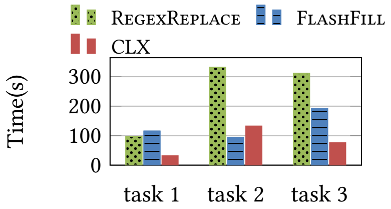

Figure 14: Completion time (shorter bars are better)

had a third baseline approach, a non-PBE feature offered by TrifactaWrangler[2] allowing the user to perform string transformation through manually creating Replace operations with simple natural-language-like regexps (referred as RegexReplace). All experiments were performed on a 4-core Intel Core i7 2.8G CPU with 16GB RAM. Other related PBE systems, Foofah [11] and TDE [9], target different workloads and also share the same verification problem we claim for PBE systems, and hence, are not considered as baselines.

7.2 User Study on Verification Effort

In this section, we conduct a user study on a real-world data set to show that (1) verification is a laborious and time-consuming step for users when using the classic PBE data transformation tool (e.g., FlashFill) particularly on a large messy data set, (2) asking end users to hand-write regexp-based data transformation programs is challenging and inefficient, and (3) the CLX model we propose effectively saves the user effort in verification during data transformation and hence its interaction time does not grow fast as the size and the heterogeneity of the data increase.

Test Data Set — Finding public data sets with messy formats suitable for our experiments is very challenging. The first experiment uses a column of 331 messy phone numbers from the "Times Square Food & Beverage Locations" data set [19].

Overview — The task was to transform all phone numbers into the form "$\langle D\rangle$3-$\langle D\rangle$3-$\langle D\rangle$4". We created three test cases by randomly sampling the data set with the following data sizes and heterogeneity: "10(2)" has 10 data records and 2 patterns; "100(4)" has 100 data records and 4 patterns; "300(6)" has 300 data records and 6 patterns.

We invited 9 students in Computer Science with a basic understanding of regular expressions and not involved in our project. Before the study, we educated all participants on how to use the system. Then, each participant was asked to work on one test case on a system and we recorded their performance.

We looked into the user performances on three systems from various perspectives: *overall completion time*, *number of interactions*, and *verification time*. The *overall completion time* gave us a quick idea of how much the cost of user effort was affected when the input data was increasingly large and heterogeneous in this data transformation task. The other two metrics allowed us to check the user effort in verification. While measuring completion time is straightforward, the other two metrics need to be clarified.

Number of interactions. For FlashFill, the number of interactions is essentially the number of examples the user provides. For CLX we define the number of interactions as the number of times the user verifies (and repairs, if necessary) the inferred atomic transformation plans. We also add one for the initial labeling interaction. For RegexReplace, the number of interactions is the number of Replace operations the user creates.

Verification Time. All three systems follow different interaction paradigms. However, we can divide the interaction process of into two parts, *verification* and *specification*: the user is either busy inputting (typing keyboards, selecting, etc.) or paused to verify the correctness of the transformed data or synthesized/hand-written regular expressions.

Measuring verification time is meaningful because we hypothesize that PBE data transformation systems become harder to use when data is large and messy not because the user has to provide a lot more input, but it becomes harder to verify the transformed data at the instance level.

Results — As shown in Figure 11a, "100(4)" cost 1.1× more time than "10(2)" on CLX, and "300(6)" cost 1.2× more time than "10(2)" on CLX. As for FlashFill, "100(4)" cost 2.4× more time than "10(2)", and "300(6)" cost 9.1× more time than "10(2)". Thus, in this user study, the user effort required by CLX grew slower than that of FlashFill. Also, RegexReplace cost significantly more user effort than CLX but its cost grew not as quickly as FlashFill. This shows good evidence that (1) manually writing data transformation script is cumbersome, (2) the user interaction time grows very fast in FlashFill when data size and heterogeneity increase, and (3) the user interaction time in CLX also grows, but not as fast.

Now, we dive deeper into understanding the causes for observation (2) and (3). Figure 11b shows the number of interactions in all test cases on all systems. We see that all three systems required a similar number of interactions in the first two test cases. Although FlashFill required 3 more interactions than

[2] TrifactaWrangler is a commercial product of Wrangler launched by Trifacta Inc. The version we used is 3.2.1

Task ID	Size	AvgLen	MaxLen	DataType
Task1	10	11.8	14	Human name
Task2	10	20.3	38	Address
Task3	100	16.6	18	Phone number

Table 5: Explainability test cases details

CLX in case “300(6)”, this could hardly be the main reason why FlashFill cost almost 5*x* more time than CLX.

We take a close look at the three systems’ interactions in the case of “300(6)” and plot the timestamps of each interaction in Figure 11c. The result shows that, in FlashFill, as the user was getting close to achieving a perfect transformation, it took the user an increasingly longer amount of time to make an interaction with the system, whereas the interaction time intervals were relatively stable in CLX and RegexReplace. Obviously, the user spent a longer time in each interaction NOT because an example became harder to type in (phone numbers have relatively similar lengths). We observed that, without any help from FlashFill, the user had to eyeball the entire data set to identify the data records that were still not correctly transformed, and it became harder and harder to do so simply because there were fewer of them. Figure 12 presents the average verification time on all systems in each test case. “100(4)” cost 1.0× more verification time than “10(2)” on CLX, and “300(6)” cost 1.3× more verification time than “10(2)” on CLX. As for FlashFill, “100(4)” cost 3.4× more verification time than “10(2)”, and “300(6)” cost 11.4× more verification time than “10(2)”. The fact that the verification time on FlashFill also grew significantly as the data became larger and messier supports our analysis and claim.

To summarize, this user study presents evidence that FlashFill becomes much harder to use as the data becomes larger and messier mainly because verification is more challenging. In contrast, CLX users generally are not affected by this issue.

7.3 User Study on Explainability

Through a new user study with the same 9 participants on three tasks, we demonstrate that (1) FlashFill users lack understanding about the inferred transformation logic, and hence, have inadequate insights on how the logic will work, and show that (2) the simple program generated by CLX improves the user’s understanding of the inferred transformation logic.

Additionally, we also compared the overall completion time of three systems.

Test Set — Since it was impractical to give a user too many data pattern transformation tasks to solve, we had to limit this user study to just a few tasks. To make a fair user study, we chose tasks with various data types that cost relatively same user effort on all three systems. From the benchmark test set we will introduce in Section 7.4, we randomly chose 3 test cases that each is supposed to require same user effort on both CLX and FlashFill: Example 11 from FlashFill (task 1), Example 3 from PredProg (task 2) and “phone-10-long” from SyGus (task 3). Statistics (number of rows, average/max/min string length of the raw data) about the three data sets are shown in Table 5.

Overview — We designed 3 multiple choice questions for every task examining how well the user understood the transformation regardless of the system he/she interacted with. All the questions were formulated as “Given the input string as *x*, what is the expected output”. All questions are shown in Appendix C in the technical report [12].

Sources	# tests	AvgSize	AvgLen	MaxLen	DataType
SyGus [26]	27	63.3	11.8	63	car model ids, human name, phone number, university name and address
FlashFill [6]	10	10.3	15.8	57	log entry, phone number, human name, date, name and position, file directory, url, product name
BlinkFill [24]	4	10.8	14.9	37	city name and country, human name, product id, address
PredProg [25]	3	10.0	12.7	38	human name, address
Prose [22]	3	39.3	10.2	44	country and number, email, human name and affiliation
Overall	47	43.6	13.0	63	

Table 6: Benchmark test cases details

During the user study, we asked every participant to participate all three tasks, each on a different system (completion time was measured). Upon completion, each participant was asked to answer all questions based on the transformation results or the synthetic programs generated by the system.

Explainability Results — The correct rates for all 3 tasks using all systems are presented in Figure 13. The result shows that the participants were able to answer these questions almost perfectly using CLX, but struggled to get even half correct using FlashFill. RegexReplace also achieved a success rate similar to CLX, but required higher user effort and expertise.

The result suggests that FlashFill users have insufficient understanding about the inferred transformation logic and CLX improves the users’ understanding in all tasks, which provides evidence that verification in CLX can be easier.

Overall Completion Time — The average completion time for each task using all three systems is presented in Figure 14. Compared to FlashFill, the participants using CLX spent 30% less time on average: ∼ 70% less time on task 1 and ∼ 60% less time on task 3, but ∼ 40% more time on task 2. Task 1 and task 3 have similar heterogeneity but task 3 (100 records) is bigger than task 1 (10 records). The participants using FlashFill typically spent much more time on understanding the data formats at the beginning and verifying the transformation result in solving task 3. This provides more evidence that CLX saves the verification effort. Task 2 is small (10 data records) but heterogeneous. Both FlashFill and CLX made imperfect transformation logic synthesis, and the participants had to make several corrections or repairs. We believe CLX lost in this case simply because the data set is too small, and as a result, CLX was not able to exploit its advantage in saving user effort on large-scale data set. The study also gives evidence that CLX is sometimes effective in saving user verification effort in small-scale data transformation tasks.

7.4 Expressivity and Efficiency Tests

In a simulation test using a large benchmark test set, we demonstrate that (1) the expressive power of CLX is comparable to the other two baseline systems FlashFill and RegexReplace, and (2) CLX is also pretty efficient in costing user interaction effort.

Test Set — We created a benchmark of 47 data pattern transformation test cases using a mixture of public string transformation test sets and example tasks from related research publications (will be released upon the acceptance of the paper). The information about the number of test cases from each source, average raw input data size (number of rows), average/max data instance length, and data types of these test cases are shown in Table 6.

Baselines	CLX Wins	Tie	CLX Loses
vs. FlashFill	17 (36%)	17 (36%)	13 (28%)
vs. RegexReplace	33 (70%)	12 (26%)	2 (4%)

Table 7: User effort simulation comparison.

A detailed description of the benchmark test set is shown in Appendix D in the technical report [12].

Overview — We evaluated CLX against 47 benchmark tests. As conducting an actual user study on all 47 benchmarks is not feasible, we simulated a user following the "lazy approach" used by Gulwani et al. [8]: a simulated user selected a target pattern or multiple target patterns and then repaired the atomic transformation plan for each source pattern if the system proposed answer was imperfect.

Also, we tested the other two systems against the same benchmark test suite. As with CLX, we simulated a user on FlashFill; this user provided the first positive example on the first data record in a non-standard pattern, and then iteratively provided positive examples for the data record on which the synthetic string transformation program failed. On RegexReplace, the simulated user specified a Replace operation with two regular expressions indicating the matching string pattern and the transformed pattern, and iteratively specified new parameterized Replace operations for the next ill-formatted data record until all data were in the correct format.

Evaluation Metrics — In experiments, we measured how much user effort all three systems required. Because systems follow different interaction models, a direct comparison of the user effort is impossible. We quantify the user effort by *Step*, which is defined differently as follows

- For CLX, the total Steps is the sum of the number of correct patterns the user chooses (Selection) and the number of repairs for the source patterns whose default atomic transformation plans are incorrect (Repair). In the end, we also check if the system has synthesized a "perfect" program: a program that successfully transforms all data.
- For FlashFill, the total Steps is the sum of the number of input examples to provide and the number of data records that the system fails to transform.
- For RegexReplace, each specified Replace operation is counted as 2 Steps as the user needs to type two regular expressions for each Replace, which is about twice the effort of giving an example in FlashFill.

In each test, for any system, if not all data records were correctly transformed, we added the number of data records that the system fails to transform correctly to its total *Step* value as a punishment. In this way, we had a coarse estimation of the user effort in all three systems on the 47 benchmarks.

Expressivity Results — CLX could synthesize right transformations for 42/47 (~ 90%) test cases, whereas FlashFill reached 45/47 (~ 96%). This suggests that the expressive power of CLX is comparable to that of FlashFill.

There were five test cases where CLX failed to yield a perfect transformation. Only one of the failures was due to the expressiveness of the language itself, the others could be fixed if there were more representative examples in the raw data. "Example 13" in FlashFill requires the inference of advanced conditionals (Contains keyword "picture") that UniFi cannot currently express, but adding support for these conditionals in UniFi is straightforward. The failures in the remaining four test cases were mainly caused by the lack of the target pattern examples in the data set. For example, one of the test cases we failed is a name transformation task, where there is a last name "McMillan" to extract. However, all data in the target pattern contained last names comprising one uppercase letter followed by multiple lowercase letters and hence our system did not realize "McMillan" needed to be extracted. We think if the input data is large and representative enough, we should be able to successfully capture all desired data patterns.

RegexReplace allows the user to specify any regular expression replace operations, hence it was able to correctly transform all the input data existed in the test set, because the user could directly write operations replacing the exact string of an individual data record into its desired form. However, similar to UniFi, RegexReplace is also limited by the expressive power of regular expressions and cannot support advanced conditionals. As such, it covered 46/47 (~ 98%) test cases.

User Effort Results — As the *Step* metric is a potentially noisy measure of user effort, it is more reasonable to check whether CLX costs more or less effort than other baselines, rather than to compare absolute *Step* numbers. The aggregated result is shown in Table 7. It suggests CLX often requires less or at least equal user effort than both PBE systems. Compared to RegexReplace, CLX almost always costs less or equal user effort. A detailed discussion about the user effort on CLX and comparison with other systems is in Appendix E in the technical report [12].

8 RELATED WORK

Data Transformation — FlashFill (now a feature in Excel) is an influential work for syntactic transformation by Gulwani [6]. It designed an expressive string transformation language and proposed the algorithm based on version space algebra to discover a program in the designed language. It was recently integrated to PROSE SDK released by Microsoft. A more recent PBE project, TDE [9], also targets string transformation. Similar to FlashFill, TDE requires the user to verify at the instance level and the generated program is unexplainable to the user. Other related PBE data cleaning projects include [11, 24].

Another thread of seminal research including [21], Wrangler [13] and Trifacta created by Hellerstein et al. follow a different interaction paradigm called "predictive interaction". They proposed an inference-enhanced visual platform supporting many different data wrangling and profiling tasks. Based on the user selection of columns, rows or text, the system intelligently suggests possible data transformation operations, such as Split, Fold, or pattern-based extraction operations.

Pattern Profiling — In our project, we focus on clustering ad hoc string data based on structures and derive the structure information. The LearnPADS [4] project is somewhat related. It presents a learning algorithm using statistics over symbols and tokenized data chunks to discover pattern structure. LearnPADS assumes that all data entries follow a repeating high-level pattern structure. However, this assumption may not hold for some of the workload elements. In contrast, we create a bottom-up pattern discovery algorithm that does not make this assumption. Plus, the output of LearnPADS (i.e., PADS program [3]) is hard for a human to read, whereas our pattern cluster hierarchy is simpler to understand. Most recently, Datamaran[5] has proposed methodologies for discovering structure information in a data set whose record boundaries are unknown, but for the same reasons as LearnPADS, Datamaran is not suitable for our problem.

Program Synthesis — Program synthesis has garnered wide interest in domains where the end users might not have good programming skills or programs are hard to maintain or reuse including data science and database systems. Researchers have built various program synthesis applications to generate SQL queries [16, 20, 27], regular expressions [1, 17], data cleaning programs [6, 28], and more.

Researchers have proposed various techniques for program synthesis. [7, 10] proposed a constraint-based program synthesis technique using logic solvers. However, constraint-based techniques are mainly applicable in the context where finding a satisfying solution is challenging, but we prefer a high-quality program rather than a satisfying program. Version space algebra is another important technique that is applied by [6, 14, 15, 18]. [2] recently focuses on using deep learning for program synthesis. Most of these projects rely on user inputs to reduce the search space until a quality program can be discovered; they share the hope that there is one simple solution matching most, if not all, user-provided example pairs. In our case, transformation plans for different heterogeneous patterns can be quite distinct. Thus, applying the version space algebra technique is difficult.

9 CONCLUSION AND FUTURE WORK

Data transformation is a difficult human-intensive task. PBE is a leading approach of using computational inference to reduce human burden in data transformation. However, we observe that standard PBE for data transformation is still difficult to use due to its laborious and unreliable verification process.

We proposed a new data transformation paradigm CLX to alleviate the above issue. In CLX, we build data patterns to help the user quickly identify both well-formatted and ill-formatted data which immediately saves the verification time. CLX also infers regexp replace operations as the desired transformation, which many users are familiar with and boosts their confidence in verification.

We presented an instantiation of CLX with a focus on data pattern transformation including (1) a pattern profiling algorithm that hierarchically clusters both the raw input data and the transformed data based on data patterns, (2) a DSL, UniFi, that can express many data pattern transformation tasks and can be interpreted as a set of simple regular expression replace operations, (3) algorithms inferring a correct UniFi program.

We presented two user studies. In a user study on data sets of various sizes, when the data size grew by a factor of 30, the user verification time required by CLX grew by 1.3× whereas that required by FlashFill grew by 11.4×. The comprehensibility user study shows the CLX users achieved a success rate about twice that of the FlashFill users. The results provide good evidence that CLX greatly alleviates the verification issue.

Although building a highly-expressive data pattern transformation tool is not the central goal of this paper, we are happy to see that the expressive power and user effort efficiency of our initial design of CLX is comparable to those of FlashFill in a simulation study on a large test set in another test.

CLX is a data transformation paradigm that can be used not only for data pattern transformation but other data transformation or transformation tasks too. For example, given a set of heterogeneous spreadsheet tables storing the same information from different organizations, CLX can be used to synthesize programs converting all tables into the same standard format. Building such an instantiation of CLX will be our future work.

Reverse-Engineering Conjunctive Queries from Provenance Examples

Daniel Deutch

ABSTRACT

The *provenance* of a query result details relevant parts of the input data as well as the computation leading to each output tuple. Multiple lines of work have studied the tracking and presentation of provenance, showing its effectiveness in explaining and justifying query results. The willingness of application owners to share provenance information for these purposes may however be hindered by the resulting exposure of the underlying query logic, which may be proprietary and confidential. We therefore formalize and study the following problem: when a (small) subset of the query results along with their provenance is given, what information is revealed about the underlying query? Our model is based on the provenance semiring framework and applies to many previously proposed provenance models. We analyze two flavors of the problem: (1) how many queries may be consistent with a given provenance example? and (2) what is the complexity of inferring a consistent query, or one that is a "best fit"? Our theoretical analysis shows that there may be many (for some models, even infinitely many in presence of self-joins) consistent queries, yet we provide practically efficient algorithms to find (best-fit) such queries. We experimentally show that the algorithms are generally successful in correctly reverse engineering queries, even when given only a few output examples and their provenance.

1 INTRODUCTION

Provenance information is a form of meta-data that is associated with query results, to describe the origin of each piece of data and the computational process leading to its generation. In particular, provenance was shown to be useful as means of providing explanations for query results and allowing for their validation [6, 8, 12, 15, 16, 21, 23, 29, 30, 36]. On the other hand, query owners who publish this information for their users may wish to keep the original query private due to its proprietary logic or due to criteria they wish to keep obfuscated. Thus, owners may wonder if their query can be reverse engineered from a few leaked outputs and their provenance w.r.t this query.

Example 1.1. Consider a bank whose clients must meet certain criteria to have their loan requests approved: they must have a positive credit score and one guarantor associated with the private banking division to co-sign the loan. If a client is already associated with the private banking division, she does not need a guarantor.

The bank's database contains the tables shown in Figures 1a, 1b, 1c, and 1d. The tables correspond to clients and their balance (table *B*), pairs of possible guarantors and borrowers (table *G*), clients with positive credit score (table *PCS*) and clients associated with the private banking division (table *PB*), respectively (ignore the *prov.* column for now).

The following Conjunctive Query (CQ), Q_{real}, captures the bank's loan conditions as specified above:

$$Q_{real}(id_1, b_2) :- B(id_1, b_1), B(id_2, b_2), G(id_2, id_1), PCS(id_1), PB(id_2)$$

It takes the balance of two clients, specifies that the second client is the guarantor of the first, and makes sure that the borrowing client has a positive credit score and that the guarantor is associated with the private banking division. The output is a table of ids and balances where for each borrower id, we show how much security the bank has for the loan, represented as the balance of the guarantor.

The bank may wish to explain to each applicant the reason underlying the answer to its own request, but to avoid exposure of the general criteria, i.e. of the query Q_{real}, since these criteria are part of the bank's confidential business strategy. If other clients obtain some of these explanations, they may understand the general criteria. The question then arises: given examples of the output and explanations provided for multiple clients, can one infer the underlying query?

In the above example, the answers and explanations can be formally defined as output and provenance examples. This leads us to define and study for first time on the modeling and algorithmic challenges stemming from the problem of reverse engineering queries from output and provenance examples.

Modeling. We propose a novel formal model for the problem, as follows. We are given output tuples, and their provenance, represented as instances of the previously proposed semiring model [30]. We have chosen the semiring model due to its generality: as shown in [29], many previously proposed provenance models may be captured via corresponding choices of semirings. Intuitively, different semirings represent different granularities of explanations given to users (see Example 1.2 in this section). We then formally define what it means for a CQ to be consistent with output examples and their provenance, thus defining the *query-by-provenance* problem. Intuitively, we look for a CQ that, when evaluated with respect to the input database *does not only yield the specified example tuples, but also its derivation of these tuples (i.e. their provenance) is "consistent" with the prescription made by the provenance.* We do not expect the full provenance to be provided (i.e. all explanations for a loan being approved); instead, we define "consistency" of provenance in a less restrictive manner, by leveraging the inclusion property of provenance from [29]. Last, we define the notion of inclusion-minimality to capture the idea of the query not only matching the provenance, but rather being a "best-fit" for it.

Theoretical Analysis. We then study in depth the query-by-provenance problem, for five different choices of semirings, namely, provenance polynomials [29, 30], trio provenance [36], positive

boolean expressions [32], and why-provenance [12]. Each semiring corresponds to an explanation with a different granularity. We next demonstrate two such provenance semirings, namely provenance polynomials ($\mathbb{N}[X]$) and why-provenance (Why(X)), in the context of our running example.

Example 1.2. Reconsider the query Q_{real} and the database in Example 1.1. Tuples in the database are associated with annotations (a to l), intuitively serving as the tuple identifiers (note that the annotations are not part of the relations). Figure 1e presents two output tuples of the query when evaluated on the database. Consider for instance the first row describing the provenance of the tuple $(2, 1000)$ (the id of the borrower with the balance of the guarantor). The $\mathbb{N}[X]$ column shows the polynomial $2b^2eik + badij$, which consists of three monomials (a monomial with coefficient x is considered as x monomials), each corresponding to a different assignment of input tuples to the atoms of Q_{real}, or different explanations for approving the loan request of the client with id 2. For instance, $2b^2eik$ stems from two assignments (implied by the coefficient 2) that use the tuple annotated by b twice and the tuples annotated by e, i, k once. This explanation immediately exposes the number of query atoms (5, as is the number of annotations in the monomial) and the number atoms from each relation. In the context of loan conditions, this explanation exposes that a borrower can be her own guarantor (from the double use of the tuple b). In contrast, in the $Why(X)$ model, we represent each explanation as the **set** of tuples that contributed to the formation of the output tuple, thus "dropping" both coefficients and exponents: $beik + badij$. Considering this kind of explanation, we no longer know the number of query atoms and the number of atoms from each relation. In particular, we no longer expose that a client associated with the private banking division does not need a guarantor.

We study two factors that determine to what extent does a set of output examples and their provenance reveal a hidden underlying query, as follows. The first factor is the number of possible consistent queries, and the second is the complexity of reverse-engineering a consistent query. In more detail, when the provenance is given in $\mathbb{N}[X]$ or $\mathbb{B}[X]$, we provide a bound on the number of consistent queries which is exponential in the sum of arities of all relations whose tuples participate in a single provenance monomial, and provide an example where there are indeed exponentially many consistent queries. We then show that finding a consistent query w.r.t $\mathbb{N}[X]\backslash\mathbb{B}[X]$-examples is NP-complete in the number of attributes of the output tuple, and we design a practically efficient algorithm.

Reconstructing queries from examples of why, trio or PosBool provenance is more cumbersome: there may be infinitely many consistent and inclusion-minimal queries that lead to the same provenance (with different exponents, due to self-joins, that are abstracted away in these models). To this end, we prove a small world property, namely that if a consistent query exists, then there exists such query of size bounded by some parameters of the input. The bound by itself does not suffice for an efficient algorithm (trying all detailed expressions of sizes up to the bound would be inefficient), but we leverage it in devising an efficient algorithm for these provenance semirings. The algorithm is similar to the $\mathbb{N}[X]$ and $\mathbb{B}[X]$ case but also includes an option to expand the monomials, gradually, generating self joins when necessary.

Experimental Analysis. We have also conducted an experimental study of our algorithms, assessing their ability to reverse engineer the correct TPC-H [40] queries as well as highly complex join queries presented as a baseline in [43]. We have executed the queries while tracking provenance, and then showed our algorithms randomly sampled portions of the output and provenance. We report how many examples were required for the algorithms to correctly identify the underlying query, and what were the differences between the actual and inferred query when incorrect. In the vast majority of the cases, our algorithms converged to the underlying query after having viewed only a small number of examples; when this was not the case, the inferred query was typically similar to the actual one, e.g. containing additional constants due to the same value recurring in the viewed examples. Last, further experiments indicate the computational efficiency of our algorithms. Our experiments show that, although theoretically provenance examples may correspond to a large or even infinite number of queries, in practice, publishing provenance information, even for a small number of output tuples, reveals the full logic of the query. Hence, in this respect, there is no advantage in publishing a less detailed form of provenance.

2 RELATED WORK

Reverse Engineering Queries from Partial/Full Output. There is a large body of literature on learning queries from examples, in different variants. A first axis of these variants concerns learning a query whose output *precisely* matches the example (e.g. [33, 41, 43]), versus one whose output contains the example tuples and possibly more (e.g. [33–35, 38] and the somewhat different problem in [44]). The first is mostly useful e.g. in a use-case where an actual query was run and its result, but not the query itself, is available. This may be the case if e.g. the result was exported and sent. The second, that we adopt here, is geared towards examples provided manually by a user, who may not be expected to provide a full account of the output. Another distinguishing factor between works in this area is the domain of queries that are inferred; due to the complexity of the problem, it is typical (e.g. [10, 35, 43]) to restrict the attention to join queries, and many works also impose further restrictions on the join graph [17, 41]. We do not impose such restrictions and are able to infer complex CQs. Last, there is a prominent line of work on query-by-example in the context of *data exploration* [3, 9, 10, 24, 37]. Here users typically provide an initial set of examples, leading to the generation of a consistent query (or multiple such queries); the queries and/or their results are presented to users, who may in turn provide feedback used to refine the queries, and so on. In our settings, the number of examples required for convergence to the actual intended query was typically small. In cases where more examples are needed, an interactive approach is expected to be useful in our setting as well. Works along the lines of [2, 7, 42] explored the problem of reverse engineering queries from positive and negative examples and the general complexity of different variations of the problem.

The fundamental difference between our work and previous work in this field in this area is the assumed input - output examples and provenance information (in particular no foreign keys are known; in fact, we do not even need to know the entire input database, but rather just tuples used in explanations). *While our approach requires more input, it greatly reduces the search space for the query. The advantage becomes more significant as the database size increases and the schema becomes more complex.* Furthermore, we are able to leverage the provenance information and reconstruct the original query, or a very similar one (1) in a highly complex setting where the underlying queries includes multiple joins and self-joins, (2) with only very few examples (up to 5 were typically sufficient to obtain over 90% recall, and less than 20 in all but one case were sufficient to converge to the actual underlying query), and (3) in split-seconds for a small number of examples, and in 1.3 seconds even with 500 examples. No previous work, to our knowledge, has exhibited the combination of these characteristics.

Data Provenance. Data Provenance has been extensively studied, for different formalisms including relational algebra, XML query languages, Nested Relational Calculus, and functional programs (see e.g. [11, 15, 25, 26, 28, 30, 36, 39]). In contrast to these lines of work that focus on provenance tracking and usages, we have focused on learning queries from output examples and their partial provenance, based on the semiring framework. This includes quite a few of the models proposed in the literature, but by no means all of them. Investigating query-by-provenance for other provenance models is an intriguing direction for future work.

The high-level question of what can be learned from provenance has been extensively studied in the context of workflow privacy, e.g. [13, 18–20, 27]. In contrast, we do not focus on black-box modules, but rather on detailed fine-grained provenance obtained from queries. This makes the technical results of these works inapplicable to our setting. [14] describes a general framework for provenance security, but, for the relational database case, focuses on what parts of the *data* are disclosed, while the underlying query is assumed to be known.

Last, we note that in [4] we have leveraged provenance information for designing a user-interactive SPARQL interface, including a component of inferring SPARQL queries from examples and provenance. There are many differences in the model, and consequently none of our results here follow from [4]. In particular, our focus in [4] was on single output nodes which if translated to the relational settings means $k = 1$ (recall that k is the output arity); in that setting it is consequently PTIME to find a consistent query (compare to our NP-hardness result). SPARQL is also bounded to 2 attributes per relation, implying that $r = 2n$, as opposed to the relational setting where the number of attributes is not necessarily 2. Indeed, a prominent challenge in our experimental study stemmed from the number of variables, in particular for the TPC-H queries, where $n << r$.

3 PRELIMINARIES

3.1 Conjunctive Queries

We will focus in this paper on CQs (see e.g. [31]). Fix a database schema $\mathcal{S}$ with relation names $\{\mathcal{R}_1, ..., \mathcal{R}_n\}$ over a domain C of constants. Further fix a domain $\mathcal{V}$ of variables. A *CQ* Q over $\mathcal{S}$ is an expression of the form $T(\vec{u}) : -\mathcal{R}_1(\vec{v_1}), \ldots, \mathcal{R}_l(\vec{v_l})$ where T is a relation name not in $\mathcal{S}$. For all $1 \leq i \leq n$, $\vec{v_i}$ is a vector of the form $(x_1, \ldots, x_k)$ where $\forall 1 \leq j \leq k.\ x_j \in \mathcal{V} \cup C$. $T(\vec{u})$ is the query head, denoted $head(Q)$, and $\mathcal{R}_1(\vec{v_1}), \ldots, \mathcal{R}_l(\vec{v_l})$ is the query body and is denoted $body(Q)$. The variables appearing in $\vec{u}$ are called the *head variables* of Q, and each of them must also appear in the body. We use CQ to denote the class of all CQs, omitting details of the schema when clear from context.

We next define the notion of *derivations* for CQs. A derivation α for a query $Q \in CQ$ with respect to a database instance D is a mapping of the relational atoms of Q to tuples in D that respects relation names and induces a mapping over arguments, i.e. if a relational atom $R(x_1, ..., x_n)$ is mapped to a tuple $R(a_1, ..., a_n)$ then we say that x_i is mapped to a_i (denoted $\alpha(x_i) = a_i$). We require that a variable x_i will not be mapped to multiple distinct values, and a constant x_i will be mapped to itself. We define $\alpha(head(Q))$ as the tuple obtained from $head(Q)$ by replacing each occurrence of a variable x_i by $\alpha(x_i)$.

Example 3.1. Reconsider our example query Q_{real} presented in Example 1.2 (the database is depicted in Figures 1a, 1b, 1c, and 1d). Now, consider the result tuple (1, 300). It is obtained through the derivation that maps the atoms to six distinct tuples from the database to the three atoms (in order of the atoms). These are the tuples annotated by **a, c, f, h, l**. The tuple (2, 1000) is obtained through three derivations: the first (second and third) maps the tuple annotated **b** (**b**) to the first atom, the tuple annotated by **a** (**b**) to the second atom, the tuple annotated by **d** (**e**) to the third atom, the tuple annotated by **i** (**i**) to the fourth, and **j** (**k**) to the remaining atom.

3.2 Provenance

The tracking of *provenance* to explain query results has been extensively studied in multiple lines of work, and [29] has shown that different such models may be captured using the *semiring approach* (originally proposed in [30]). We next overview several aspects of the approach that we will use in our formal framework.

Commutative Semirings. A *commutative monoid* is an algebraic structure $(M, +_M, 0_M)$ where $+_M$ is an associative and commutative binary operation and 0_M is an identity for $+_M$. A *commutative semiring* is then a structure $(K, +_K, \cdot_K, 0_K, 1_K)$ where $(K, +_K, 0_K)$ and $(K, \cdot_K, 1_K)$ are commutative monoids, $\cdot_K$ is distributive over $+_K$, and $a \cdot_K 0_K = 0 \cdot_K a = 0_K$.

Annotated Databases. We will capture provenance through the notion of databases whose tuples are associated ("annotated") with elements of a commutative semiring. For a schema $\mathcal{S}$ with relation names $\{\mathcal{R}_1, ..., \mathcal{R}_n\}$, denote by $Tup(\mathcal{R}_i)$ the set of all (possibly infinitely many) possible tuples of $\mathcal{R}_i$.

Definition 3.2 (adapted from [30]). A *K-relation* for a relation name $\mathcal{R}_i$ and a commutative semiring K is a function R :

$Tup(\mathcal{R}_i) \mapsto K$ such that its *support* defined by $\text{supp}(R) \equiv \{t \mid R(t) \neq 0\}$ is finite. We say that $R(t)$ is the annotation of t in R. A K-database D over a schema $\{\mathcal{R}_1, ..., \mathcal{R}_n\}$ is then a collection of K-relations, over each $\mathcal{R}_i$.

Intuitively a K-relation maps each tuple to its annotation. We will sometimes use $D(t)$ to denote the annotation of t in its relation in a database D. We furthermore say that a K-relation is *abstractly tagged* if each tuple is annotated by a distinct element of K (intuitively, its identifier).

Provenance-Aware Query Results. We then define CQs as mappings from K-databases to K-relations. Intuitively we define the annotation (provenance) of an output tuple as a combination of annotations of input tuples. This combination is based on the query derivations, via the intuitive association of alternative derivations with the semiring "+" operation, and of joint use of tuples in a derivation with the "·" operation.

Definition 3.3 (adapted from [30]). Let D be a K-database and let $Q \in CQ$, with T being the relation name in $head(Q)$. For every tuple $t \in T$, let α_t be the set of derivations of Q w.r.t. D that yield t. $Q(D)$ is defined to be a K-relation T s.t. for every t, $T(t) = \sum_{\alpha \in \alpha_t} \prod_{t' \in Im(\alpha)} D(t')$. $Im(\alpha)$ is the image of α.

Summation and multiplication in the above definition are done in an arbitrary semiring K. Different semirings give different interpretations to the operations [29].

Provenance Polynomials ($\mathbb{N}[X]$). The most general form of provenance for positive relational algebra (see [30]) is the *semiring of polynomials with natural numbers as coefficients*, namely $(\mathbb{N}[X], +, \cdot, 0, 1)$. The idea is that given a set of basic annotations X (elements of which may be assigned to input tuples), the output of a query is represented by a sum of products as in Def. 3.3, with only the basic equivalence laws of commutative semirings in place. Coefficients serve in a sense as "shorthand" for multiple derivations using the same tuples, and exponents as "shorthand" for multiple uses of a tuple in a derivation. In Example 3.1, we see that a tuple may have several derivations, serving as the explanations for it. The two monomials are separated by a + sign, as opposed to a single monomial. We address this as part of our solution presented in Section 5.

Many additional forms of provenance have been proposed in the literature, varying in their level of abstraction and the details they reveal on the derivations. [29] showed that these can be captured by congruence relations. Formally, consider the function $f_K : \mathbb{N}[X] \mapsto \mathbb{N}[X]$ as a congruence relation defined by $P_1 \equiv P_2$ if $f_K(P_1) = f_K(P_2)$, where f_K varies based on the semiring K. We exemplify these notions using our running example of the third row in Figure 1e.

Boolean Provenance Polynomials ($\mathbb{B}[X]$). The boolean provenance semiring, $(\mathbb{B}[X], +, \cdot, 0, 1)$, is the semiring of polynomials over variables X, where coefficients are either 1 or 0 (intuitively corresponding to boolean coefficients). We can think of the $\mathbb{B}[X]$ semiring as the $\mathbb{N}[X]$ semiring after applying the homomorphism $f_{\mathbb{B}}[X] : \mathbb{N}[X] \mapsto \mathbb{N}[X]$ which maps all non-zero coefficients to 1. In the third row of our example, the polynomial $2b^2eik + badij$ becomes $b^2eik + badij$ after mapping the two coefficients 2, 1 to 1.

In the context of our loan example, if we were to obtain the provenance as $\mathbb{N}[X]$ or $\mathbb{B}[X]$, we could infer that a client can get a loan without needing a guarantor.

Trio. This semiring can again be modeled as the image of the surjective homomorphism $f_{trio} : \mathbb{N}[X] \mapsto \mathbb{N}[X]$ dropping all exponents in the provenance polynomial. Consider again the third row of our example. For instance, the polynomial $2b^2eik + badij$ becomes $2beik + badij$ after the function f_{trio} maps all exponents to 1.

Why. A natural approach to provenance tracking, referred to as *why*-provenance [12], capturing each derivation as a *set* of the annotations of tuples used in the derivation. The overall why-provenance is thus a *set of such sets*. As shown (in a slightly different way) in [29], this corresponds to using provenance polynomials but without "caring" about exponents and coefficients. Formally, consider the function $f_{why} : \mathbb{N}[X] \mapsto \mathbb{N}[X]$ that *drops all coefficients and exponents* of its input polynomial. Using our example again, the polynomial $2b^2eik + badij$ is converted to $beik + badij$ under f_{why}.

Positive Boolean Expressions. This is a semiring of positive boolean expressions over variables X, i.e., the expressions are composed of disjunction, conjunction, and constants which are true or false. Formally, we define $f_{PosBool} : \mathbb{N}[X] \mapsto \mathbb{N}[X]$ that dropping all exponents and coefficients in the provenance polynomial, and considers + as $\vee$ and · as $\wedge$, i.e., allowing for the absorption of monomials. For the purpose of the demonstration, consider the abstract polynomial $2b^2eik + baeik$. Under $f_{PosBool}$ it is converted to $beik$ since all exponents and coefficients, and the monomial $baeik$ are absorbed into $beik$ $((b \wedge b \wedge e \wedge i \wedge k) \vee (b \wedge a \wedge e \wedge i \wedge k) \equiv b \wedge e \wedge i \wedge k)$.

In our running example, trio, why and PosBool provenance reveals less information about the loan conditions, e.g., who is the guarantor of the client with id 2 in Figure 1e.

As we demonstrated, each provenance model represents the provenance in a specific level of detail, and all models other than $\mathbb{N}[X]$ incur some loss of information in the provenance description.

4 QUERY-BY-PROVENANCE

We define in this section the problem of learning queries from examples and their provenance. We first introduce the notion of such examples, using provenance.

Definition 4.1 (Examples with provenance). Given a semiring K, a *K-example* is a pair (I, O) where I is an abstractly-tagged K-database called the *input* and O is a K-relation called the *output*.

Intuitively, annotations in the input only serve as identifiers, and those in the output serve as explanations – combinations of annotations of input tuples contributing to the output.

We next define the notion of a query being consistent with a K-example. In the context of query-by-example, a query is consistent if its evaluation result includes all example tuples (but maybe others as well). We resort to [29] for the appropriate generalization to the provenance-aware settings:

Definition 4.2. Let $(K, +_K, \cdot_K, 0, 1)$ be a semiring and define $a \leq_K b$ iff $\exists c.\ a +_K c = b$. If $\leq_K$ is a (partial) order relation then we say that K is naturally ordered.

Given two K-relations R_1, R_2 we say that $R_1 \subseteq_K R_2$ iff $\forall t. R_1(t) \leq_K R_2(t)$.

Note that if $R_1 \subseteq_K R_2$ then in particular $supp(R_1) \subseteq supp(R_2)$, so the notion of containment w.r.t. a semiring is indeed a faithful extension of "standard" relation containment. In terms of provenance, we note that for $\mathbb{N}[X]$ and $Why(X)$, the natural order corresponds to inclusion of monomials: $p_1 \leq p_2$ if every monomial in p_1 appears in p_2. The order relation has different interpretations in other semirings.

We are now ready to define the notion of consistency with respect to a K-example, and introduce our problem statement. Intuitively, we look for a query whose output is contained in the example output, and for each example tuple, the provenance is "reflected" in the computation of the tuple by the query.

Definition 4.3 (Problem Statement). Given a K-example (I,O) and a CQ Q we say that Q is consistent with respect to the example if $O \subseteq_K Q(I)$. QUERY-BY-PROVENANCE is the problem of finding a consistent query for a given K-example.

The above definition allows multiple CQs to be consistent with a given K-example. This is in line with the conventional wisdom in query-by-example. Throughout the paper we will always assume that the provenance is non-empty, since if it is empty, we return to the setting of the classic query-by-example problem.

A consistent query can be very general, as we demonstrate in the following example. A natural desideratum (employed in the context of "query-by-example"), is that the query is "inclusion-minimal". This notion extends naturally to K-databases.

Definition 4.4. A consistent query Q (w.r.t. a given K-example Ex) is inclusion-minimal if for every query Q' such that $Q' \subsetneq_K Q$ (i.e. for every K-database D it holds that $Q'(D) \subseteq_K Q(D)$, but not vice-versa), Q' is not consistent w.r.t. Ex.

We next demonstrate the notion of consistent and inclusion-minimal queries with respect to a given K-example.

Example 4.5. We now treat Figure 1e as an $\mathbb{N}[X]$-example. Consistent queries must derive the example tuples in the ways specified in the polynomials (and possibly in additional ways). The query Q_{real} from Example 1.2 is of course a consistent query with respect to it, since it generates the example tuples and the provenance of each of them according to Q_{real} is the same as that provided in the example. Q_{real} is not the only consistent query, since the following query, $Q_{general}$ (which simply performs a Cartesian product), is also consistent:

$$Q_{general}(id_1, b_2) : -B(id_1, b_1), B(id_2, b_2), G(id_3, id_4), \\ PCS(id_5), PB(id_6)$$

However, Q_{real} is also an inclusion-minimal query, as opposed to $Q_{general}$ since $Q_{real} \subsetneq Q_{general}$.

In the following section we study the complexity of the above computational problems for the different models of provenance. We will analyze the complexity with respect to the different facets of the input, notations for which are provided in Table 1.

Table 1: Notations

Ex	K-example
I	Input database
O	Output relation and its provenance
m	Total number of monomials
k	Number of attributes of the output relation
n	(Maximal) Number of elements in a monomial
r	Sum of arities in the atoms of a query body
d	Number of distinct relation names in the provenance

We list our results for the QUERY-BY-PROVENANCE problem in Table 2. The columns of the table list: the bound for the number of possible consistent queries for each of the semirings, the maximal length of a consistent query if one exists, and the lower and upper bounds of finding a consistent query. Each result has a reference to the relevant proposition. Some of the proofs are omitted for brevity and can be found in the full version [22].

5 LEARNING FROM $\mathbb{N}[X]$, $\mathbb{B}[X]$-EXAMPLES

We start our study with the case where the given provenance consists of $\mathbb{N}[X]$ expressions. This is the most informative form of provenance under the semiring framework, and thus the most informative explanation. In particular, we note that given the $\mathbb{N}[X]$ provenance, the number of query atoms (and the relations occurring in them) are trivially identifiable. What remains is the choice of variables to appear in the query atoms (body and head), and as a consequence, decide how to order the tuples in each monomial.

We first bound the number of possible consistent queries:

Proposition 5.1. *For every choice of $r, k \in \mathbb{N}$, every $\mathbb{N}[X]$-example has at most $O(B_r r^k 2^r)$ consistent queries, where B_r is the Bell number of r. Furthermore, there exists an $\mathbb{N}[X]$-example whose output tuples have arity of k, and monomials have arity of r, for which there exists exponentially many (in both r and k) consistent queries.*

Proof. We start by analyzing the case for boolean queries, i.e., $k = 0$. Consider the set of indexes $\{1, \ldots, r\}$ in the query body. Every partition of this set of indexes defines a different consistent query, since the partition determines exactly which indexes will have the same variable, assuming we impose an order on the query atoms (e.g., the query $Q() : -R(x, x, x), R(x, x, x), T(x, y)$ is determined by the partition $\{1, 2, 3, 4, 5, 6, 7\}, \{8\}$). We can thus say that the maximum number of consistent boolean queries w.r.t an $\mathbb{N}[X]$-example is the number of partitions of the set $\{1, \ldots, r\}$ into disjoint non-empty subsets. This number is the Bell number B_r. Each subset of the partition can then either be instantiated with a constant or with a distinct variable. As there can be at most r subsets in the partition, the number of options is bounded by 2^r. In the general case, when queries are not boolean but have k output attributes, we further have to choose which variables will be projected to the head. Since the maximum number of unique variables in the query body is r, there are at most r^k options to do so. Therefore the number of consistent queries can be bounded by $B_r r^k 2^r$. For the second part of the claim, consider an $\mathbb{N}[X]$-example for which a query with a single constant at every index, both in the head of the query and its body, is consistent (e.g. $Q(1, 1) : -R(1, 1, 1), R(1, 1, 1), T(1, 1)$). In this case, replacing every subset of 1s with different variables, will also result in a consistent query. As there are exponentially many subsets of attributes to the query, there are exponentially many consistent queries w.r.t the $\mathbb{N}[X]$-example. □

We have shown a bound for the number of different consistent queries, but it is also important to note that there can be multiple inclusion-minimal queries. It is easy to show an example where there are may be exponentially many inclusion-minimal queries. We next show an upper bound

Table 2: Results for the QUERY-BY-PROVENANCE Problem

Semiring	Number of consistent queries	Small world query length	Lower bound	Upper bound
$\mathbb{N}[X]$	$O(B_r r^k 2^r)$ (Prop. 5.1)	n (Trivial)	NP-complete in k (Prop. 5.4)	$O(n^{2k}m + krn^k)$ (Prop. 5.2)
$\mathbb{B}[X]$				
$Trio(X)$	∞ (Prop. 6.1)	$k + d(n-1)$ (Prop. 6.5)	Find minimal sized query is NP-complete in k (Prop. 6.4)	$O(n^{O(k)}mkr)$ (Prop. 6.7)
$PosBool(X)$				
$Why(X)$				

5.1 An Efficient Algorithm for Finding a Query

Although the number of query atoms is known from the given example, finding a consistent query efficiently is non-trivial. An important observation in this respect is that we can focus on finding atoms that "cover" the attributes of the output relation (i.e. that include the right values of the output tuples, in the right order), and the number of required such atoms is at most k (the arity of the output relation). We may need further atoms so that the query realizes all provenance tokens (eventually, these atoms will also be useful in imposing e.g. join constraints), and this is where care is needed to avoid an exponential blow-up with respect to the provenance size. To this end, we observe that we may generate a "most general" part of the query simply by generating atoms with fresh variables, and without considering all permutations of parts that do not contribute to the head. This will suffice to guarantee a consistent query, but may lead to the generation of a too general query; this issue will be addressed in Section 5.2.

```
Algorithm 1: FindConsistentQuery (N[X])
      input  : An $\mathbb{N}[X]$ example $Ex = (I, O)$
      output : A consistent query $Q$ or an answer that none
               exists
  1 Let $(t_1, M_1), ..., (t_m, M_m)$ be the tuples and
      corresponding provenance monomials of $O$ ;
  2 $(V, E) \leftarrow BuildLabeledGraph((t_1, M_1), (t_2, M_2))$ ;
  3 foreach consistent matchings $E' \subseteq E$ s.t. $|E'| \leq k$ do
  4     if $\cup_{e \in E'} label(e) = \{1, \ldots, k\}$ then
  5         $Q \leftarrow BuildQueryFromMatch(E', Ex)$ ;
  6         foreach $1 < j < m$ do
  7             if not consistent$(Q, t_j, M_j)$ then
  8                 Go to next matching ;
  9         return $Q$ ;
 10 Output "No consistent query exists";
```

We next detail the construction, shown in Algorithm 1. We separate (line 1) monomials so that each (t_i, M_i) is a tuple along with a single monomial of its provenance expression. We then start by picking two tuples and monomials (see below a heuristic for making such a pick) and denote the tuples by t_1 and t_2 and their provenance by $M_1 = a_1 \cdot \ldots \cdot a_n$ and $M_2 = b_1 \cdot \ldots \cdot b_n$ respectively. Our goal is to find all "matches" of *parts* of the monomials so that all output attributes are covered. To this end, we define (line 2) a full bipartite graph $G = (V_1 \cup V_2, E)$ where each of V_1 and V_2 is a set of n nodes labeled by $a_1, \ldots, a_n$ and $b_1, \ldots, b_n$ respectively. We also define labels on each edge, with the label of (a_i, b_j) being the set of all attributes that are *covered* by a_i, b_j, in the following sense: an output attribute A is covered if there is an input attribute A' whose value in the tuple corresponding to a_i (b_j), matches the value of the attribute A in t_1 (respectively t_2).

We then (lines 3-4) find all matchings, *of size k or less*, that cover all output attributes; namely, that the union of sets appearing as labels of the matching's edges equals $\{1, ..., k\}$. As part of the matching, we also specify which subset of the edge label attributes is chosen to be covered by each edge (the number of such options is exponential in k). It is easy to observe that if such a cover (of any size) exists, then there exists a cover of size k or less. We further require that the matching is consistent in the sense that the permutation that it implies is consistent.

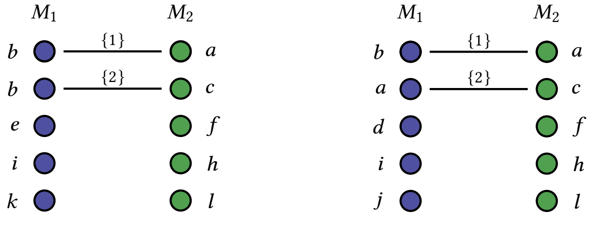
For each such matching we generate (line 5) a "most general query" Q corresponding to it, as follows. We first consider the matched pairs a_i, b_j one by one, and generate a query atom for each pair. This is done by assigning the same variable to the head attribute A covered by the edge and to the attribute covering it in the new atom A'. Note that the query generation is done here based only on k pairs of provenance atoms, rather than all n atoms, since we only examine the k edges of the matching.

To this end, we further generate for each provenance token a_i that was not included in the matching a new query atom with the relation name of the tuple corresponding to a_i, and fresh variables. Intuitively, we impose minimal additional constraints, while covering all head attributes and achieving the required query size of n.

Each such query Q is considered as a "candidate", and its consistency needs to be verified with respect to the other tuples of the example (line 7). One way of doing so is simply by evaluating the query with respect to the input, checking that the output tuples are generated, and their provenance includes those appearing in the example. As a more efficient solution, we test for consistency of Q with respect to each example tuple by first assigning the output tuple values to the head variables, as well as to the occurrences of these variables in the body of Q (by our construction, they can occur in at most k query atoms). For query atoms corresponding to provenance annotations that have not participated in the cover, we only need to check that for each relation name, there is the same number of query atoms and of provenance annotations relating to it. A subtlety here is in handling coefficients; for the part of provenance that has participated in the cover, we can count the number of assignments. This number is multiplied by the number of ways to order the other atoms (which is a simple combinatorial computation), and the result should exceed the provided coefficient.

Proposition 5.2. *Given a $\mathbb{N}[X]$-example, Algorithm 1 finds a consistent query if one exists.*

Choosing the two tuples. For correctness and worst case complexity guarantees, any choice of tuples as a starting point for the algorithm (line 1) would suffice. Naturally, this choice still affects the practical performance, and we aim at minimizing the number of candidate matchings. A simple but effective heuristic is to choose two tuples and monomials for which the number of distinct values (both in the output tuple and in input tuples participating in the derivations) is maximal.



(a) Matching A **(b) Matching B**

Figure 2: Matchings for Example 5.3

Example 5.3. Reconsider our running example depicted in Figure 1e. Assume that the monomials b^2eik and $acfhl$ were picked for graph generation. Each monomial forms a side in the bipartite graph. The algorithm now traverses all partial matchings of size ≤ 2, and checks whether aligning two tuples that are connected by an edge, one below the other, forms a vector of constants that also appears in an attribute of the two corresponding output tuples. Figure 2a depicts a matching of size 2 which consists of the edges $(b, a), (b, c)$ where the first attribute of input tuples **b** and **a** covers the first output attribute (aligning the tuple b below the tuple a creates the constants vector $\binom{2}{1}$ that appear in the first attribute of the output tuple), and the second attribute of input tuples **b** and **c** covers the second output attribute (aligning the tuple b below the tuple c creates the constants vector $\binom{1000}{300}$ that appears in the second attribute of the output tuple).

Generating a query based on this matching results in the query $Q_{general}$ from Example 4.5, since the first and second projected variables have been set to the first and third attributes of the most general atoms $B(id_1, b_1)$ and $B(id_2, b_2)$, respectively and the other atoms remain most general with no joins and projected attributes. The algorithm now verifies the consistency of $Q_{general}$ with respect to the other monomials by assigning the output tuple to the head, e.g. assigning id_1 and b_2 to 2 and 1000 (for the output tuple (2, 1000)), and returns $Q_{general}$. There are other valid partial matchings of these two tuples that will yield a somewhat different query to $Q_{general}$. If we were to choose the monomials $badij$ and $acfhl$, we would have the different matching shown in Figure 2b (where the edges (b, a) and (a, c) cover the head attributes). Note that, in general, a single edge can cover several attributes of the output.

$Q_{general}$ is a very general query, and is probably not the original one. We will adapt our solution so that it finds a more "precise" query, i.e., an inclusion-minimal query (Definition 4.4 in Section 4) in the next subsection.

Complexity. The algorithm's complexity is $O(n^{2k}m + krn^k)$: at most n^k matchings are considered; for each matching, a single query is generated, and consistency is validated in $O(n^k)$ for each of the m example tuples. Furthermore, for each of the matchings, we scan the attributes of the tuples in the matching in $O(kr)$. The exponential factor only involves k, which is much smaller than n and m in practice. Can we do even better? We can show that if $P \neq NP$, there is no algorithm running in time polynomial in k.

Proposition 5.4. *Deciding the existence of a consistent query with respect to a given $\mathbb{N}[X]$-example is NP-complete in k.*

5.2 Achieving a tight fit

To find inclusion-minimal queries, we next refine Algorithm 1 as follows. We do not halt when finding a single consistent query, but instead find all of those queries obtained for some matching. For each consistent query Q, we examine queries obtained from Q by (i) equating variables and (ii) replacing variables by constants where possible (i.e. via an exact containment mapping [1]). We refer to both as *variable equating*. To explore the possible combinations of variable equatings, we use an algorithm inspired by data mining techniques (e.g., [5]): in each iteration, the algorithm starts from a minimal set of variable equatings that was not yet determined to be (in)consistent with the example. E.g., in the first iteration it starts by equating a particular pair of variables. The algorithm then tries, one-by-one, to add variable equatings to the set, while applying transitive closure to ensure the set reflects an equivalence relation. If an additional equating leads to an inconsistent query, it is discarded. Each equatings set obtained in this manner corresponds to a homomorphism h over the variables of the query Q, and we use $h(Q)$ to denote the query resulting from replacing each variable x by $h(x)$.

Importantly, by equating variables or replacing variables by constants we only impose further constraints and obtain no new derivations. In particular, the following result holds, as a simple consequence of Theorem 7.11 in [29] (note that we must keep the number of atoms intact to be consistent with the provenance):

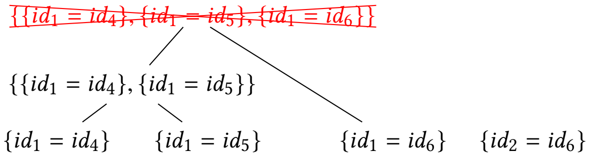
Proposition 5.5. *Let Q be a CQ over a set of variables $\mathcal{V}$. Let $h : \mathcal{V} \mapsto \mathcal{V} \cup C$ be a homomorphism. For every $\mathbb{N}[X]$-example Ex, if Q is not consistent with Ex, then neither is $h(Q)$.*

We can model the homomorphism process between queries, achieved by variable equating, as a lattice whose leaves represent a single variable equating in the query and its top element is the query with a single variable in all atoms. Every variable equating implies a move from the current lattice node to a parent of that node (see next an illustration and example). By this model, the proposition above actually determines that if a query represented by a node in the lattice is consistent, then all of the queries represented by the descendants of this node are also consistent and furthermore, all queries represented by the frontier of the lattice are consistent. We next use these observations to establish an algorithm for finding an inclusion-minimal query.

Consequently, the algorithm finds a *maximal set of variable equatings* that is consistent with the query, by attempting to add at most $O(r^2)$ different equatings, since there are $\binom{r}{2}$ pairs of variables (r is the sum of arities of the atoms in the body of Q, see Table 1). We record every query that was found to be (in)consistent – in particular, every subset of a consistent set of equatings is also consistent – and use it in the following iterations (which again find maximal sets of equatings).

Checking for consistency. This check may be done very efficiently for query atoms that contribute to the head, since we only need to check that equality holds for the provenance annotations assigned to them. For other atoms we no longer have their consistency as a given and in the worst case we would need to examine all matchings of these query atoms to provenance annotations.

Example 5.6. Reconsider our running example query $Q_{general}$ in Example 4.5. A part of the lattice is depicted in Figure 3. The algorithm starts by considering individually each pair of variables as well as pairs of variables and constants co-appearing in the two output tuples or in the tuples used in their provenance. In our example, when considering the lattice element $\{id_1 = id_4\}$, the



~~{{id1 = id4}, {id1 = id5}, {id1 = id6}}~~
{{id1 = id4}, {id1 = id5}}
{id1 = id4}
{id1 = id5}
{id1 = id6}
{id2 = id6}

Figure 3: Part of the lattice in Example 5.6

algorithm will find that the query $Q_{id_1=id_4}$ (i.e. $Q_{general}$ after equating id_1 and id_4), is still consistent. Next, the algorithm will find that equating id_1, id_5 in $Q_{id_1=id_5}$ also yields a consistent query so it will proceed with $Q_{id_1=id_4,id_1=id_5}$. However, if we try to add the equality $id_1 = id_6$, the consistency check will discover that $Q_{id_1=id_4,id_1=id_5,id_1=id_6}$ is not consistent anymore, so we will not continue on this path of the lattice (marked with a red "x" in Figure 3). Of course, multiple steps may yield the same equivalence classes in which case we perform the computation only once. The resulting query is Q_{real} shown in Example 1.2. Any further step with respect to Q_{real} leads to an inconsistent query, and so it is returned as output.

Proposition 5.7. *Given a consistent query w.r.t an $\mathbb{N}[X]$-example, the procedure finds an inclusion-minimal query.*

For each consistent query found by Algorithm 1, there may be multiple inclusion-minimal queries obtained in such a manner (though the number of such queries observed in practice was not very large, see Section 7). If we wish to provide a single query as output, when multiple inclusion-minimal queries are obtained, a natural heuristic that we employ is to prefer a query with the least number of unique variables (this was implemented in our experimental study).

Adapting the Solution for $\mathbb{B}[X]$. In the $\mathbb{B}[X]$ semiring, exponents are kept but coefficients are not, so we can adapt the algorithm of $\mathbb{N}[X]$ (Algorithm 1), omitting the treatment of coefficients. In $\mathbb{N}[X]$, for the part of the provenance that has participated in the cover, we count the number of assignments and multiply by the number of ways to order the other atoms (which is a simple combinatorial computation), and verify that the result exceeds the provided coefficient. In $\mathbb{B}[X]$, we remove this step of the algorithm.

6 LEARNING FROM WHY, TRIO, AND POSBOOL EXAMPLES

We next study the problem of learning queries from $Why(X)$-examples. This semiring is less detailed than $\mathbb{N}[X]$ and thus often easier to store and present, but is in turn more challenging for query inference. We will adapt the solution to the $Trio(X)$ and $PosBool(X)$ semirings.

A natural approach is to reduce the problem of learning from a $Why(X)$-example to that of learning from an $\mathbb{N}[X]$-example (note that a $Why(X)$-example without self-joins is equivalent to an $\mathbb{N}[X]$-example). Recall that the differences are the lack of coefficients and the lack of exponents. The former is trivial to address (see solution for $\mathbb{B}[X]$ in the previous section), but the latter means that we do not know the number of query atoms. In particular, for $Why(X)$-examples we have:

Proposition 6.1. *There exists a $Why(X)$-example with an infinite number of non-equivalent consistent queries.*

A first plausible idea is to consider the $Why(X)$-example as an $\mathbb{N}[X]$-example, i.e., assume the number of query atoms is equal to the number of tuples in the largest monomial of the example. Surprisingly, we cannot be sure that this suffices:

Proposition 6.2. *There exists a $Why(X)$ example for which there is no consistent CQ with n atoms (recall that n is the length of the largest monomial, see Table 1), but there exists a consistent CQ with more atoms.*

prov.	A	B	C
a	1	2	3
b	3	4	5
c	6	7	8
d	7	6	8

(a) Relation R

A	B	C	prov.
1	1	5	$a \cdot b$
6	7	8	$c \cdot d$

(b) $Why(X)$ Example

Figure 4: Source and $Why(X)$ Example for Prop. 6.2

Proof. Let *Ex* denote the example depicted in Figure 4. A consistent query with two atoms can impose two possible orderings on the tuples in each monomial. We show that both orderings do not form a consistent query. Consider the first ordering of the tuples. A consistent query needs to be satisfied by the assignments:

$$Q(1,1,5) : -R(1,2,3), R(3,4,5)$$
$$Q(6,7,8) : -R(6,7,8), R(7,6,8)$$

But no query can be satisfied by these two assignments because the first assignment requires that the second variable in the head will be bound by the first variable in the first atom in the body. But, the second assignment requires that the second variable in the head will be different from the variable in the mentioned position. Thus, there is no query that is satisfied by both assignments.

Consider the second ordering. A consistent query needs to be satisfied by the assignments:

$$Q(1,1,5) : -R(3,4,5), R(1,2,3)$$
$$Q(6,7,8) : -R(6,7,8), R(7,6,8)$$

Again, observe that in the first assignment, the first variable in the head must be bound by the first variable in the second atom in the body. But, in the second assignment, the first variable in the head is different from the variable in the mentioned position. Thus, again, there is no query that is satisfied by both assignments, establishing that there is no consistent query of length 2 w.r.t *Ex*.

Now, consider the monomials are $a \cdot a \cdot b$ and $c \cdot d \cdot d$. A consistent query w.r.t these monomials needs to satisfy the assignments:

$$Q(1,1,5) : -R(1,2,3), R(1,2,3), R(3,4,5)$$
$$Q(6,7,8) : -R(6,7,8), R(7,6,8), R(7,6,8)$$

Hence, the following query is consistent:

$$Q(x,y,z) : -R(x,w,u), R(y,v,u), R(k,m,z)$$

□

However, finding one consistent query is not difficult, using a method that takes all possible tuple alignments into account:

Proposition 6.3. *If there exists a consistent query w.r.t a given $Why(X)$-example, there is a consistent query of length n^m.*

Proof. Denote the example as *Ex* and the consistent query as Q'. Consider the query Q which has at most n^m atoms and is built in the following manner: have each tuple in *Ex* participate in all possible permutations of tuples in the rows above and below it with the same relation, imposing an order on the tuples in a monomial and then treat the resulting monomials as an $\mathbb{N}[X]$-example, and create a query by replacing each unique constant column with a variable (see previous example). We first show that Q is safe (note that Q' is consistent, so it is in particular safe). Suppose the atoms that have attributes projected to the head in Q' are $a'_1, \ldots, a'_i$. Take the tuples to which they are mapped to in each row j, $t^j_1, \ldots, t^j_i$, then Q also contains atoms $a_1, \ldots, a_i$ mapped to $t^j_1, \ldots, t^j_i$, respectively in each row j (this is because in part of the ordering imposed on the monomials, $t^1_1, \ldots, t^m_1$ appear one below another and the same goes for $t^1_x, \ldots, t^m_x$ for every $2 \leq x \leq i$). Therefore, the same attributes of $a'_1, \ldots, a'_i$ exist in $a_1, \ldots, a_i$ and can also be projected to the head in Q. Furthermore, Q is consistent by the way it was built. Every atom was created for a specific combination of tuples, so every atom of Q can be mapped to a specific tuple appearing in every row. In addition, for every row j, the atoms of Q cover all tuples in this row since an atom was created for each permutation of tuples, and in particular, there is at least one atom that was created to match each tuple in row j. □

Based on this result, we can find a consistent query in a straightforward way. However, a query that has n^m atoms is very long and probably overfits the example. In general, in the $\mathbb{N}[X]$ case, the number of query atoms is set by the provenance and the only degree of freedom is variable equatings. On the other hand, for the $Why(X)$ case, the number of query atoms is also flexible. This calls for a different criterion of "tight fit" for $Why(X)$ provenance, which is minimizing the number of atoms in a consistent query. In general, we can show the following result regarding this criterion:

Proposition 6.4. *Given a $Why(X)$-example, deciding the existence of a consistent query with $\leq n$ atoms is NP-complete in k.*

We can however show a "small world" property, that will guide our solution.

Proposition 6.5. *For any $Why(X)$-example, if there exists a consistent query then there exists a consistent query with $k+d\cdot(n-1)$ atoms or less, where d is the number of distinct relation names occurring in the provenance monomials (see Table 1).*

Intuitively, there are at most k atoms contributing to the head. The worst case is when only one "duplicated" annotation contributes to the head, and then in each provenance monomial there are at most $n-1$ remaining annotations. If the query includes a single relation name ($d = 1$), then a query with at most $n-1$ more atoms would be consistent. Otherwise, as many atoms may be needed for each relation name.

Together with our algorithm for $\mathbb{N}[X]$, Proposition 6.5 dictates a simple algorithm that exhaustively goes through all $\mathbb{N}[X]$ expressions that are compatible with the $Why(X)$ expressions appearing in the example, and whose sizes are up to $k + d\cdot(n-1)$. This, however, would be highly inefficient.

Instead of the inefficient exhaustive algorithm, we next present a much more efficient algorithm for finding a consistent query of minimal length. The algorithm will operate greedily by duplicating atoms in the query body when a self-join is implied by one of the provenance monomials.

The pseudo-code for an efficient algorithm for finding CQs consistent with a given $Why(X)$-example is given in Algorithm 2. The idea is to traverse the examples one by one, trying to "expand" (by adding atoms) candidate queries computed thus far to be consistent with the current example. We start (line 1), as in the $\mathbb{N}[X]$ case, by "splitting" monomials if needed so that each tuple is associated with a single monomial. We maintain a map $\boldsymbol{Q}$ whose values are candidate queries, and keys are the parts of the query that contribute to the head, in a canonical form (e.g. atoms are lexicographically ordered). This will allow us to maintain only a single representative for each such "contributing part", where the representative is consistent with all the examples observed so far. For the first step (line 2) we initialize $\boldsymbol{Q}$ so that it includes only (t_1, M_1) (just for the first iteration, we store an example rather than a query). We then traverse the remaining examples one by one (line 3). In each iteration i, we consider all queries in $\boldsymbol{Q}$; for each such query Q, we build a bipartite graph (line 6) whose one side is the annotations appearing in M_i, and the other side is the *atoms of* Q. The label on each edge is the set of head attributes covered jointly by the two sides: in the first iteration this is exactly as in the $\mathbb{N}[X]$ algorithm, and in subsequent iterations we keep track of covered attributes by each query atom. Then, instead of looking for *matchings* in the bipartite graph, we find (line 7) all *sub-graphs* whose edges cover all head attributes (again specifying a choice of attributes subset for each edge). Intuitively, having e edges adjacent to the same provenance annotation corresponds to the same annotation appearing with exponent e, so we "duplicate" it e times (lines 8-10). On the other hand, if multiple edges are adjacent to a single query atom, we also need to "split" (Lines 11-13) each such atom, i.e. to replace it by multiple atoms (as many as the number of edges connected to it). Intuitively each copy will contribute to the generation of a single annotation in the monomial. Now (line 14), we construct a query Q' based on the matching and the previous query "version" Q: the head is built as in Algorithm 1, and if there were x atoms not contributing to the head with relation name R in Q, then the number of such atoms in Q' is the maximum of x and the number of annotations in M_i of tuples in R that were not matched. Now, we "combine" Q' with Q'' which is the currently stored version of a query with the same contributing atoms (lines 15- 16). Combining means setting number of atoms for each relation name not contributing to the head to be the maximum of this number in Q' and Q''.

Algorithm 2 stores queries according to the atoms that have the same variables as the ones in the head. Each matching that does not stem from the existing matchings in $\boldsymbol{Q}$ (i.e., splitting some of the atoms in an existing cover) will not result in a consistent query since it will not be consistent with the previous rows. The number of combinations of size k can there be out of n different relations is n^k. $\boldsymbol{Q}$ does not store sets of contributing atoms that are subsets of other existing keys.

Complexity. The number of keys in $\boldsymbol{Q}$ is exponential only in k; the loops thus iterate at most $m \cdot n^k \cdot n^k \cdot (n + n^2)$ times, so the overall complexity is $O(n^{O(k)} \cdot mkr)$.

Achieving a tight fit. Algorithm 2 produces a set of candidate queries, which may not be syntactically minimal. To discard atoms that are "clearly" redundant, we first try removing atoms not contributing to the head, and test for consistency. We then perform the process of variable equating as in Section 5.2.

Example 6.6. Reconsider our running example, but now with the why-provenance given in Figure 1e. If we start from the first monomials of the tuples (2, 1000) and (1, 300) then we generate a bipartite graph with $V_1 = \{b, e, i, k\}$ and $V_2 = \{a, c, f, h, l\}$, and obtain the cover E' (seen in Figure 5a) where the edge (b, a)

Algorithm 2: FindConsistentQuery (Why(X))

```
input : A $Why(X)$ example Ex
output: A set of consistent queries (possibly empty, if none exists)
Let $(t_1, M_1), ..., (t_m, M_m)$ be the tuples and corresponding provenance monomials of $Ex$ ;
$\mathcal{Q} \leftarrow \{NULL : (t_1, M_1)\}$ ;
foreach $2 \le i \le m$ do
    foreach $Q \in$ values($\mathcal{Q}$) do
        $\mathcal{Q} \leftarrow \mathcal{Q} - \{Q\}$ ;
        $(V_1 \cup V_2, E) \leftarrow BuildGraph(Q, (t_i, M_i))$ ;
        foreach sub-graph $E' \subseteq E$ s.t. $|E'| \le k$ and $\cup_{e \in E'}$ label$(e) = \{1, \dots, k\}$ do
            foreach provenance annotation $a$ in $M_i$ do
                if $a$ is an endpoint of more than one edge in $E'$ then
                    $E' \leftarrow split(E', a)$ ;
            foreach atom $C \in Q$ do
                if $C$ is an endpoint of more than one edge in $E'$ then
                    $E' \leftarrow split(E', C)$ ;
            $Q' \leftarrow BuildQuery(E', Q)$;
            $Q'' \leftarrow \mathcal{Q}.get(contribs(Q'))$ ;
            $\mathcal{Q}.put(contribs(Q'), combine(Q', Q''))$ ;
return $values(\mathcal{Q})$ ;
```

covers the first head attribute and (b, c) covers the second. The fact that the tuple **b** is connected to two edges will lead to the split of this tuple to the atoms $B(id_1, b_1)$ and $B(id_2, b_2)$. When we continue with E', no duplication is performed, and we get a query Q with the two atoms $B(id_1, b_1)$, $B(id_2, b_2)$ contributing to the head, and three most general atoms. Then, we match Q to the monomial $badij$, resulting in a sub-graph matching both $B(id_1, b_1)$ and $B(id_2, b_2)$ to **b** and **a**, respectively. After variables equating (see Subsection 5.2), we obtain the query Q_{real} shown in Example 1.2 (other covers are possible, but they will also result in Q_{real} after variable equating). If instead we start with the monomials $badij$ and $acfhl$, the partial matching chosen will be the edge (b, a) which covers the first head attribute and the edge (a, c) which covers the second and forming the atoms $B(id_1, b_1)$, $B(id_2, b_2)$ again. Continuing to the monomial $beik$, we would split the tuple b into two tuples since the matching will include the edges $(B(id_1, b_1), b)$ that covers the first head attribute and $(B(id_2, b_2), b)$ which covers the second.

Proposition 6.7. *Given a Why(X)-example, Algorithm 2 finds a consistent query if one exists.*

Adapting the Solution for $Trio(X)$ and $PosBool(X)$. In the $Trio(X)$ semiring coefficients are kept but exponents are not. To handle this case we employ Algorithm 2, with a simple modification: upon checking consistency of a candidate query with a tuple, then we further check that there are as many derivations that use the tuples of the monomial as dictated by the coefficient (as done in Section 5). In the semiring of positive boolean expressions ($PosBool(X)$) + and · are interpreted as disjunction and conjunction, respectively. If the expressions are given in DNF, Algorithm 2 may be used here as well. The only difference is the possible absorption of monomials ($a + a \cdot b \equiv a$), but we already assume that only a subset of the monomials are given. If the expressions are given in an arbitrary form there is an additional (exponential time) pre-processing step of transforming them into DNF.

7 IMPLEMENTATION AND EXPERIMENTS

Our experimental study is composed of experiments based on the actual output and provenance of the benchmark queries in [40, 43] measuring both accuracy and scalability. All experiments were performed on Windows 8, 64-bit, with 8GB of RAM and Intel Core Duo i7 2.59 GHz processor. We have implemented our algorithms in JAVA with MS SQL server as the underlying database management system.

As we have shown in Sections 5 and 6, the algorithms for the $\mathbb{N}[X]$ and $Why(X)$ semirings also capture the other semirings we have studied, with slight modifications. Namely, the algorithms for $\mathbb{N}[X]$ also apply for the $\mathbb{B}[X]$ semiring, ignoring the treatment of coefficients, and the algorithms presented for $Why(X)$ also capture the $PosBool(X)$ semiring (since there is only an absorption of monomials), and the $Trio(X)$ semiring with the handling of coefficients as done for $\mathbb{N}[X]$ in Algorithm 1. Hence, our experiments focus on the $\mathbb{N}[X]$ and $Why(X)$ models. In particular, Algorithm 1 will behave in the same manner for $\mathbb{B}[X]$-examples as for $\mathbb{N}[X]$-examples, and Algorithm 2 will behave in the same manner for $PosBool(X) \backslash Trio(X)$-examples as for $Why(X)$-examples.

To examine our approach, we have used multiple queries with varying complexity. Namely, Q1–Q6 from [43] as well as (modified, to drop aggregation and arithmetics) the TPC-H queries TQ2–TQ5, TQ8 and TQ10. The queries have 2–8 atoms, 18–60 variables, and multiple instances of self-joins (we show Q6 for illustration in Figure 6; the reader is referred to [40, 43] for the other queries).

7.1 Accuracy

We have used the system to "reverse engineer" the queries mentioned above. This part of the experiments had two objectives: (1) understanding the number of examples needed to infer the exact query (2) measure the precision and recall of the query inferred by the system with comparison to the original. We have evaluated each query using a provenance-aware query engine, and have then sampled random fragments (of a given size that we vary) of the output database and its provenance (we have tried both $\mathbb{N}[X]$ and Why(X)), feeding it to our system. In each experiment we have gradually added random examples until our algorithm has retrieved the original query. This was repeated 3 times. We report (1) the *worst-case* (as observed in the 3 executions) number of examples needed until the original query is inferred, and (2) for fewer examples (i.e. before convergence to the actual query),

Table 3: Results for the TPC-H query set and the queries from [43] with $\mathbb{N}[X]$ provenance

Query	Worst-case number of examples to learn the original query	Difference between original and inferred queries for fewer examples
Q1 (TQ3)	14	The inferred Query includes an extra join on a “status" attribute of two relations. Only 2–3 values are possible for this attribute, and equality often holds.
Q2	2	
Q3	5	For 2 examples, the inferred query contained an extra constant. For 3 and 4 examples, it included an extra join.
Q4	19	For 2 examples, the inferred query included an extra constant. For 3–18, it included an extra join on a highly skewed “status" attribute.
Q5	11	The inferred query included an extra join on a “name" attribute.
Q6	3	The inferred query included an extra constant.
TQ4	234	The inferred query included an extra join on “orderstatus" and “linestatus" attributes of two relations (they have two possible values). One of the original join conditions has led to the occurrence of the same value in these attributes in the vast majority of joined tuples.
TQ10	4	The inferred query contained an extra constant.
TQ2	3	The inferred query contained an extra constant.
TQ5	3	The inferred query contained an extra constant.
TQ8	18	For 2 examples, the inferred query contained an extra constant. For 4-17 exam– –ples, the query had an extra join between a “status" attribute of two relations.

$ans(a, b) : -supplier(c, a, add, k, p, d, c_1),$
$partsupp(h, c, v, j, c_2), nation(w, na_2, r, c_8),$
$part(h, i, z, q, t, s, e, rp_2, c_3), region(r, u, c_7),$
$partsupp(h, o, x, n, c_4), nation(k, na1, r, c_6),$
$supplier(o, b, y, w, p_2, d_2, c_5)$

Figure 6: $Q6$

the differences between the inferred queries and the actual one in the worst-case run of the experiment.

The results are reported in Table 3. For some queries the convergence is immediate, and achieved when viewing only 2–5 examples. For other queries, more examples are needed, but with one exception (TQ4), we converge to the original query after viewing at most 19 tuples for the different queries. For TQ4 only a very small fraction of the output tuples reveal that an extra join should not have appeared, and so we need one of these tuples to appear in the sample. Furthermore, even for smaller sets of examples, the inferred query was not “far" from the actual query. The most commonly observed difference involved extra constants occurring in the inferred query (this typically happened for a small number of examples, where a constant co-occurred by chance). Another type of error was an extra join in the inferred query; this happened often when two relations involved in the query had a binary or trinary attribute (such as the “status" attribute occurring in multiple variants in TPC-H relations), which is furthermore skewed (for instance, when other join conditions almost always imply equality of the relevant attributes). We have also measured the precision and recall of the output of the inferred query w.r.t. that of the original one. Obviously, when the original query was obtained, the precision and recall were 100%. Even when presented with fewer examples, in almost all cases already with 5 examples, the precision was 100% and the recall was above 90%. The only exception was Q5 with 75% recall for 5 examples.

The results for $Why(X)$ are shown in Table 4. For queries with no self-join, the observed results were naturally the same as in the $\mathbb{N}[X]$ case; we thus report the results only for queries with self-joins (some queries included multiple self joins). When presented with a very small number of examples, our algorithm was not always able to detect the self-joins (see comments in Table 7); but the overall number of examples required for convergence has only marginally increased with respect to the $\mathbb{N}[X]$ case.

7.2 Execution Times

As we have established in the accuracy experiments, a small number of examples will usually suffice to infer the original query. To also account for the execution time of our algorithms, we have increased the number of examples up to 500, which is about twice as many examples needed to infer each of the queries. The results for $\mathbb{N}[X]$ provenance and Q1–Q6 exhibit good scalability: the computation time for 500 examples was 0.4 seconds for Q1 (TQ3), 0.1 seconds for Q2, 0.7 seconds for Q3, 1 second for Q4 and 0.4 and 1.1 seconds for Q5 and Q6 respectively. The performance for the TPC-H queries was similarly scalable: for 500 examples, the computation time of TQ2 and TQ10 (which are the queries with the maximum number of head attributes: 8 and 7, resp.) was 0.2 and 0.4 seconds respectively. The runtimes for TQ4 and TQ8 were 0.1, 0.9 seconds resp. The number of example for TQ5 was limited due to the query output size. For 15 examples, the runtime for this query was 0.2 seconds. We have repeated the experiment using $Why(X)$ provenance. The computation time was generally fast, and only slightly slower than the $\mathbb{N}[X]$ case, with a max runtime of 1.3 seconds for Q4 and TQ8. This is consistent with our complexity analysis.

Effect of Tuples Choice. Recall that Algorithm 1 starts by finding consistent queries w.r.t two example tuples and explanations. In Section 5, we have described a heuristic that chooses the two tuples with the least number of shared values. We have measured the effect of this optimization on Q6 and found that using the optimization leads to a single matching in the graph, as oppose to a random choice of tuples that has led to 4 matchings. Making such a random choice, instead of using our optimization led to a runtime which was more than 1.3 times slower on average.

8 DISCUSSION AND CONCLUSIONS

We have formalized and studied the problem of “query-by-provenance", where queries are inferred from example output tuples and their

Table 4: Results for the TPC-H query set and the queries from [43] containing self-joins with $Why(X)$ provenance

Query	Worst-case number of examples to learn the original query	Difference between original and inferred queries for fewer examples
Q2	2	
Q3	5	The inferred query for 2–4 examples did not include self-joins.
Q4	19	For 2–3 examples, the inferred query did not include self-joins. For 4–18 examples, the query had an extra join on a "status" attribute.
Q5	13	The inferred query for 2–12 examples did not include self-joins.
Q6	3	The inferred query included an extra constant.
TQ8	18	For 2–3 examples, the inferred query contained an extra constant. For 4-17 the query had an extra join between a "status" attribute of two relations.

provenance. We have theoretically analyzed and experimentally demonstrated the effectiveness of the approach in inferring highly complex CQs, including ones with multiple self-joins, based on a small number of output and provenance examples and their provenance. Note that for UCQs, a stronger definition is needed.

A notable provenance model that we have not discussed so far is that of lineage [16], which entails a set representation of the provenance, i.e., the contributing input tuples' annotations for a given output tuple are represented as a set. The semiring model can support lineage, and the interpretation of Definition 4.2 in this case is simply that each output example is associated with a subset of its contributing tuples. In general, this means that without looking at the full input database or at least its schema, we gain very little information (e.g. we are not guaranteed that the given annotations come from a relation that is projected to the head). In particular it is straightforward to show a reduction from the classic reverse engineering query problem, which is intractable by [42].

A Six-dimensional Analysis of In-memory Aggregation

Puya Memarzia [1], Suprio Ray [2], and Virendra C. Bhavsar [3]

Faculty of Computer Science, University of New Brunswick, Fredericton, Canada {[1] pmemarzi, [2] sray, [3] bhavsar}@unb.ca

ABSTRACT

Aggregation is widely used to extract useful information from large volumes of data. In-memory databases are rising in popularity due to the demands of big data analytics applications. Many different algorithms and data structures can be used for in-memory aggregation, but their relative performance characteristics are inadequately studied. Prior studies in aggregation primarily focused on small selections of query workloads and data structures, or I/O performance. We present a comprehensive analysis of in-memory aggregation that covers baseline and state-of-the-art algorithms and data structures. We describe 6 analysis dimensions which represent the independent variables in our experiments: (1) algorithm and data structure, (2) query and aggregate function, (3) key distribution and skew, (4) group by cardinality, (5) dataset size and memory usage, and (6) concurrency and multithread scaling. We conduct extensive evaluations with the goal of identifying the trade-offs of each algorithm and offering insights to practitioners. We also provide a glimpse on how the CPU cache and TLB are affected by these dimensions. We show that some persisting notions about aggregation, such as the relative performance of hashing and sorting, do not necessarily apply to modern platforms and state-of-the-art implementations. Our results show that the ideal approach in a given situation depends on the input and the workload. For instance, sorting algorithms are faster in holistic aggregate queries, whereas hash tables perform better in distributive queries.

1 INTRODUCTION

Despite recent advances in processing power, storage capacity, and transfer speeds, our need for greater query efficiency continues to grow at a rapid pace. Aggregation is an essential and ubiquitous data operation used in many database and query processing systems. It is considered to be the most expensive operation after joins, and is an essential component in analytical queries. All 21 queries in the popular TPC-H benchmark include aggregate functions [12]. A common aggregation workload involves grouping the dataset tuples by their key and then applying an aggregate function to each group.

Many prior studies on in-memory aggregation limited the scope of their research to a narrow set of algorithms, datasets, and queries. For example, many studies do not evaluate holistic aggregate functions [11, 32, 49]. The datasets used in most studies are based on a methodology proposed by Grey et al. [18]. These datasets do not evaluate the impact of data shuffling, or enforce deterministic group-by cardinality where possible. Some studies only evaluate a proposed algorithm against a naive implementation, rather than comparing it with other state-of-the-art implementations [20, 45]. Other studies have focused on secondary aspects, such as optimizing query planning for aggregations [48], distributed and parallel algorithms [11, 20, 40, 49, 50], and iceberg queries [45]. Additionally, some data structures have been proposed for in-memory query processing or as drop-in replacements for other popular data structures, but have not been extensively studied in the context of aggregation workloads [4, 26, 29]. Real-world applications cover a much more diverse set of scenarios, and understanding them requires a broader and more fundamental view. Due to these limitations, it is difficult to gauge the usefulness of these studies in other scenarios.

Figure 1: An overview of the analysis dimensions

Different combinations of methodologies and evaluation parameters can produce very different conclusions. Applying the results from an isolated study to a general case may result in poor performance. For example, methods and optimizations for distributive aggregation are not necessarily ideal for holistic workloads. Our goal is to conduct a comprehensive study on the fundamental algorithms and data structures used for aggregation. This paper examines six fundamental dimensions that affect main memory aggregation. These dimensions represent well-known parameters which can be used as independent variables in our experiments. Figure 1 depicts an overview of the analysis dimensions. Figure 12 depicts a decision flow chart that summarizes our observations.

Dimension 1: Algorithm and Data Structure. In recent years, there have been many studies on main-memory data structures, such as tree-based indexes and hash tables. Many of these data structures can be used for in-memory aggregation. Aggregation algorithms can be categorized by the data structure used to store the data. Based on this we divide the algorithms into three main categories: sort-based, hash-based, and tree-based algorithms. We propose a framework that aims to cover many of the scenarios that could be encountered in real workloads. Over the course of this paper, we evaluate and discuss implementations from all three categories.

Dimension 2: Query and Aggregate Function. An aggregation query is primarily defined by its aggregate function. These functions are typically organized into three categories: distributive, algebraic, and holistic [17]. Distributive aggregate functions, such as *Count*, can be independently computed in a distributed manner. Algebraic aggregates are constructed by combining several distributive aggregates. For example, the *Average* function is a combination of *Sum* and *Count*. Holistic aggregate functions, such as *Median*, cannot be distributed in the same way as the two

Series ISSN: 2367-2005

10.5441/002/edbt.2019.26

previous categories because they are sensitive to the sort order of the data. Aggregation queries are also categorized based on whether their output is a single value (scalar), or a series of rows (vector). We evaluate a set of queries that cover both distributive and holistic, and vector and scalar categories.

Dimension 3: Key Distribution and Skew. The skew and distribution of the data can have a major impact on algorithm performance. Popular relational database benchmarks, such as TPC-H [12], generally focus on querying data that is non-skewed and uniformly distributed. However, it has been shown that these cases are not necessarily representative of real-world applications [13, 22]. Recently, researchers have proposed a skewed variant of the TPC-H benchmark [10]. The sizes of cities and the length and frequency of words can be modeled with Zipfian distributions, and measurement errors often follow Gaussian distributions [18]. Furthermore, skewed keys can be encountered as a result of joins [6] and composite queries. Our datasets are based on the specifications defined by [18] with a few additions. We cover the impact of both skew and ordering.

Dimension 4: Group-by Cardinality. Group-by cardinality is related to skew in the sense that both dimensions affect the number of duplicate keys. However, the group-by cardinality of a dataset directly determines the size (number of groups) of the aggregation result set. Prior studies have indicated that group-by cardinality has a major impact on the relative performance of different aggregation methods [2, 20, 24, 32]. These studies claim that hashing performs faster than sorting when the group-by cardinality is low relative to the dataset size, and that this performance advantage is reversed when the cardinality is high. We find that the accuracy of this claim depends on the implementation. We evaluate the performance impact of group-by cardinality, as well as its relationship with CPU cache and TLB misses.

Dimension 5: Dataset Size and Memory Usage. Recent advances in computer hardware have encouraged the use of main-memory database systems. These systems often focus on analytical queries, where aggregation is a key operation. Although memory has become cheaper and denser, this is offset by the increasing demands of the industry. Our goal is to shed some light on the trade-off between memory efficiency and performance.

Dimension 6: Concurrency and Multithreaded Scaling. Nowadays, query processing systems are expected to support intra-query parallelism in addition to interquery parallelism. Concurrency imposes additional challenges, such as reducing synchronization overhead, eliminating race conditions, and multithreaded scaling. We explore the viability and scalability of several multi-threaded implementations.

The key contributions of this paper are:

- Evaluation of aggregation queries using sort-based, hash-based, and tree-based implementations
- Methodology to generate synthetic datasets that expands on prior work
- Extensive experiments that include comparison of distributive and holistic aggregate functions, vector and scalar aggregates, range searches, evaluation of memory efficiency and TLB and cache misses, and multithreaded scaling
- Insights on performance trends and suggestions for practitioners

The remainder of this paper is organized as follows: We describe the queries in Section 2. We elaborate on the algorithms and data structures in Section 3. In Section 4 we specify the characteristics of our synthetic datasets. We present and discuss our experimental setup and evaluation results in Section 5, and summarize our findings in Section 6. In Section 7 we categorize and explore the related work. Finally, we conclude the paper in Section 8.

2 QUERIES

In this section, we describe the queries used for our experiments. In Table 1 we describe each query along with a simple example. Our goal is to evaluate and compare different aggregation variants. There are three main categories of aggregate functions: distributive, algebraic, and holistic. Distributive functions, such as *Count* and *Sum*, can be processed in a distributed manner. This means that the input can be split and processed in multiple partitions, and then the intermediate results can be combined to produce the final result. Algebraic functions consist of two or more Distributive functions. For instance, *Average* can be broken down into two distributive functions: *Count* and *Sum*. Holistic aggregate functions cannot be decomposed into multiple distributive functions, and require all of the input data to be processed together. For example, if an input is split into two partitions and the *Mode* is calculated for each partition, it is impossible to accurately determine the Mode for the total dataset. Other examples of Holistic functions include *Rank*, *Median*, and *Quantile*.

The output of an aggregation can be either in *Vector* or *Scalar* format. In Vector aggregates, a row is returned in the output for each unique key in the designated column(s). These columns are commonly specified using the *group-by* or *having* keywords. The output value is returned as a new column next to the group-by column. Scalar aggregates process all the input rows and produce a single scalar value as the result.

Sometimes it is desirable to filter the aggregation output based on user defined thresholds or ranges. We study an example of a range search combined with a vector aggregate function in *Q7*. In a real-world environment, it may be possible to push the range conditions to an earlier point in the query plan, but if several different range scans are desired, early filtering may not be possible. The main purpose of this query is to evaluate each data structure's efficiency at performing a range search in addition to the aggregation.

3 DATA STRUCTURES AND ALGORITHMS

In this section, we introduce the data structures and algorithms that we use to implement aggregate queries. We divide these algorithms into three categories: sort-based, hash-based, and tree-based. In order to facilitate reproducibility, we have selected open-source data structures and sort algorithms where possible. We also consider several state-of-the-art data structures, such as ART[26], HOT[8], and Libcuckoo[29]. Since the performance of algorithms can shift with hardware architectures, we also consider some of the more fundamental algorithms and data structures, such as a B+Tree [7]. Throughout this section we will state theoretical time complexities using n as the number of elements and k as the number of bits per key.

The implementation of an aggregate operator can be broken down into two main phases: the *build* phase and the *iterate* phase. Consider this example using a hash table and a vector aggregate function (refer to Q1 in Table 1). During the build phase, each key (created from the group-by attribute or attributes) is looked up in the hash table. If it does not exist, it is inserted with a starting value of one. Otherwise, the value for the existing key is incremented. Once the build phase is complete the iterate phase reads the key-value pairs from the hash table and writes

Table 1: Aggregation Queries

Query	SQL Representation (example)	Aggregate Function	Category	Output Format

Q1	`SELECT product_id, COUNT(*)`
	`FROM sales GROUP BY product_id`
		Count	Distributive	Vector

Q2	`SELECT student_id, AVG(grade)`
	`FROM grades GROUP BY student_id`
		Average	Algebraic	Vector

Q3	`SELECT product_id, MEDIAN(amount)`
	`FROM products GROUP BY product_id`
		Median	Holistic	Vector

Q4	`SELECT COUNT(sale_id)`
	`FROM sales`
		Count	Distributive	Scalar

Q5	`SELECT AVG(grade)`
	`FROM grades`
		Average	Algebraic	Scalar

Q6	`SELECT MEDIAN(part_id)`
	`FROM parts`
		Median	Holistic	Scalar

Q7	`SELECT product_id, COUNT(*)`
	`FROM sales WHERE product_id`
	`BETWEEN 500 AND 1000`
	`GROUP BY product_id`
		Count with Range Condition	Distributive	Vector

the resulting items to the output. A similar procedure is used for tree data structures. The calculation of the aggregate value during the build phase (early aggregation) is only possible when the aggregate function is distributive or algebraic. As a result, holistic aggregate values cannot be calculated until all records have been inserted. Sort-based approaches "build" a sorted array using the group-by attributes. As a result, all the values for each group are placed in consecutive locations. The aggregate values are calculated by iterating through the groups.

3.1 Sort-based Aggregation Algorithms

Sorting algorithms are a crucial building block in any query processing system. Many popular database systems, such as Microsoft SQL and Oracle, employ both sort-based and hash-based algorithms. We examine several algorithms designed for sorting arrays of fixed length integers, although some of the approaches could be adapted to variable length strings.

3.1.1 ***Quicksort.*** Quicksort is a sorting method based on the concept of divide and conquer that was invented by Tony Hoare [19] and remains very popular to this day. The average time complexity of Quicksort is $O(n\log(n))$. The worst case time complexity is considerably worse at $O(n^2)$, but this is rare, and is mitigated on modern implementations [21, 35] .

3.1.2 ***Introsort.*** Introspective sort (Introsort) is a hybrid sorting algorithm that was proposed by David Musser [33]. Introsort can be regarded as an algorithm that builds on Quicksort and improves its worst case performance. This sorting algorithm starts by sorting the dataset with Quicksort. When the recursion depth passes a certain threshold, the algorithm switches to Heapsort. This threshold is defined as the logarithm of the number of elements being sorted. This algorithm guarantees a worst case time complexity of $O(n\log(n))$.

The GCC variant of Introsort [21] differs from the original algorithm in two ways. Firstly, the recursion depth is set to $2 * \log(n)$. Secondly, the algorithm switches to Insertion sort, which is fast on small data chunk, but has a time complexity of $O(n^2)$.

3.1.3 ***Radix Sort (MSB and LSB).*** Radix sorting works by sorting the data one bit (binary digit) at a time. There are two variants of Radix Sort, based on the order in which the bits are processed: Most Significant Bit (MSB) Radix Sort, and Least Significant Bit (LSB) Radix Sort. As the names suggest, MSB sorts the data starting from the top (leftmost) bits, and works its way down. In comparison, LSB starts from the bottom bits. The time complexity of Radix sort is $O(k * n)$ where k is the key width (number of bits in the key), and n is the number of elements.

3.1.4 ***Spreadsort.*** Spreadsort is a hybrid sorting algorithm that combines the best traits of Radix and comparison-based sorting. This algorithm was invented by Steven J. Ross in 2002 [37]. Spreadsort uses MSB Radix partitioning until the size of the partitions reaches a predefined threshold, at which point it switches to comparison-based sorting using Introsort. Comparison-based sorting is more efficient on small sequences of data compared to Radix partitioning. The time complexity of the MSB Radix phase is $O(n\log(k/s+s))$ where k is the key width, and s is the maximum number of splits (default is 11 for 32 bit integers). As mentioned, time complexity of Introsort is $O(n\log(n))$.

3.1.5 ***Sorting Microbenchmarks.*** In order to obtain a basic understanding of the performance of these algorithms and how they compare, we evaluate five integer sorting algorithms on a variety of datasets. The tested algorithms are: Quicksort, Introsort, MSB Radix Sort, LSB Radix Sort, and Spreadsort. We test each algorithm on five data distributions: random integers between one and five, random integers between one and one million, random integers between one thousand and one million, presorted sequential integers, and reverse sorted sequential integers. We measure the time to sort ten million integers from each distribution. The results, depicted in Figure 2, show that Introsort and Spreadsort generally outperform the other sorting algorithms.

3.2 Hash-based Aggregation Algorithms

Hash tables are particularly efficient in workloads that require fast random lookups, which they perform in constant time. A hash function transforms a key into an address within the table. However, hash tables do not generally guarantee any ordering of the keys (lexicographical or chronological). It is possible to pre-sort the data and construct a hash function that guarantees

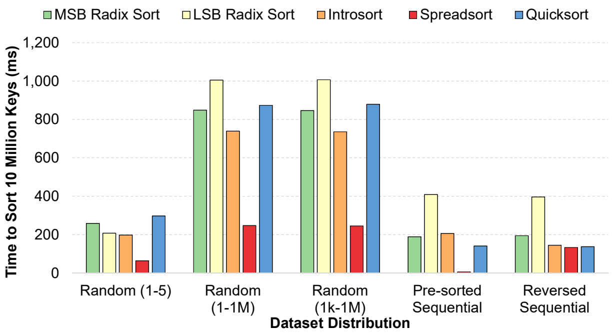

Figure 2: Sort Algorithm Microbenchmark

ordered keys (minimal perfect hashing [15, 30]). However, the impact on query execution time would be quite severe.

Hash tables are not well-suited to gradual dynamic growth, as growing the table may entail rehashing all existing elements as well. In principle, a hash table's size could be tuned to anticipate the dataset group-by cardinality. However, in practice it is difficult to estimate the cardinality, particularly when there are several group-by columns. Cardinality estimation errors result in excessive memory usage if too high, and costly rehash operations if too low. In our experiments we assume that only the size of the dataset is known, hence we set the initial size of the hash tables accordingly.

Hash tables can be categorized based on their collision resolution scheme. Collision resolution defines how a hash table resolves conflicts caused by multiple keys hashing to the same location. We now describe four collision resolution schemes and the implementations that use them: linear probing, quadratic probing, separate chaining, and cuckoo hashing.

3.2.1 ***Linear probing.*** Linear probing is part of the family of collision resolution techniques called open addressing. Open addressing hash tables typically store all the items in one contiguous array. They do not use pointers to link data items. Linear probing specifies the method used to search the hash table. An insertion begins from the hash index and probes forward in increments of one until the first empty bucket is found. Linear probing hash tables do not need to allocate extra memory to store new items as long as the table has empty slots. However, they may encounter an issue called primary clustering, where colliding records form long sequences of occupied slots. These sequences displace incoming keys, and they grow each time they do so, resulting in the high number of displacement of records.

We implement a custom linear probing hash table using several industry best practices, such as maintaining a power of two table size. If the desired size is not a power of two then the nearest greater power of two is chosen. This is a popular optimization that allows the table modulo operation to be replaced with a much faster bitwise AND. The downside to this policy is that is easier to overshoot the available memory. In order to resolve this, our implementation falls back to the modulo operation and the table size is set to the nearest prime number if possible, and the exact size parameter is used as the final fallback.

3.2.2 ***Quadratic probing.*** Quadratic probing is an open addressing scheme that is very similar to linear probing. Like linear probing it calculates a hash index and searches the table until a match is found. Rather than probing in increments of one, a quadratic function is used to determine each successive probe index. For example, with an arbitrary hash function $h(x)$ and quadratic function $f(x) = x^2$, the algorithm probes $h(x)$, $h(x)+1$, $h(x)+4$, $h(x)+9$ instead of a linear probe sequence of $h(x)$, $h(x)+1$, $h(x)+2$, $h(x)+3$. This approach greatly reduces the likelihood of clustering, but it does so at the cost of reducing data locality.

Google **Sparse Hash** and **Dense Hash** [41] are based on open addressing with quadratic probing. Sparse Hash favors memory efficiency over speed, whereas Dense Hash targets faster speed at the expense of higher memory usage.

3.2.3 ***Separate chaining.*** Separate chaining is a way of resolving collisions by chaining key-value pairs to each other with pointers. Buckets with colliding items resemble a single linked list. The main advantages of separate chaining include fast insert performance, and relatively versatile growth. The use of pointer-linked buckets reduces data locality, which is important for lookups and updates. However, unlike linear probing, separate chaining hash tables do not suffer from primary clustering.

Separate chaining hash tables remain popular in recent works [2, 3, 9, 39]. Templated separate chaining hash tables are included as part of the Boost and standard C++ libraries. Additionally, the Intel TBB library provides versatile hash tables that support concurrent insertion and iteration.

3.2.4 ***Cuckoo Hashing.*** Cuckoo hashing was originally proposed by Pagh et al. [34]. Its core concept is to store items in one of two tables, each with a corresponding hash function (this can be extended to additional tables). If a bucket is occupied by another item, the existing item is displaced and reinserted into the other table. This process continues until all items stabilize, or the number of displacements exceeds an arbitrary threshold. Cuckoo hashing provides a guarantee that reads take no more than two lookups. Its main drawback is relatively slower and less predictable insert operations, and the possibility of failed insertions.

In [29], researchers from Intel labs presented a concurrent cuckoo hashing technique **Libcuckoo**. Libcuckoo introduces improvements to the insertion algorithm by leveraging hardware transactional memory (HTM). This hardware feature allows concurrent modifications of shared data structures to be atomic. Their experimental results indicate that Libcuckoo outperforms MemC3 [14], and Intel TBB [35].

3.3 Tree-based Aggregation Algorithms

Hash-based and sort-based aggregation approaches are very popular, mainly due to a heavy focus of past studies on "write once read once" (WORO) aggregation workloads, as opposed to "write once read many" (WORM). We consider several tree data structures, and assess their viability for aggregation.

Trees are commonly used to evaluate range conditions. However, aggregation benchmarks, such as TPC-H, do not include range queries. Tree data structures are well suited to incremental dynamic growth. The trade-off is higher time complexities for both insert and lookup operations, compared to hash tables.

We divide the tree data structures into *comparison trees* and *radix trees.* Comparison trees have traditionally served as indexing structures, but Radix trees are being increasing adopted in recent main memory databases, such as HyPer [23] and Silo [44]. The *Btree* family and *Ttree* are comparison trees, and *ART* and *Judy* are Radix trees.

3.3.1 ***Btree.*** The *B-tree* is a popular tree data structure that was initially invented in 1971 by Bayer et al. [5], and forms the basis for many modern variants [7, 28]. A B-tree is a balanced *m-way* tree where *m* is the maximum number of children per

Table 2: Data Structure Time Complexity

Data Structure	Average Case Insert	Worst Case Insert	Average Case Search	Worst Case Search
ART	$O(k)$	$O(k)$	$O(k)$	$O(k)$
Judy	$O(k)$	$O(k)$	$O(k)$	$O(k)$
Btree	$O(\log(n))$	$O(\log(n))$	$O(\log(n))$	$O(\log(n))$
Ttree	$O(\log(n))$	$O(\log(n))$	$O(\log(n))$	$O(\log(n))$
Separate Chaining	$O(1)$	$O(n)$	$O(1)$	$O(n)$
Linear Probing	$O(1)$	$O(n)$	$O(1)$	$O(n)$
Quadratic Probing	$O(1)$	$O(\log(n))$	$O(1)$	$O(\log(n))$
Cuckoo Hashing	$O(1)$ (amortized)	$O(n)$ (rehash)	$O(1)$	$O(1)$

node. The B-tree is perhaps best recognized as a popular disk-based data structure used for database indexing, although they are also used for in-memory indexes. The defining characteristics of B-trees are that they are shallow and wide due to using a high fanout. This reduces the number of node lookups as each node contains multiple data items. B-trees may also include pointers between leaf nodes to facilitate more efficient range scans. The time complexity for inserting n items into a B-tree is $O(n\log(n))$. We use a cache-optimized implementation based on the *STX B+tree* [7] which we will henceforth refer to as *Btree*.

3.3.2 ***Ttree****.* *Ttree* (spelled "T-tree" in the literature) was originally proposed in 1986 by Lehman et al. [25]. Its intended purpose was to provide an index that could outperform and replace the disk-oriented B-tree for in-memory operations. Although the Ttree showed a lot of promise when it was first introduced, we show in section 3.4 that advancements in hardware design have rendered it obsolete on modern processors.

3.3.3 ***ART****.* ART (Adaptive Radix Tree) [26] is a Radix tree variant with a variable fan-out. Its inventors present it as a data structure that is as fast as a hash table, with the added bonus of sorted output, range queries, and prefix queries. ART uses SIMD instructions to concurrently compare multiple keys in parallel. ART saves on memory consumption by using dynamic node sizes and merging inner nodes when possible. Radix trees have several key advantages compared to comparison trees. The height of a radix tree depends on the length of the keys, rather than the number of keys. Additionally, in contrast with comparison trees, they do not need to perform re-balancing operations.

We also considered *HOT* [8], which builds on the same principles as ART. However, we found its performance with integer keys to be noticeably worse, as its main focus is string keys.

3.3.4 ***Judy Arrays****.* Judy Arrays (henceforth referred to as Judy) were invented by Doug Baskins [4], and defined as a type of sparse dynamic array designed for sorting, counting, and searching. They are intended to replace common data structures such as hash tables and trees. Judy is implemented as a 256-way Radix tree that uses variable fan out and a total of 20 compression techniques to reduce memory consumption and improve cache efficiency [1]. Judy is fine-tuned to minimize cache misses on 64 byte cache-lines. Like many other tree data structures, the size of a Judy array dynamically grows with the data and does not need to be pre-allocated.

3.4 Data Structure Microbenchmarks

We use a microbenchmark to evaluate each data structure's efficiency in a store and lookup workload. We separately measure the time it takes to build the data structure (build phase), and the time to read all the items in the data structure (iterate phase). All hash tables are sized to the number of elements. The results are depicted in Figure 3 using the abbreviations outlined in Table 3. With the exception of Hash_LC, the build phase is faster on all the hash tables due $O(1)$ insert complexity. Hash_LC performs poorly in the build phase because it is designed as a concurrent data structure. We evaluate its concurrent scalability in Section 5.8. Hash_LP and Hash_Dense provide the fastest overall times. Btree is noticeably faster in the iterate phase, but it takes a relatively long time to build due to the cost of balancing the tree. Due to the relatively poor performance exhibited by Ttree in both phases, we opt to omit it from subsequent experiments.

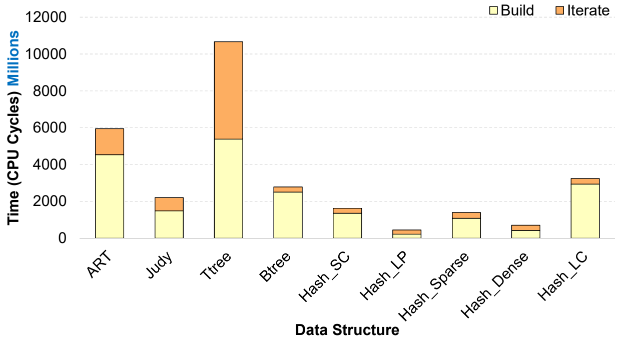

Figure 3: Data Structure Microbenchmark

3.5 Time Complexity

It is a well known fact that time complexities for algorithms are not always the best predictors of real-world performance. This is due to a number of factors, including hidden constants and overheads arising from the implementation, hardware characteristics such as CPU architecture cache and TLB, compiler optimizations, and operating systems. On modern systems, cache misses are particularly expensive. Nevertheless, time complexity is widely used as a mean to understand and compare the relative performance of different algorithms.

Table 2 provides an overview of the known time complexities for each of the data structures that we evaluate. Here n denotes the number of elements, and k the number of bits in the key.

4 DATASETS

In order to effectively evaluate the algorithms, we generate a set of synthetic datasets that vary in terms of input size, group-by cardinality, key distribution, and key range. Our datasets are based on the highly popular input distributions described in prior works [11, 18, 20]. We employ several modifications to these datasets, with the goal of expanding the data characteristics

Table 3: Algorithms and Data Structures

Label	Type	Description
ART	Tree	Adaptive Radix Tree [26]
Judy	Tree	Judy Array [4]
Btree	Tree	STX B+Tree [7]
Hash_SC	Hash	std::unordered_map [21] (Separate Chaining)
Hash_LP	Hash	Linear Probing (Custom)
Hash_Sparse	Hash	Google Sparse Hash [41]
Hash_Dense	Hash	Google Dense Hash [41]
Hash_LC	Hash	Intel libcuckoo [29]
Introsort	Sort	std::sort (Introsort) [21]
Spreadsort	Sort	Boost Spreadsort [42]

Table 4: Dataset Distributions

Abbreviation	Description	Cardinality
Rseq	Repeating Sequential	Deterministic
Rseq-Shf	Rseq Uniform Shuffled	Deterministic
Hhit	Heavy Hitter	Deterministic
Hhit-Shf	Hhit Uniformly Shuffled	Deterministic
Zipf	Zipfian	Probabilistic
MovC	Moving Cluster	Probabilistic

that we evaluate. Some datasets, such as the sequential dataset, produce very predictable patterns. For such datasets, we generate an additional variant with uniform random shuffling. In [11] it is mentioned that the group-by cardinality is often probabilistic. We enforce deterministic group-by cardinality in cases where the target distribution of the dataset would not be affected.

Throughout this paper we use *random* to refer to a uniform random function with a fixed seed, and *shuffling* refers to the use of the aforementioned function to shuffle all the records in a dataset. The number of records in the dataset is denoted as n records and the group-by cardinality is c.

In the repeating sequential dataset (*RSeq*), we generate a series of segments that contain multiple number sequences. The number of segments is equal to the group-by cardinality, and the number of records in each segment is equal to the dataset size divided by the cardinality. A shuffled variant of the repeating sequential dataset (*RSeq-Shf*) is also generated. This dataset mimics transactional data where the key incrementally increases.

In the heavy hitter dataset (*HHit*), a random key from the key range accounts for 50% of the total keys. The remaining keys are produced at least once to satisfy the group-by cardinality, and then chosen on a random basis. In a variant of this dataset, the resulting records are shuffled so that the heavy hitters are not concentrated in the first half of the dataset. Real-world examples of heavy hitters include top selling products, and network nodes with the highest traffic.

In the Zipfian dataset (*Zipf*), the distribution of the keys is skewed using Zipf's law [36]. According to Zipf's law, the frequency of each key is inversely proportional to its rank. We first generate a Zipfian sequence with the desired cardinality c and Zipf exponent $e = 0.5$. Then we take n random samples from this sequence to build n records. The final group-by cardinality is non-deterministic and may drift away from the target cardinality as c approaches n. The Zipf distribution is used to model many big data phenomena, such as word frequency, website traffic, and city population.

Table 5: Experiment Parameters

Dataset	Repeating Sequential, Heavy Hitter, Moving Cluster, Zipfian
Dataset Size	100M, 10M, 1M, 100k
Group-by Cardinality	100, 1000, 10000, 100000, 1000000, 10000000
Algorithm	Hash_LP, Hash_SC, Hash_LC, Hash_Sparse, Hash_Dense, ART, Judy, Btree, Introsort, Spreadsort, Hash_TBBSC, Sort_BI, Sort_QSLB
Thread Count	1, 2, 3, 4, 5, 6, 7, 8 (logical core count)
Query	Q1 (Vector Distributive), Q3 (Vector Holistic), Q6 (Scalar Distributive), Q7 (Vector Distributive with Range)

In the moving cluster dataset (MovC), the keys are chosen from a window that gradually slides. The i^{th} key is randomly selected from the range $\lfloor (c - W)i/n \rfloor$ to $\lfloor (c - W)i/n + W \rfloor$, where the window size $W = 64$ and the cardinality c is greater than the window size ($c >= W$). The moving cluster dataset provides a gradual shift in data locality and is similar to workloads encountered in streaming or spatial applications.

5 RESULTS AND ANALYSIS

In this section we evaluate the efficiency of the aggregation algorithms. We examine and compare the performance impact of dataset size, group-by cardinality, key skew and distribution, data structure algorithm, and the query and aggregation functions. We also evaluate peak memory usage as a measure of each algorithm's memory efficiency. The experimental parameters are outlined in Table 5.

For each experiment the input dataset is preloaded into main memory. We do not measure the time to read the input from disk. Throughout this paper we aim to understand how each of these dimensions can affect main memory aggregation workloads. Due to space constraints we only show the results for Q1, Q3, Q6 and Q7. We start the experiments with two common vector aggregation queries (Q1 and Q3) in Section 5.2. Due to the popularity of these queries, we further analyze these queries by evaluating cache and TLB misses in Section 5.3, memory usage for different dataset sizes in Section 5.4, and data distributions in Section 5.5. Additionally, we evaluate range searches (Q7) in Section 5.6 and scalar aggregation queries (Q6) in Section 5.7. We examine multithreaded scaling in Section 5.8. Finally, we summarize our findings in Section 6. We now outline our experimental setup.

5.1 Platform Specifications

The experiments are evaluated on a machine with an Intel Core i7 6700HQ processor at 3.5GHz, 16GB of DDR4 RAM at 2133MHz, and a 512GB SSD. The CPU is a quad core based on the Skylake microarchitecture, with hyper-threading (8 logical cores), 256KB of L1 cache, 1MB of L2 cache, and 6MB of L3 cache. The TLB can hold 64 entries in the L1 Data TLB, and 1536 entries in the L2 Shared TLB (4KB pages). The code is compiled and run on Ubuntu Linux 16.04 LTS, using the GCC 7.2.0 compiler, and the -O3 and -march=native optimization flags. We now present and discuss the experimental results.

5.2 Results - Vector Aggregation

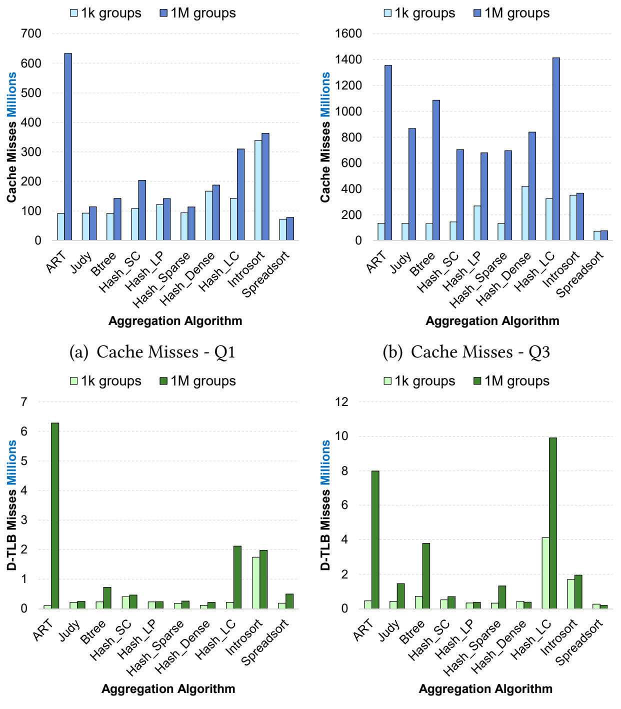
We begin our experiments by evaluating Q1 and Q3 (see Table 1), which are based on commonly used aggregate functions. Due to space constraints and the similarity between Algebraic and Distributive functions, we do not show results for Q2. In these experiments, we keep the dataset size at a constant 100M and vary the group-by cardinality from 10^2 to 10^7. In each chart we measure the query execution time for a given query and dataset distribution, and the group-by cardinality increases from left to right. The results for Q1 (Vector COUNT) and Q3 (Vector MEDIAN) are shown in Figures 4 and 5 respectively. A larger group-by cardinality means more unique keys, and fewer duplicates. In tree-based algorithms the data structure dynamically grows to accommodate the group-by cardinality. This is reflected in the gradual increase in query execution time. The insert performance of ART and Judy depends on the length of the keys, which increases with cardinality. Additionally, the compression employed by ART and Judy are more heavily used at high cardinality.

The results for Q3 show that Spreadsort is the fastest algorithm across the board. The overall trend shows that hash-based algorithms, such as Hash_SC and Hash_LP, are competitive with Spreadsort until the group-by cardinality exceeds 10^4. The execution times for both Spreadsort and Introsort show considerably less variance, whereas the worsening of data locality results in sharp declines in performance for the hash-based and tree-based implementations. The performance of Hash_Sparse dramatically worsens at 10^7 groups, suggesting that the combination of Hash_Sparse's gradual growth policy and the extra space needed by this query result in a much steeper decline in performance compared to Q1.

In order to understand why Hash_LP outperforms all the other algorithms in Q1, we need to consider several factors. Firstly, the average insert time complexity (as shown in Table 2) is unaffected by group-by cardinality. Secondly, the cache-friendly layout of Hash_LP takes great advantage of data locality compared to the other hash tables. Lastly, compared to Q3, Q1 does not require additional memory to store the values associated with each key. This reduces the pressure on the cache and TLB, and allows Hash_LP to compete with memory efficient approaches such as Spreadsort. We further explore cache and TLB behavior in Section 5.3 and memory consumption in Section 5.4.

5.3 Results - Cache and TLB misses

Cache and TLB behavior are metrics of algorithm efficiency. Together with runtime and memory efficiency, they paint a picture of how different algorithms compare with each other. Processing large volumes of data in main memory often leads to many cache and TLB misses, which can hinder performance. A cache miss can sometimes be satisfied by a TLB hit, but a TLB miss incurs a page table lookup, which is considerably more expensive. Using



(a) Cache Misses - Q1

(b) Cache Misses - Q3

(c) TLB misses - Q1

(d) TLB misses - Q3

Figure 6: Cache and TLB misses - Rseq 100M Dataset

the *perf* tool, we measure the CPU cache misses and data-TLB (D-TLB) misses of Q1 and Q3 with low cardinality (10^3 groups) and high cardinality (10^6 groups) datasets. The results are depicted in Figure 6.

It is interesting to compare the results in Figure 6(c) with the performance discrepancy between Hash_LP and Spreadsort in Q1. At low cardinality, the number of TLB misses is relatively close between the two algorithms. However, at high cardinality, Spreadsort exhibits considerably higher TLB misses. Similarly, in Figure 4(a) we see the runtime gap between the two algorithms widen in Hash_LP's favor as the cardinality increases to 10^7.

Although this metric is not a guaranteed way to predict the relative performance of the algorithms, it is a fairly reliable measure of scalability and overall efficiency. The cache behavior of Spreadsort is consistently good. Other algorithms, such as ART, exhibit large jumps in both cache and TLB misses. This correlates with similar gaps in the query runtimes, and it is noted in [8] that ART's memory efficiency and performance may degrade if it creates many small nodes due to the dataset distribution.

5.4 Results - Memory Efficiency

Memory efficiency is a performance metric that is arguably as important as runtime speed. We now measure the peak memory consumption at various dataset sizes.

To do so we lock the group-by cardinality at 10^3 and vary the dataset size from 10^5 up to 10^8. These measurements are taken by using the Linux */usr/bin/time -v* tool to acquire the *maximum resident set size* for each configuration. The results for Q1 are depicted in Table 6 and the memory usage of Q3 is shown in Table 7. The results show that the hash tables consume the most memory, followed by the tree data structures. The sort algorithms are the most memory efficient because they sort the data in-place. In order to maintain good insert performance, most hash tables consume more memory than they need to store the items, and some will only resize to powers of two. Hash_Dense's memory usage is particularly high because it uses 6× the size of the entries in the hash table when performing a resize. After the resize is completed, the memory usage shrinks down to 4× the previous size. Comparing Tables 6 and 7, we see a jump in memory usage from Q1 to Q3. This is due to the fact that Q3 requires the data structures to store the keys and all associated values in main memory, whereas Q1 only requires the keys and a count value. Consequently, holistic queries like Q3 will generally consume more memory.

Table 6: Peak Memory Usage (MB) - Q1 on Rseq 10^3 Groups

Dataset Size Algorithm	10^5	10^6	10^7	10^8
ART	4.45	11.61	131.61	1027.44

Spreadsort	4.31	11.66	131.59	1027.48

5.5 Results - Dataset Distribution

These experiments show the performance impact of the data key distribution. The results are presented in Figures 7(a) and 7(b). In each figure, we vary the key distribution while keeping the dataset size at a constant 100 million records. To get a better understanding of how this factor ties in with cardinality, we show results for both low and high cardinality (10^3 and 10^6 groups).

The results point out that Zipf and Rseq-Shf are generally the most performance-sensitive datasets. The shuffled variants of Rseq and HHit take longer to run due to a loss of memory locality. By comparing the two figures we can see that this effect is amplified by group-by cardinality, as it increases the range of keys that must be looked up in the cache. In the low cardinality dataset, the number of unique keys is small compared to the dataset size. Introsort is the overall slowest algorithm at low cardinality and its performance is around the middle of the pack at high cardinality. This is in line with prior works suggesting that sort-based aggregation is faster when the group-by cardinality is high [32]. However, as we can see in the results produced by Spreadsort, the algorithm also performs well at low cardinality which contradicts earlier claims. Due to this, it may be worth revisiting hybrid sort-hash aggregation algorithms in the future.

(d) Hhit-shf

(e) MovC

(f) Zipf

Figure 9: Scalar Aggregation Q6 - 100M records

The results also highlight an interesting trend when it comes to shuffled/unordered data. Observe that ART's performance in Figure 7(b) significantly worsens when going from Rseq to Rseq-Shf or indeed any unordered distribution. The combination of high cardinality and unordered data increase pressure on the cache and TLB. If we consider how well Spreadsort performs in these situations, then the results indicate that presorting the data before invoking the ART-based aggregate operator could significantly improve performance. However, careful consideration of the algorithm and dataset is required to avoid increasing the runtime.

5.6 Results - Range Search

The goal of this experiment is to evaluate algorithms that provide a native range search feature, and combine this with a typical aggregation query. Although it is possible to implement an integer range search on a hash table, this would not work for strings and other keys with non-discrete domains. Consequently, we focus on the tree-based aggregation algorithms. Q7 calculates the vector count aggregates for a range of keys. The tuples that do not satisfy the range condition could be filtered out before building the index (if the range is known in advance). We assume that (a) the data has already been loaded into the data structure, and (b) this is a a Write Once Read Many (WORM) workload, and multiple range searches will be satisfied by the same index.

We evaluate the time it takes to perform a range search on each of the tree-based data structures for ranges that cover 25%, 50% and 75% of the group-by cardinality (the smaller ranges are run first). The results are shown in Figure 8. In Figure 8(c), we see that the time to build the tree dominates the runtime. The search times shown in Figures 8(a) and 8(b) indicate that Btree significantly outperforms the other algorithms if the tree is prebuilt. This is likely due to the pointers that link each leaf node, resulting in one $O(\log(n))$ lookup operation to find the lower bound of the search, and a series of pointer lookups to complete the search. At low cardinality (10^3 groups), the range search time for ART is 12% lower than Judy, but it is 94% higher at high cardinality (10^6 groups). If we factor in the build time and consider the workload WORO, then ART is the fastest algorithm.

5.7 Results - Scalar Aggregation

Unlike Vector aggregate functions, which output a row for each unique key, Scalar aggregate functions return a single row. We evaluate Q6 on the tree-based and sort-based aggregation algorithms. Hash tables are unsuitable for this query because the keys need to be in lexicographical order to calculate the median. Figure 9 shows the query execution time for Q6 with different datasets. The overall winner of this workload is the Spreadsort algorithm. In the case of a dynamic or WORM workload, a tree-based algorithm would have two advantages of faster lookups and requiring considerably less computation for new inserts. A good candidate for tree-based scalar aggregation is Judy, as it outperforms Introsort on all the datasets, and comes close to the

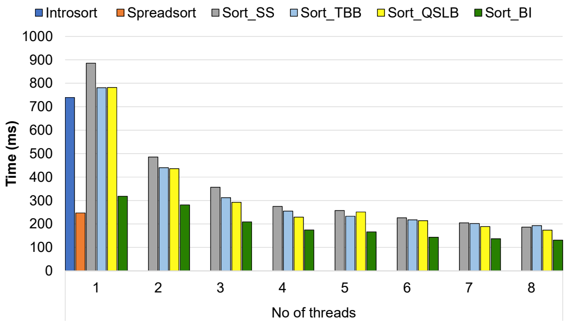

Figure 10: Parallel Sort Algorithm Microbenchmark

Figure 11: Multithreaded Scaling - Rseq 100M

performance of Spreadsort in three out of the six datasets. Although ART wins over Judy in some cases, it is inconsistent and its worse case performance is significantly worse, rendering it a poor candidate for this workload. The conclusion is in line with our expectation. To calculate the scalar median of a set of keys, Spreadsort is the fastest algorithm. If an index has already been built then Judy is usually the quickest in producing the answer.

5.8 Multithreaded Scalability

A concurrent algorithm's ability to provide a performance advantage over a serial implementation depends on two main factors: the problem size, and the algorithmic efficiency. Considerations pertaining to algorithmic efficiency include various overheads associated with concurrency, such as contention and synchronization. In order to implement concurrent aggregate operators, a suitable data structure must fulfill three requirements. Firstly, they must be designed for data-level parallelism that can scale with an increasing number of threads. Secondly, they must support thread-safe insert and update operations. It is not uncommon to encounter data structures that support concurrent *put* and *get* operations, but provide no way to safely modify existing values. Lastly, they must provide a means to iterate through their content, preferably without requiring prior knowledge of the range of values. In this section, we evaluate the performance and scalability of concurrent data structures and algorithms which fulfill all three criteria. We considered and ultimately rejected several candidate tree data structures. HOT [8] does not support concurrent incrementing of values (needed by Q1) or multiple values per key (needed by Q3). BwTree [28, 46] is a concurrent B+Tree originally proposed by Microsoft. However, our preliminary experiments found its performance to be very poor, as limitations in its API prevent efficient update operations. These characteristics have been discovered by other researchers as well [47]. The concurrent variant of ART [27] currently lacks any form of iterator, which is essential to our workloads.

Table 8: Concurrent Algorithms and Data Structures

Label	Type	Description
Hash_TBBSC	Hash	TBB Separate Chaining (Concurrent Unordered Map [35])
Hash_LC	Hash	Intel Libcuckoo [29]
Sort_BI	Sort	Block Indirect Sort [42]
Sort_QSLB	Sort	Quicksort with Load Balancing (GCC Parallel Sort [43])

We use a microbenchmark to select two parallel sorting algorithms from among four candidates. We vary the number of threads from one to eight, and include the two fastest single-threaded sorting algorithms for comparison. The workload consists of sorting random integers between 1-1M, similar to the microbenchmark presented in Section 3. The results are shown in Figure 10. Sort_BI is a novel sorting algorithm, based on the concept of dividing the data into many parts, sorting them in parallel, and then merging them [42]. Sort_TBB is a Quicksort variant that uses TBB task groups to create worker threads as needed (up to number of threads specified). Sort_SS (Samplesort) [42] is a generalization of Quicksort that splits the data into multiple buckets, instead of dividing the data into two partitions using a pivot. Lastly, Sort_QSLB [43] is a parallel Quicksort with load balancing. Considering the performance and scalability at 8 threads, we select the Sort_BI and Sort_QSLB algorithms to implement sort-based aggregate operators.

We selected four concurrent algorithms and algorithms, listed in Table 8, all of which are actively maintained open-source projects. We introduced Hash_LC in Section 3, and Hash_TBBSC is a concurrent separate chaining hash table that is similar to Hash_SC. We evaluate the multithreaded scaling for Q1 and Q3, on both low and high dataset cardinality. The results are depicted in Figure 11. We observe that both hash tables are faster in Q1, and Hash_TBBSC outperforms Hash_LC regardless of the cardinality. Sort-based approaches take the lead in Q3. The gap between sorting and hashing increases at higher cardinalities. This echoes our previous single-threaded results. The performance of Hash_TBBSC degrades significantly in Q3, because storing the values requires the use of a concurrent data structure (in this case a concurrent vector) as the value type. This is a limitation of the hash table implementation, which results in additional overhead due to synchronization and fragmentation [35]. We also considered implementing Q3 using TBB's concurrent multimap, but the performance was significantly worse. Hash_LC does not suffer from these issues, as it provides an interface for user-defined *upsert* functions. We observe similar trends with other data distributions, which we omit here due to space constraints.

6 SUMMARY AND DISCUSSION

Based on the insights we gained from our experiments, we present a decision flow chart in Figure 12 that summarizes our main observations with regards to the algorithms and data structures. We acknowledge that our experiments do not cover all possible situations and configurations, and our conclusions are based on these computational results and observations.

We start by picking a branch depending on the output format of the aggregation query. If the query is scalar, the workload determines the best algorithm. If query workload is "Write Once Read Once" (WORO) then the Spreadsort algorithm provides the fastest overall runtimes. If we require a reusable data structure that can satisfy multiple queries of this category, then Judy is a more suitable option. Going back to the start node, if the aggregation query is vector, our decision is determined by the aggregate function category. Holistic aggregates (such as Q3) are considerably faster, and more memory efficient with the sorting algorithms, particularly Spreadsort (single-threaded) and Sort_BI (multithreaded). This advantage is more noticeable at high group-by cardinality. If the query is distributive (such as Q1) then our experiments show that Hash_LP (single-threaded) and Hash_TBBSC (multithreaded) are the fastest algorithms. For aggregate queries that include a range condition, we found that Btree greatly outperformed the other algorithms in terms of search times. This advantage is only relevant if we assume that the tree has been prebuilt. Otherwise, ART is the best performer in this category, due to its advantage in build times.

7 RELATED WORK

There have been a broad range of studies on the topic of aggregation. With the growing popularity of in-memory analytics in recent years, memory-based algorithms have gained a lot of attention. We explore some of the work that is thematically close to our research.

Some studies have proposed novel index structures for database operations. Notably, recent studies have looked into replacing comparison trees with radix trees. In [26] Leis et al. proposed an adaptive radix tree (ART) designed for in-memory query processing. The authors evaluated their data structure with the TPC-C benchmark, which does not focus on analytical queries or aggregation. Based on a similar concept Binna et al. propose HOT [8] (Height Optimized Trie). The core concepts behind this approach are reducing the height of the tree on sparsely distributed keys, and the use of AVX2 SIMD instructions for intra-cycle parallelism. The authors demonstrate that HOT significantly outperforms other indexes, such as ART [26], STX B+tree [7], and Masstree [31], on insert/read workloads with string keys. However, for integer keys, ART maintains a notable performance advantage in insert performance, and is competitive in read performance.

The duality of hashing and sorting for database operations is a topic that continues to generate interest. The preferred approach has changed many times as hardware, algorithms, and data have evolved over the years. Early database systems relied heavily on sort-based algorithms. As memory capacity increased, hash-based algorithms started to gain traction [16]. In 2009 Kim et al. [24] compared cache-optimized sorting and hashing algorithms and concluded that hashing is still superior. In [38] Satish et al. compared several sorting algorithms on CPUs and GPUs. Their experiments found that Radix Sort is faster on small keys, and Merge Sort with SIMD optimizations is faster on large keys. They predicted that Merge Sort would become the preferred sorting method in future database systems. It can be argued that this prediction has yet to materialize.

Müller et al. proposed an approach to hashing and sorting with an algorithm that can switch between them in real time [32]. The authors modeled their algorithm based on their observation that hashing performs better on datasets with low cardinality, but sorting is faster when there is high data cardinality. This holds true with some basic hashing or sorting algorithms, but there are algorithms for which this model does not apply. Their approach adjusts to the cardinality and skew of the dataset by setting a threshold on the number of groups found in each cache-sized chunk of the data. This approach cannot be used for holistic aggregation queries, as the data is divided into chunks.

Balkesen et al. [2] compared the performance of highly optimized sort-merge and radix-hashing algorithms for joins. Their implementations leveraged the extra SIMD width and processing cores found in modern processors. They found that hashing outperformed sorting, although the gap got much smaller for very large datasets. The authors predicted that sorting may eventually outperform hashing in the future, if the SIMD registers and data key sizes continue to expand.

Parallel aggregation algorithms focus on determining efficient concurrent designs for shared data structures. A key question in parallel aggregation is whether threads should be allowed to work independently, or to work on a shared data structure. Cieslewicz et al. [11] present a framework to select a parallel strategy based on a sample from the dataset. Surprisingly, the authors claim that sort-based aggregation can only be faster than hash-based aggregation if the input is presorted. We found that in the context of single threaded algorithms, sort-based aggregation is quite competitive with hash-based.

In [49], the authors examined several previously proposed parallel algorithms, and propose a new algorithm called PLAT based on the concept of partitioning, and a combination of local and global hash tables. Most of these algorithms do not support holistic aggregation, because they split the data into multiple hash tables in order to reduce contention. Furthermore, none of the algorithms are ideal for scalar aggregation as they do not guarantee lexicographical ordering of the keys.

8 CONCLUSION

Aggregation is an integral aspect of big data analytics. With rising RAM capacities, in-memory aggregation is growing in importance. There are many different factors that can affect the performance of an aggregation workload. Knowing and understanding these factors is essential for making better design and implementation decisions.

We presented a six dimensional analysis of in-memory aggregation. We used microbenchmarks to assess the viability of 20 different algorithms, and implemented aggregation operators using 14 of those algorithms. Our extensive experimental framework covered a wide range of data structures and algorithms, including serial and concurrent implementations. We also varied the query workloads, datasets, and the number of threads. We gained a lot of useful insights from these experiments. Our results show that some persisting notions about aggregation do not necessarily apply to modern hardware and algorithms, and that there are certain combinations that work surprisingly better than conventional wisdom would suggest (see Figure 12).

To our knowledge, this is the first performance evaluation that conducted such a comprehensive study of aggregation. We demonstrated with extensive experimental evaluation that the ideal approach in a given situation depends on the input and the workload. For instance, sorting-based approaches are faster in holistic aggregation queries, whereas hash-based approaches perform better in distributive aggregation queries.

Abstract

Hardware specialization has been considered as a promising way to overcome the power wall, ushering in heterogeneous computing paradigm. Meanwhile, several trends, such as cloud computing and advanced FPGA technology, are converging to eliminate the barriers to custom hardware deployment, allowing it to be both technologically and economically feasible. In this paper, we conduct a pioneering study of hardware specialization for OLTP databases and present a fast and power-efficient transaction processing system built on FPGA, called BionicDB. With an order of magnitude higher power-efficiency inherently offered by FPGA, BionicDB performs faster or comparable to state-of-the-art software OLTP system by accelerating indexing and inter-worker communication.

1 INTRODUCTION

For the past decade, multicore has been a dominant scaling path. However, multicore hardware is getting more and more stagnant over time due to the growing scalability pressure and continuing power wall[16, 21]. To tackle the situation, hardware specialization has garnered a great deal of attention. It is widely regarded as a way to provide substantial power saving, while providing application-specific acceleration at the expense of generality [22, 30, 32, 34, 38, 44, 45].

In the meantime, field-programmable gate array (FPGA) technology has been matured, making custom hardware deployment more viable and economical. Its reconfigurability can return economic gains in accommodating quickly changing application demands by lifting manufacturing burden; we can reconfigure hardware to update or patch on-the-fly, as we do so for software. More importantly, inherent power efficiency of FPGA provides a great opportunity to overcome the power wall. Although running at low clock frequency, fine-grained, massive parallelism of FPGA could potentially compensate the low clock frequency with suitable custom hardware design on top.

For these reasons, datacenters increasingly integrate FPGA as a primary platform to run various custom accelerators for some data-intensive applications, such as search engine, deep learning and OLAP databases [4, 38]. Characteristically, those are compute-bound, dataflow applications. For such workloads, FPGA's massive fine-grained parallelism holds great promise for compute acceleration while CPU's limited and stagnant parallelism becomes a major computation bottleneck in dealing with huge data volume.

However, hardware specialization for transaction processing (OLTP) has been rarely explored. It has even been regarded as questionable because of OLTP's very different characteristics from previous cases: OLTP is generally bound by memory stalls and communication, rather than computation. In this situation, computation acceleration does not promise meaningful performance gain. Meanwhile, multicore CPU is returning diminishing performance gain with growing power consumption, putting scalability efforts at risk.

Inspired by the findings and technology trends, we conclude that it is imperative to explore an OLTP-oriented hardware that is power-efficient to operate under restrictive power budget and fast enough to meet performance requirement at the same time. FPGA can easily satisfy the power goal, but the question is how fast it can be while preserving the power efficiency.

In this paper, we report the design and implementation of BionicDB on FPGA as a case of hardware specialization for OLTP. BionicDB is an OLTP-oriented hardware optimized for in-memory, partitioned databases. Preserving the inherent power efficiency of FPGA, it achieves high performance thanks to various OLTP-oriented custom hardware that accelerate 1) index and 2) inter-worker communication. Also, it takes a hybrid processor-accelerator (software-hardware) architecture to complement each other. Our experimental results show that BionicDB can achieve an order of magnitude power saving while providing competitive performance compared to state-of-the-art software system; with the same number of worker threads, BionicDB can be faster by up to 4.5x when fully utilized and maintains comparable performance in TPC-C transactions where BionicDB is substantially underutilized.

The main contributions of this paper are as follows.

- We establish a holistic strategy for fast and power-efficient OLTP through hardware specialization.
- We propose index pipelining and transaction interleaving for index acceleartion.
- We suggest on-chip message-passing for faster inter-worker communication in partitioned databases.
- We show that hybrid processor-accelerator (software-hardware) approach is required for OLTP.

The remainder of this paper is organized as follows. Section 2 covers background on FPGA. Section 3 discusses design decisions, laying the foundations of BionicDB. Section 4 describes how BionicDB works in detail. Section 5 evaluates BionicDB, comparing to a software OLTP system. Section 6 summarizes related work. Section 7 contains our conclusion and suggests possible future research directions.

2 FIELD PROGRAMMABLE GATE ARRAYS

FPGA is a reconfigurable hardware platform and becoming an enabling technology for hardware specialization for a wide variety of application. Its main advantages are low power consumption and massive fine-grained parallelism that can be leveraged for acceleration. While CPU still remains as a central processing resource, certain CPU-unfriendly work can be offloaded to custom accelerator built on FPGAs for higher efficiency.

The main building blocks of FPGA that enable reconfigurability are lookup tables (LUT), flip-flops (FF) and programmable routing fabric. The first two components are used to implement logic functions, and the routing fabric interconnects them programmably. In addition to the programmable elements, modern FPGA chips commonly include hardwired blocks for higher efficiency, such as

Table 1: Design summary

block RAMs (BRAMs), digital signal processors (DSPs) and even embedded processors. Hardware can be designed with hardware description language (HDL) and CAD tools provided by a vendor compile HDL code into a bitstream that physically implements the hardware design on a target chip.

FPGA trades efficiency for reconfigurability, largely because of the area/speed/power overhead from programmable fabric, residing in a middle ground between ASIC and CPU in terms of efficiency and flexibility; ASIC provides the highest efficiency with lowest flexibility, while CPU provides the opposite. But FPGA can be an excellent platform for applications where the volume of production does not justify ASIC manufacturing. In datacenters where servers are dynamically re-purposed for a changing set of applications, a FPGA-augmented server can reprogram both software and hardware at runtime, allowing more efficient resource provisioning [38]. It also provides a chance to free up a number of CPUs from cycle-consuming jobs and spare them for more suitable (SW-friendly) tasks, returning higher datacenter efficiency.

3 DESIGN

BionicDB aims to provide 1) power saving 2) and high performance at the same time for OLTP. Software-only systems on low-power processors usually end up trading one for another; [40] reports that an ARM processor sacrifices performance by 3x with merely 25% energy efficiency gain, compared to a Xeon processor when running a high-performance in-memory OLTP. Therefore, we leverage hardware specialization with FPGA to achieve both goals. Table 1 summarizes the specific challenges and solutions to address them.

3.1 Acceleration Strategy

We start from understanding bottlenecks in modern OLTP to identify “what to accelerate" and establish a strategy on “how to accelerate". Typically, OLTP systems serve massively concurrent transactions that make small random updates to databases [1, 20]. Such workload characteristic naturally gives high pressure on indexing and thread coordination.

Index. Although OLTP databases heavily rely on index, the CPU is frequently bound by memory stalls from dependent pointer chasing within an index probe, wasting huge amounts of cycles. For example, a recent study reported roughly 40% overhead from index in a state-of-the-art software OLTP system [24]. But existing software solutions are limited to overcome the memory wall [19, 25]: 1) cache optimizations and bigger cache are easily undermined by OLTP's access randomness; 2) prefetching often fails to hide memory latency due to the lack of computation to overlap with; 3) software pipelining is inefficient with irregularity; 4) and group/dynamic prefetching is bound by the limited size of the instruction window of a CPU.

BionicDB alleviates the memory stalls through index pipelining. The key concept of index pipelining is to overlap multiple index accesses through hardware pipelining. It can provide higher memory-level parallelism, thereby improving single-worker performance. Also, we aim to exploit index parallelism not only within a transaction, but also across transactions. For that, transaction interleaving captures inter-transaction index parallelism, improving the utilization of index pipelining. Figure 1a illustrates how we can achieve higher memory-level parallelism with these techniques.

Figure 1: OLTP acceleration strategy

Communication. Partitioned databases can simplify the hardware complexity; theoretically, database resources are core-private eliminating the burden of complex thread coordination, such as concurrent index implementation. For that reason, we adopt DORA [35, 36] which is a scalable partitioned database.

In regard to performance, it has very low overhead for a single-partition transaction because inter-worker communication does not take place at all. However, it requires inter-worker communication overhead when a transaction spans across partitions (multi-site transaction). Recent studies [7, 8, 12] have revisited message-passing semantic for partitioned databases, but software message-passing can involve 1) memory latency when a message is evicted from cache and 2) thread synchronization at concurrent message queues that can be a scalability bottleneck. Despite the problems, there is no alternative or a bypass for software, because the shared-memory is the only available communication semantic in most CPUs. In other words, the shared-memory bottlenecks are inevitable with software message-passing even when application-level communication semantic is purely message-passing.

For faster communication in partitioned database, As illustrated in Figure 1b, BionicDB provides an on-chip message-passing method that can completely eliminate the overhead of software message-passing. As a result, multisite transactions, a remaining concern in partitioned databases, can be accelerated.

3.2 Hybrid Hardware-Software Approach

While software-only is inefficient for the challenges of memory stalls and communication, the heavy control-flow in transaction logic, such as conditional branches and dynamic loops, makes

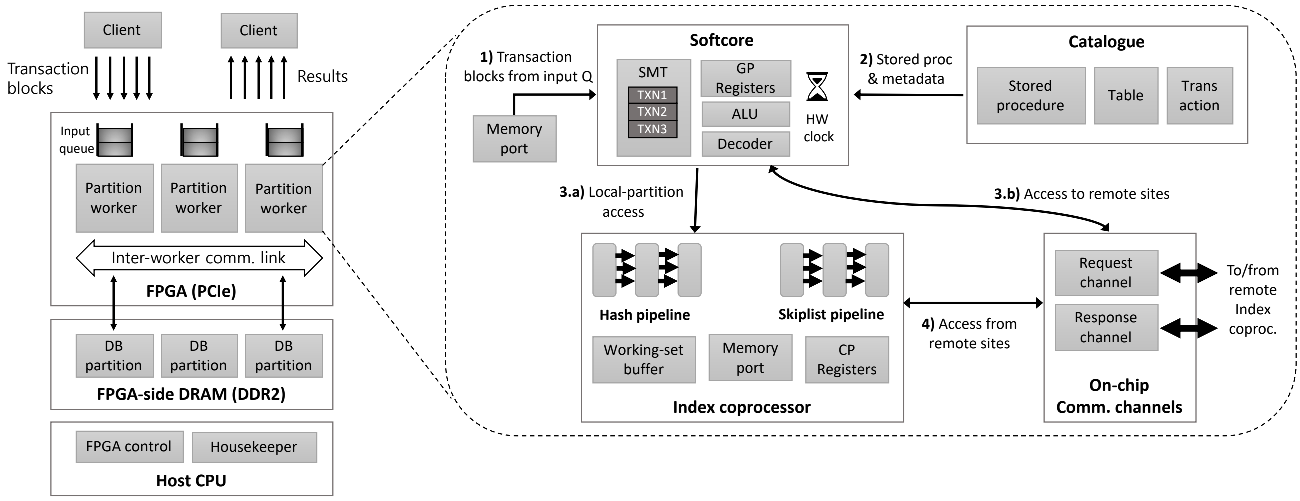

Figure 2: Architecture of BionicDB and the processing flow within a partition worker: 1) ingesting an input transaction block from memory, 2) fetching stored procedure code and metadata from the catalogue, 3.a) dispatching an index operation to the local index coprocessor 3.b) or to a remote site through the on-chip communication channels and 4) processing an index operation from remote workers.

general-purpose processor technology indispensable. This naturally leads to hybrid processor-accelerator approach that can deal with the inefficiency of both hardware-only (dynamic control-flow) and software-only (memory stalls, inter-worker communication) solutions.

The next question is how to integrate them. In our hardware environment where FPGA is connected through PCIe, the excessive PCIe latency (1us) between FPGA and host CPU can absorb most acceleration benefits. Therefore, we implement a custom softcore (microprocessor built around reconfigurable fabric) and acceleration fabric altogether on a PCIe-attached FPGA chip for tight integration, moving the majority of the OLTP components. The mission of the softcore is to execute pre-compiled stored procedures, while interacting with the index/communication acceleration fabric. As a result, hardware and software can closely collaborate, complementing each other. We design a custom core from the scratch, rather than using a vendor-provided softcore, to easily implement custom features and to integrate with the acceleration fabric more efficiently.

Although unexplored in this work, upcoming in-socket FPGA hardware [33] where FPGA is placed closer to host CPU is promising for hybrid software-hardware approach in that it allows to re-use existing software ecosystem, while enabling fast FPGA roundtrips thanks to low-latency interconnects, such as QPI.

4 ARCHITECTURE

4.1 Hardware Description

We build BionicDB on Micron HC-2 machine (formerly, Convey HC-2)[1] which contains four Xilinx Virtex-5 LX330 FPGA chips on a PCIe card and two-socket Intel Xeon X5670 processors. The memory subsystem of the FPGA card includes 64GB of DDR2 RAM, 8 memory controllers and 16 scatter-gather DIMMs. It can provide up to 80GB/s memory bandwidth for random 64-bit accesses when its 16 scatter-gather DIMMs are fully utilized with all FPGA chips enabled. However, current implementation of BionicDB uses only a single FPGA chip out of 4 and 8 DIMMs out of 16, bound by the maximum bandwidth of 10GB/s. It is also worth noting that in-memory OLTP is typically bound by memory latency, rather than bandwidth, due to small random accesses.

4.2 Overview

Figure 2 illustrates the architecture of BionicDB. BionicDB implements OLTP functionalities (stored procedure execution, indexing, concurrency control and transaction management) on a PCIe-attached FPGA chip, leaving a few background housekeeping jobs (signaling FPGA to start/stop, memory management, interactions with clients) to the host CPU. The database is partitioned, entirely residing in FPGA-side on-board DRAM. Each partition is accessed by a single partition worker in FPGA, and we fit multiple partition workers on a FPGA chip as many as its logic capacity allows for thread-level parallelism. The main components of a partition worker are 1) stored procedure execution engine and 2) acceleration fabric. The former includes the softcore and the catalogue that stores stored procedures and metadata, and the latter is composed of a local index coprocessor and communication channels.

We briefly describe the processing flow during transaction execution. The client should upload a pre-compiled stored procedure along with all metadata to the catalogue in advance. After that, the client can submit a transaction block to BionicDB for executing the transaction. Then, a partition worker fetches the transaction block from its input queue (step 1 in Figure 2). Once a transaction block arrives, the softcore fetches the corresponding stored procedure code from the catalogue and executes it (step 2 in Figure 2). During the execution of a stored procedure, it makes a database access by asynchronously passing an index request to the local index coprocessor or a remote site through the communication channels (step 3 in Figure 2). Meanwhile, the index operations issued by the local softcore (foreground requests) can be overlapped in the index coprocessor. The index operations from remote sites (background requests) also can be overlapped in the index coprocessor (step 4 in Figure 2). After a batch of transactions is entirely executed, the transactions are committed in serial order.

4.3 Softcore

In BionicDB, a transaction can be executed by invoking an associated stored procedure that is pre-compiled with BionicDB instructions (will be described in this section). Then, the softcore executes the instructions while interacting with the index accelerator where most performance gains come from.

Stored procedure execution. A stored procedure is composed of three parts: 1) transaction logic code, 2) commit handler and 3) abort handler. The first part represents the original transaction logic and the rest implements a commit protocol (currently, commit/abort handlers should be defined by users). Depending on the execution results during transaction logic, BionicDB moves on to either the commit or the abort handler.

Once a stored procedure is registered, a client can submit a transaction block to BionicDB to invoke the transaction at runtime. A transaction block contains a transaction ID, input data and buffers for result sets, intermediate data and transaction logs. When it receives a transaction block, the softcore executes the matching stored procedure code with the transaction ID, using the input data and buffers in the transaction block. In the example shown in Figure 3, the stored procedure (left) tries to search a tuple with a key at offset 0 and update a tuple with a key at offset 8 in the transaction block (right).

When generating a stored procedure, a compiler should translate SQL statements into machine code, as Hekaton does with T-SQL [14] (we used manually-written stored procedures, as the compiler is beyond the scope of this paper). A client can register a new transaction or change an existing one by uploading the stored procedure code to BionicDB along with metadata to work with, such as transaction information and table schema. It does not require FPGA reconfiguration that involves hours-long synthesis, so BionicDB can accommodate workload changes quickly.

Instruction set architecture. The instruction set of BionicDB is composed of a subset of typical CPU instructions and DB instructions that encapsulate index operations (see Table 2). Figure 4 briefly illustrates how the softcore processes each instruction type during stored procedure execution. CPU instructions are directly executed by the softcore in five steps as simple RISC CPUs do: Instruction Fetch, Decode, Execute, Memory and Writeback. We ruled out instruction pipelining and out-of-order execution as previous studies showed that such features do not translate into meaningful improvement in OLTP [6, 17].

Instruction	Type
INSERT	DB
SEARCH	DB
SCAN	DB
UPDATE	DB
REMOVE	DB
ADD/SUB/MUL/DIV/MOV	CPU
CMP	CPU
LOAD/STORE	CPU
JMP/BE/BLE/BLT/BGT/BGE	CPU
RET	CPU
COMMIT/ABORT	CPU

Table 2: BionicDB instructions. DB instructions invoke index operations provided by the index coprocessor.

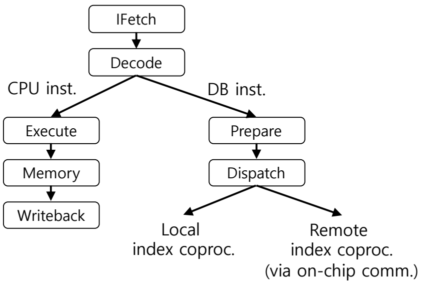

Figure 4: Instruction execution steps of the softcore.

DB instructions are added for invoking indexing services provided by the index coprocessor. For DB instructions, the softcore collects metadata in Prepare stage, such as index type (hash or skiplist) and transaction begin timestamp. In the next stage (Dispatch), the softcore passes the DB instruction with the metadata to the local index coprocessor or a remote one via on-chip communication channels, depending on the destination partition. DB instructions are asynchronously forwarded for overlapping multiple index operations.

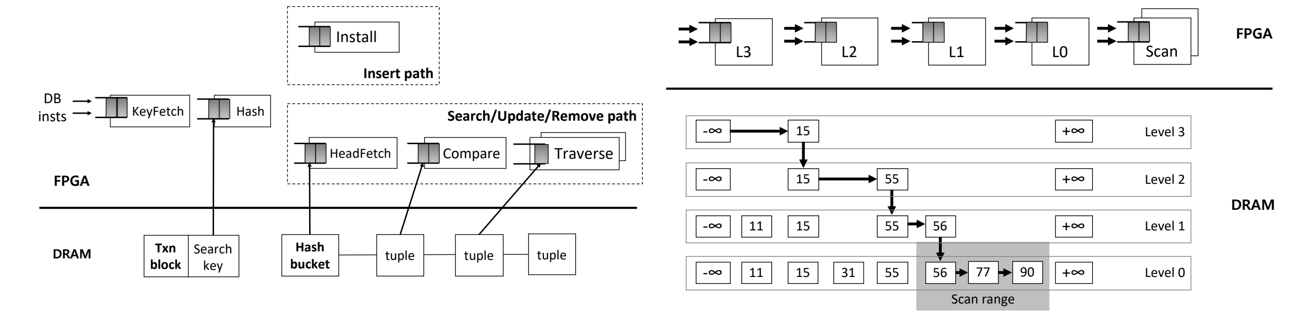
General-purpose registers (GP registers) are available to store data or pointers, and special-purpose registers, including a program counter (PC) and a status register that contains carry/zero/sign/overflow flags, are also available as typical CPUs. Additionally, coprocessor registers (CP registers) are provided; the result of a DB instruction is returned asynchronously to a CP register specified in the DB instruction. Then, the softcore can copy the result from the CP register to a GP register by executing a RET instruction. Therefore, a DB instruction must be paired with a RET instruction on the same CP register. The GP/CP register files are implemented on BRAMs, instead of flip-flops, for resource efficiency, and 256 GP/CP registers are provided to a single softcore. General-purpose cache memory was not implemented.

The addressing mode is base-offset. At the beginning of a transaction, a BionicDB worker sets a base address register with the start address of a transaction block and reaches memory locations within the block by adding the base address and an offset value. The offset value could be either the content of a GP register or an immediate value which is inlined to an instruction directly.

4.4 Index Coprocessor

The index coprocessor processes DB instructions from the local softcore or a remote one. The key technique for acceleration is hardware pipelining. We decompose an index algorithm into sub-functions that can work in parallel and implement each sub-function as a hardware pipeline stage. Each pipeline stage is a finite-state machine that is awakened on source data arrival from off-chip DRAM, performs a certain task, issues memory requests designating the next stage as a destination and moves on to the next incoming instruction. There could be multiple outstanding DB instructions between neighboring stages.

Index pipelining can overlap multiple index accesses, achieving higher memory-level parallelism. But pipeline hazards can happen when different stages access the same memory location. We describe details of each index and discuss how to prevent pipeline hazards in the following sections. Figure 5 shows the



(a) Hash index. Sub-functions of hash index operations are mapped to hardware pipeline stages.

(b) Skiplist. Sub-ranges of skiplist are mapped to hardware pipeline stages. Scan is done by dedicated modules.

Figure 5: Index pipelining to overlap multiple index accesses. Hash index deals with point access and skiplist provides range scan.

index pipelining with hash and skiplist indexes. For point access, BionicDB implements hash index that processes INSERT, SEARCH, UPDATE and REMOVE instructions. Skiplist index can handle SCAN instructions for range query, INSERT and REMOVE instructions. Both indexes support variable-length key.

4.4.1 Hash index for point access We illustrate how the HW hash index works in Figure 5a. KeyFetch stage takes a DB instruction and issues memory requests to fetch a search key from a transaction block, designating Hash stage as a destination. Then, the memory response containing the search key is queued at Hash stage. Hash stage takes the search key from its input queue, computes a hash value and loads a hash table entry with the hash value. (we use Sdbm hash function[2] for its minimal use of hardware resources; it requires neither a huge lookup table nor an expensive operation like modulo).

At this point, Hash stage forwards an INSERT instruction to Install stage and the other instructions to HeadFetch stage. For INSERT instruction, Install stage takes a hash table entry and appends a new tuple to the entry. For SEARCH/UPDATE/REMOVE instructions, HeadFetch stage checks the content of hash table entry. If the value is NULL indicating that there is no tuple installed, it returns a “NotFound" message to the destination CP register specified in the DB instruction. Otherwise, it issues memory requests to read the first item of a hash bucket. KeyComp stage compares the search key against the first item’s key. If they match, it examines visibility check (will be explained in Section 4.7) for concurrency control, otherwise, it passes the instruction to Traverse stage to follow a hash conflict chain.

Traverse stage follows a hash conflict chain until it finds a matching tuple or reaches the end of the chain. Unlike other stages that contain only computation without memory stalls, this stage could involve multiple memory stalls. Thus, Traverse could take much longer time with poorly distributed hashing. We decouple this stage from Compare stage so that an instruction that follows a long hash conflict chain does not block succeeding instructions that terminate at Compare stage. If hash conflict is frequent, multiple Traverse stages could be populated for balanced dataflow over the pipeline. Also, a hash function with good distribution and sufficiently large hash table could minimize the activation of Traverse stage by reducing hash conflicts.

Pipeline hazards and prevention. There are two hazards in hash index: insert-after-insert and search-after-insert (see Figure 6). In the former case, lost update can happen between in-flight inserts accessing the same hash table entry, if the following request reads a hash table entry before the preceding request updates it (see Figure 6a). Although not illustrated in the figure, a SEARCH instruction could read an inconsistent hash table entry at Hash stage before Install stage finishes updating it. In both cases, the reason for the hazards is that Hash and Install stages access the same hash table entry without coordination.

To prevent the hazards, we use a pipeline-stall based coordination scheme. BionicDB tracks the hash values of in-flight instructions that passed Hash stage in a lock table on BRAM (content-addressable memory could be used for faster check), and Hash stage checks the lock table before accessing a hash bucket. If a duplicate hash value is detected, it blocks until the lock entry disappears (see Figure 6b). The lock table entry is deleted by terminal stages when an instruction completes.

4.4.2 Skiplist for range scan For range scan, we choose skiplist because it is efficient with index pipelining for range scan (will be discussed later in this section). A skiplist index is a collection of linked lists at multiple levels [37]. A skiplist node (tower) includes a tuple and an array of pointers to the next towers at different levels. The bottom link is a list of all towers, while upper ones are short-cuts and contain towers with probabilistic distribution; the number of towers decreases exponentially from the bottom through the top, offering logarithmic time complexity on average for traversal by preferring to traverse taller towers first.

Traversal pipelining. BionicDB maps skiplist indexing on deeply pipelined datapath. Each pipeline stage covers an exclusive range of levels. We illustrate an example of index pipelining for skiplist in Figure 5b. In the example, four levels are mapped on four skiplist pipeline stages. The level 3 stage starts pointer chasing horizontally at the top level, stops at the tower having key 15 because its next tower contains an upper bound and drills down to the lower level. As it goes out-of-range, it passes the instruction to the next pipeline stage (level 2) and immediately moves on to the next incoming instruction. Meanwhile, level 2 stage takes over the instruction and performs same tasks within its coverage. The level 0 stage that exclusively owns the bottom level finally receives the request and locates the right tower for the given key, which is 56. For balanced pipelining, it is important to customize range binding properly. If skiplist towers are substantially sparser at upper levels than lower ones, upper pipeline stages could be assigned larger ranges.

Insert. During the traversal for INSERT instruction, the insert path, the pointers to the predecessor and successor towers at each

Figure 7: Skiplist hazard and prevention.

level below the new tower's height, is recorded in BRAMs. From the bottom level, the bottom-level stage installs a new tower on the insert path.

Scan. Scan does not require to record the path because it only needs to reach the bottom level. We assign a dedicated scanner module after the bottom-level stage. The bottom-level stage passes a scan request with the first tower in the scan range to the scanner. Then, a scanner collects committed and visible tuples within the scan range. The result scan set is stored in a designated buffer space in a transaction block (on DRAM), and the size of scan set is returned through a CP register. Like Traverse stage in hash index, decoupled scanner stages prevent long-running scan requests from blocking following requests that complete at the bottom-level stage. When necessary, redundant scanners could distribute heavy scan loads, ameliorating unbalanced dataflow.

Insert-insert hazard and prevention. In skiplist, only insert-insert hazard can happen. When consecutive inserts traverse down through common path, the traversal path of the following request could be invalidated when the preceding one has overwritten it with a new tower's address. Figure 7a shows an example of the insert-insert hazard. In the example, INSERT(D) request drills down a wrong tower (which is B) because the preceding insert C has not updated the tower at level 1. In turn, INSERT(D) installs a new tower on its inconsistent path, consequently, C is lost at level 1.

To prevent insert-insert hazard in skiplist, we apply a similar blocking policy to the hash index to prevent the skiplist hazard (see Figure 7b). For all in-flight INSERTs, we record the entry points of insert paths in a lock table. All skiplist pipelines should check the lock table before switching to the next tower or a lower level and block when encountering a locked traversal path. The lock is eliminated by the terminal stage (the bottom-level stage) when an INSERT operation completes.

Stall-free range scan. Unlike insert, skiplist scan can be stall-free, allowing efficient pipelining. A scan request might traverse down an inconsistent image of the skiplist, when missing towers installed by previous in-flight inserts at short-cut levels. However, all towers inserted previously are visible at the bottom link because a single dedicated pipeline stage serializes requests in order. After the bottom-level stage passes a scan request, a scanner starts pointer chasing from the first tower in the scan range. Therefore, scan does not miss any previous inserts in the end. During scan, the scanner could see towers inserted after scan started, but they are ignored by timestamp-based visibility check. In terms of performance, a scan request could choose a slower traversal path by missing recent short-cuts, but higher concurrency is more beneficial for overall performance.

4.5 Transaction Interleaving

The index coprocessor could be heavily underutilized with insufficient intra-transaction index parallelism when transactions are serially executed. As an extreme example, a single record transaction in key-value workloads that issues only a single index request can entirely eliminate the chance to overlap index accesses. To prevent the underutilization, the softcore exploits inter-transaction index parallelism by interleaving multiple transactions. We describe the details of transaction interleaving and discuss what factors could affect its efficiency.

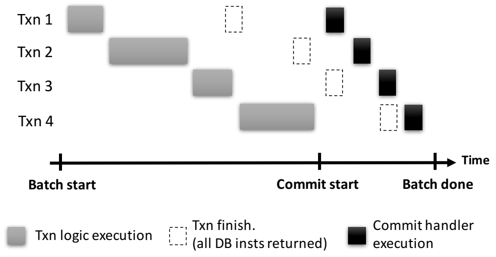

Figure 8: Transaction interleaving and 2 phase execution.

Transaction grouping. Whenever a transaction block enters the softcore, the softcore tries to add the transaction to the current batch as follows. It first checks the metadata in the catalogue to figure out how many GP/CP registers are required for the transaction. If there are enough registers remaining, the transaction joins the current batch with an exclusive range of GP/CP registers allocated. For the purpose, the softcore maintains the base GP/CP register addresses and renames the registers in the stored procedure instructions by adding the base register addresses. After that, the base register addresses are updated to indicate next available range, and the stored procedure is executed immediately. If the allocation fails, the current batch is closed and the new transaction is scheduled after the current batch commits.

Two-phase execution and interleaving. Figure 8 shows how interleaving is done. BionicDB executes transactions in two phases: 1) transaction logic and 2) commit/abort. Starting from the first transaction in a batch, the softcore executes a stored procedure code. When it reaches the end of a stored procedure, it saves the transaction context in a BRAM buffer, including program counter register, the base address of transaction block and register address range, and switches to the next transaction without waiting for outstanding DB instructions to complete.

When the first phase of a batch is finished by batch closure, it returns back to the first transaction and restores the context saved in the BRAM buffer. At this point, the program counter (PC) indicates the address of the first instruction of the commit handler. The commit handler then waits for all outstanding DB instruction to return. Depending on the results from them, the softcore continues to commit or jumps to the abort handler. Any exception, such as a DB instruction failure by CC or a voluntary abort, caught will trigger the abort handler. Then, the commit/abort handler performs a CC protocol to finish the transaction batch. After the second phase of a batch is finished, the softcore opens a new batch and executes the pending input transactions in the batch.

Discussion. With transaction interleaving, DB instructions across transactions can be overlapped. It is particularly beneficial for small transactions with insufficient intra-transaction index parallelism. Also, the overhead of transaction interleaving is marginal: transaction contexts are stored entirely in a context table on BRAMs, and a single switch takes 10 cycles to save current context and restore the next one from the context table.

The benefit of interleaving could be absorbed by data dependency within a transaction; data dependency is formed when a DB instruction requires an output from the previous DB instruction in the same transaction. Data dependency becomes a barrier that forces to wait for outstanding DB instructions to complete within a transaction, getting rid of the chance to overlap index requests in the next transactions. However, we found that current interleaving is still promising for certain workloads where transactions are small and data dependency-free (for example, YCSB transactions). To deal with heavy data dependency, it might be helpful to switch between transactions dynamically whenever desired, but current implementation does not support such dynamic scheduling.

4.6 On-chip Message-passing Channels

Partitioned databases, such as H-store and DORA, can minimize synchronization overhead across concurrent threads with single-threading policy; a partition is not thread-safe, but it is guaranteed to be accessed by a dedicated worker exclusively. Therefore, a partition worker cannot directly access a remote partition, instead, it should send a request message to a remote site. Then, a delegate worker on the remote partition processes the request on behalf of the initiator and returns a response message back. Hence, inter-worker message-passing is required when a transaction spans over multiple partitions.

To reduce the communication overhead and, thereby, accelerate cross-partition transactions, BionicDB provides on-chip message-passing channels. Unlike software message-passing that can include memory latency and thread synchronization during communication, request/response messages are directly exchanged between workers at on-chip speed without memory round-trips and thread synchronization. Despite the low clock frequency of FPGA, the communication latency is still low due to low-overhead message-passing protocol. The latency in exchanging a single pair of request and response messages takes 6 cycles in total (the latency could vary slightly depending on congestion). We believe that message-passing is a suitable communication semantic for single-threaded databases where data is strongly isolated between partition workers, while most CPUs have to conform the shared-memory semantic for backward compatibility.

Multisite transaction handling. Let us explain how a multisite transaction is processed using with the on-chip communication channels in detail. Each worker is assigned a communication link that consists of request and response channels. When the softcore decodes a DB instruction and finds out that the target partition is remote, it creates a request packet with the instruction and sends it through the request channel asynchronously. A request packet is piggybacked with a transaction timestamp for concurrency control and source/destination worker IDs for routing. At a remote site, a background unit monitors the request channel and catches an inbound request packet having a matching worker ID. In turn, the DB instruction is dispatched immediately to the remote index coprocessor as a background request. At this point, local (foreground) and remote (background) requests can be overlapped in the index coprocessor. But, it does not cause inconsistency because the index coprocessor is capable of dealing with pipeline anomalies and concurrency control. After completion of a background request, its result is sent back to the initiator through the response channel. The response message returned to the initiator is written back to the destination CP register asynchronously, and the initiator's softcore takes the result later when executing a RET instruction with the CP register.

Scaling on-chip message-passing. We discuss several scaling issues, leaving them to future work. First, the current topology of the on-chip communication is crossbar which does not scale. When scaling up BionicDB on datacenter-grade FPGAs that can fit tens or hundreds of BionicDB workers in a single chip (resource consumption will be provided in Section 5), a scalable on-chip communication topology, such as ring or tree, will be required. Also, BionicDB is currently a single-chip, single-node system.

Given that typical FPGA offerings have merely around tens of GBytes of on-board DRAM, it is vital to scale BionicDB across multiple FPGA nodes in a shared-nothing cluster like H-store [23]. Fortunately, some cloud FPGA services, such as AWS F1, support multi-chip, multi-node deployment[4]. Therefore, the message-passing channels should be diversified with additional connectivities for inter-node communication.

4.7 Concurrency Control

Currently, BionicDB employs a variant of the basic single-version timestamp CC [11]. Its strengths and weaknesses are well-known [47], but we use it for the sake of simplicity as CC is not the focus of this paper. A transaction is assigned a hardware timestamp value at the beginning. During transaction lifecycle, DB instructions issued by the transaction are packed with the transaction timestamp and passed to the index coprocessor. Then, visibility check is performed as follows by the index coprocessor against a matching tuple with the search key.

Visibility check. Each tuple is associated with latest read and write timestamps, and they are compared against the transaction timestamp when accessed. The read permission is granted on a tuple having a lower write time, and the write permission is granted on a tuple having a lower read time. If the transaction is the latest reader, read time of the tuple is updated with the transaction timestamp immediately. There are minor deviations from the original algorithm. First, any access to an uncommitted (dirty) tuple during runtime is blindly rejected without the care of the serial order and triggers transaction abort immediately. Also, read set is not buffered. If the second access to a previously visited tuple is denied by concurrent updates, the transaction should abort to ensure repeatable read.

If a DB instruction passes the visibility check, the address of the matching tuple with a “success" return code is written back to the CP register specified in the DB instruction. Otherwise, an error code is written. An UPDATE instruction only marks the dirty bit and returns without actual modification. With the tuple address returned, the softcore later performs in-place update after backing up the original tuple in UNDO log buffer in a transaction block. An REMOVE instruction returns after marking both dirty and tombstone bits.

Commit protocol. When a commit handler takes over the softcore after transaction logic execution, it collects the results from CP registers by executing RET instruction. If an error code is detected, the softcore jumps to the abort handler. After making sure successful execution, the softcore iterates write-set to cleanup dirty marks and overwrite their write time with the transaction's begin timestamp. If aborted, the abort handler restores the write-set from the UNDO logs in a transaction block and removes the dirty marks.

4.8 Logging and Recovery

Although logging and recovery are currently missing, we discuss a possible way to guarantee durability. BionicDB can adopt the VoltDB's command logging approach for recovery[29]. After executed by BionicDB, each transaction block contains the commit state and the commit timestamp of the transaction, preserving the input arguments. BionicDB can recover the database simply by re-executing the committed transaction blocks in the commit timestamp order. To this end, the host CPU should store the input transaction blocks that were processed in a durable storage before returning them to clients. After system failure, the host CPU should load the last checkpoint image and the persisted transaction blocks (command logs) from the disk. Then, the host CPU can replay the committed transaction blocks, ignoring the uncommitted ones. It must replay them in the commit timestamp order to ensure correct recovery. After recovery, the hardware clocks of BionicDB should be re-initialized to the latest commit timestamp, and the host CPU can signal BionicDB to resume transaction processing.

Figure 9: Comparison of overall performance of BionicDB to Silo on Xeon (4 chips).

5 EVALUATION

This section evaluates BionicDB for the following purposes.

- We show that BionicDB can provide high performance and substantial power saving in OLTP workloads, comparing to state-of-the-art SW system.
- We figure out how much speedup comes from each acceleration feature and which factors can limit the performance.

5.1 Experimental Setup

In all experiments, we fit the entire databases in DRAM. For BionicDB, we populated input transaction blocks in advance by host CPUs (ideally, remote clients should submit transaction blocks through network cards, and BionicDB should process them without the intervention of the host CPU). Unless stated otherwise, we report the aggregate throughput of four BionicDB workers.

5.2 Hardware

Xilinx Virtex5 LX330. We built BionicDB on a single Virtex5 LX330 FPGA chip which was manufactured with 65nm technology and released a decade ago. It contains merely 200K logic cells, allowing to fit only four BionicDB workers within a single chip. However, recent datacenter-grade FPGA chips containing millions of logic cells, such as Xilinx Virtex Ultrascale+ used in AWS F1 instances or Intel Arria 10, could accommodate tens or hundreds of BionicDB workers with a single chip [2, 5], providing ample thread-level parallelism. The clock frequency of BionicDB was set to 125MHz.

Intel Xeon E7 4807. To compare BionicDB to a software engine, we ran Silo[43] on 4 hexa-core Xeon chips (24 physical cores in total). Its clock frequency is 1.87GHz, and each core is assigned private 32KB L1I/D cache and 256KB L2 cache. L3 cache is 18MB and shared by all cores on a chip. In choosing a CPU for comparison, our focus was making sure the CPU is roughly in the same generation with Virtex5 for fairness. Xeon E7 4807 was released later (in 2011) than Virtex5 and manufactured with more advanced process technology (32nm).

5.3 Benchmarks

TPC-C. We ran a mix of the TPC-C NewOrder and Payment (50:50). Most transactions are local, but 1% of the NewOrder and 15% of the Payment transactions are cross-partition by default. We partitioned the database by Warehouse and replicated Item table which is read-only across partitions. The number of partitions was fixed to the number of workers. We modified the Payment transaction by enforcing to pick up a customer with *customer id* for both BionicDB and Silo.

YCSB. The YCSB transaction includes 16 independent DB accesses with no data dependency. The YCSB table schema consists of a 8B integer key and 1KB payload. We populated 300K records per partition, and the size of a partition is 300MB (the number of partitions is equal to the the number of workers). We ran the YCSB-C (read-only) and YCSB-E transactions. The YCSB-B (read-intensive) was ommitted due to similar results to YCSB-C. We modified the YCSB-E transaction to make it scan-only and fixed the scan range to be 50 records which is the average scan length with the default workload setting.

5.4 Overall Performance

We compared the overall performance of BionicDB and Silo in Figure 9. As explained in Section 5.1, we only presented BionicDB from 1 to 4 workers because of limited logic capacity of Virtex5 FPGA. In Figure 9a, we ran YCSB-C transactions. With the same number of workers, BionicDB outperformed Silo by 4.5x. Silo matched the throughput of 4 BionicDB workers with 24 cores enabled over 4 CPU chips. YCSB-C transaction exploited both intra-, inter-transaction parallelism provided by index pipelining and transaction interleaving thanks to sufficient index parallelism and the absence of data dependency that permits aggressive transaction interleaving.

We also ran a mix of the TPC-C NewOrder and Payment (50:50) and plotted in Figure 9b. Unlike the YCSB result, BionicDB achieved only comparable performance to Silo with the same number of workers because of insufficient index parallelism of Payment transaction (only 4 index lookups) and heavy data dependency that nearly eliminated the chance for transaction interleaving (in fact, the TPC-C transactions were executed almost in serial).

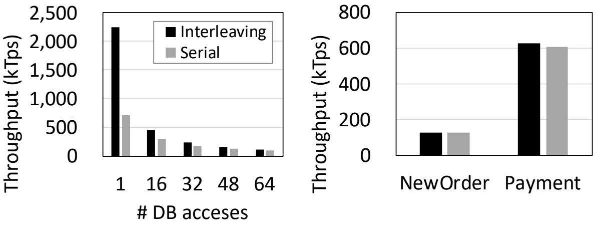
These results reveal both the promise and challenge of BionicDB at the same time. BionicDB can outperform state-of-the-art SW OLTP system when fully utilized, but it can be underutilized by insufficient index parallelism and heavy data dependency. However, the results confirm that BionicDB can provide still competitive performance even with much lower frequency (125MHz) and a limited microprocessor (no instruction-level parallelism and general-purpose cache memory), by taking a suitable acceleration approach for OLTP. From the next section, we evaluate each acceleration component to understand their impacts quantitatively.

5.5 Impact of Index Pipelining

We evaluated index pipelining in Figure 10 and Figure 11, We controlled the degree of coprocessor parallelism by changing the maximum number of in-flight DB requests over the index coprocessor. To focus on the index coprocessor, all experiments in this section run local transactions only.

Hash. In Figure 10a, we ran a non-transactional key-value workload to see the peak performance of the hash index. A single transaction repeated issuing 60 insert/search instructions in bulk for 20,000 times (in total 1.2M inserts and searches). The peak performance for insert and search reached 8.5Mops and 7Mops, respectively, and saturated between 12 and 16 index parallelism. This implies that there were 3 or 4 in-flight requests between pipeline stages in average.

We plotted the throughput of the YCSB-C (read-only) and the TPC-C NewOrder transactions in Figure 10b and Figure 10c. Both figures show the similar trend with the previous result in the



(a) YCSB-C (b) TPC-C

Figure 12: Transaction interleaving vs. serial execution.

KV workload. It proves that the transactions have sufficient intra-transaction parallelism. Figure 10d shows the performance of the TPC-C Payment transactions. Due to the limited index parallelism, the performance did not improve after 4 requests.

Skiplist. We instantiated 8-stage skiplist pipelines with an extra scanner module. The maximum height of a skiplist tower was set to 20. Figure 11a shows the performance of sequential loading. The pipeline was saturated at 8 in-flight requests. It increased sharply from 1 to 4 and modestly from 4 to 8 requests. The reason for lower pipeline parallelism than hash index is that skiplist pipeline stages contain multiple memory stalls during horizontal pointer chasing, leaving nearly no in-flight requests between stages, unlike the hash pipeline. Hence, the index parallelism was bound by the depth of pipeline. The modest curve from 4 to 8 in-flight requests is related to unbalanced dataflow over skiplist pipeline. Pipeline stages covering upper levels were less busy than lower levels as towers were sparser. Figure 11b shows the performance of point query. It shows similar trend with the previous result, but the throughput is higher because tower installation was skipped.

To measure scan performance, we ran modified YCSB-E transactions (Section 5.1) and presented the performance in Figure 11c. We can find that the pipelining efficiency was deteriorated. This is because a single scanner became a bottleneck in the pipeline. Thus, heavy scan loads should be distributed over multiple scanners for balanced pipelining. In Figure 11d, we compared the scan performance to Masstree and SW skiplist on the Xeon CPU introduced in Section 5.1. The number of workers was four across all indexes. Since its pipelining efficiency was largely eliminated, HW skiplist was slower than Masstree by 20% and SW skiplist by 5x. With extra FPGA resources, HW skiplist could be improved with deeper pipelining and multiple scanners (in this experiment, pipelining depth and the number of scanners were bound by current FPGA resource). To catch up with SW skiplist, at least 5 scanners would be required.

5.6 Impact of Transaction Interleaving

Figure 12 shows the performance comparison between transaction interleaving and serial execution. In this experiment, all transactions were local. In Figure 12a, we changed the the size of transaction footprint, or intra-transaction parallelism, by varying the number of DB instructions in a YCSB-C transaction. With a single record transaction, transaction interleaving was 3x faster than serial execution. In serial execution, the coprocessor was underutilized by small transactions. Whereas, transaction interleaving was able to overlap index requests across transactions, resulting in much higher utilization. As we increase the number of requests, the performance gap shrank. This is because coprocessor was utilized better in serial execution with more intra-transaction parallelism.

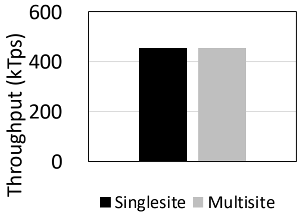


Figure 13: Single-site (100% local access) vs. multi-site transaction (75% remote, 25% local access).

Figure 12b illustrates the throughput of the TPC-C NewOrder and Payment transactions. In both transactions, there was no noticeable difference because heavy data dependency hindered transaction interleaving. The NewOrder transaction had enough intra-transaction index parallelism, but failed to exploit inter-transaction parallelism due to data dependency, leaving the coprocessor idle during commit phase. The Payment transaction's case was worse. It was not able to exploit both intra-, inter-transaction parallelism because of limited parallelism and data dependency combined, leading to significant underutilization. It is also evidenced by the modest difference in overall performance from the YCSB-C transaction that includes four times more index roundtrips.

5.7 Impact of On-chip Message-passing

Latency analysis. Table 3 compares the communication latency of on-chip message-passing against software message-passing. We assumed 20ns and 80ns for the latency of shared-cache and DDR3, respectively. Based on the estimates, we calculated the total communication latency for exchanging a single request/response pair that takes two iterations of message-passing, assuming that cache communication takes two cache reads on a modified-state cacheline, and DRAM communication takes two rounds of memory read and write. Despite the slow frequency (125MHz), the latency of on-chip message-passing is 48ns which is comparable to cache communication and much faster than DDR3 communication. If cache miss happens, the latency of software communication can rapidly increase. Also, we did not take synchronization cost into account, giving favor to software message-passing. In practice, software message-passing could suffer much higher communication latency in the presence of cache misses and thread contention.

Primitive		Latency (ns)	Total comm. delay (ns)
On-chip MP		24	48
Software MP	L3 cache	20	40
	DDR3	80	320

Table 3: Latencies of message-passing methods.

Throughput of cross-partition transactions. It is widely known that frequent multisite transactions in non-partitionable workloads can be a serious bottleneck in partitioning-based systems. We now evaluate the performance of multi-site transactions to see if the on-chip message-passing can accelerate them. We ran the cross-partition YCSB-C transactions with uniform random keys and plotted the throughput in Figure 13. In the cross-partition transaction, 75% of DB accesses are remote, and the rests are local accesses. As an ideal case, we also plotted the performance of local transactions that do not involve inter-worker communication at all. The result shows that on-chip, message-passing communication imposed negligible overhead, achieving almost same performance with the ideal case. In all other workloads, we observed the same result. This confirms that the message-passing, on-chip communication of BionicDB eliminated the overhead of communication and accelerated cross-partition transactions effectively.

5.8 Power Consumption and Resource Utilization

We estimated the power consumption of BionicDB on Virtex5 LX330 with Xilinx Power Estimator (XPE). The total power consumption was approximately 11.5W. The thermal design power (TDP) of a single Xeon E7 4807 is 95W, and the aggregate TDP of four chips is 380W.

Module	Flip-flops	Look-up tables	Block RAMs
Hash	12,932	14,504	24
Skiplist	27,300	35,968	36
Softcore	7,080	8,796	12
Catalogue	1,484	1,964	8
Communication	2,482	3,191	8
Memory arbiters	1,192	5,800	0
HC-2 modules	98,507	76,639	103
Virtex5 LX330 Total	207,360	207,360	288
Utilization	72%	70%	70%

Table 4: Resource utilization of BionicDB with 4 workers

Table 4 reports the resource utilization of BionicDB with four workers on a Virtex5 LX-330 chip. The entire hardware design consumed around 70% of FFs, LUTs and BRAMs. Almost half of the total logic cells were taken by HC-2's infrastructures, such as host interface, crossbar memory interconnects and a custom processor which were not used by BionicDB at all. Four BionicDB workers consumed approximately 70k LUTs and 53k FFs in total. Out of BionicDB resources, the skiplist index consumed almost 50%, and hash index consumed around 20%. The stored procedure execution modules, the softcore and catalogue, took only 15% thanks to the resource-efficient design choices.

6 RELATED WORK

Many existing database accelerators have focused on offloading SQL computation. They commonly exploit massive fined-grained parallelism for compute acceleration, avoiding instruction decoding overhead and memory wall. (application-specific functions are wired on datapath directly, and data stream flow over them) [18, 27].

Oracle SPARC M7 processor integrates in-memory database acceleration fabric (DAX), offloading filtering and de/compression [3]. Ibex[44] is a FPGA-based MySQL storage engine that offloads filtering and aggregation functions to FPGA. It provides the notion of near-data processing by placing the SQL accelerator between CPU and SSD. Bharat et al., suggested FPGA coprocessor for OLAP acceleration in in-memory HTAP system [41]. They offloaded filtering and data decompression to FPGA coprocessors on a PCIe board while the host CPU focus on transaction processing. The FPGA coprocessor directly accesses compressed memory-resident data, decompresses them, and performs filtering. To saturate PCIe bandwith, data scan tiles are replicated. Q100[45] is a dataflow hardware for SQL. ASIC tiles that perform SQL operators are provided, along with a custom instruction set to control data stream over the tiles. DoppioDB offloaded regular expression evaluation and analytic operators on Intel's Xeon-FPGA machine [33, 39]. Do et al. explored in-storage SQL processing inside flash memory SSD [15], but the system used embedded processors for acceleration without custom hardware. Kocberber et al. suggested Widx which is an on-chip hash indexing accelerator for OLAP workloads [26]. They identified hash index lookup as the main bottleneck due to poor memory-level parallelism in OLAP workloads and offloaded the it to on-chip acceleration fabric.

For stream acceleration, Glacier[30] implemented SQL circuits on an FPGA fabric, installed on datapath between network card and host CPU. Handshake join [42] is a highly parallel stream join algorithm with massive parallel processing resources such as FPGA or GPGPU. The key idea is fine-grained parallel join processing between two streams flowing from the opposite directions. A large number of tuple pairs are evaluated at once, exploiting massive computation parallelism. FQP[31] is a flexible stream query processor that can support changing query logic without FPGA reconfiguration. It implemented filtering and stream join operators.

For transaction processing, there have been a few studies with custom hardware approach. Cipherbase uses FPGA as a coprocessor for security, offloading expression evaluation, some index operations and en/decryption [9]. Also, there have been hardware key-value store systems with hash index [10, 13, 22, 46] and transactional graph processing on FPGA [28]. However, standalone transaction processing hardware is still missing in the landscape. Many existing SQL accelerators do not solve OLTP's main problems: memory stalls and communication. Low-end processor, such as ARM, could be a power efficient option, but it often sacrifices performance [40].

7 CONCLUSION

In this paper, we explored hardware specialization for OLTP and presented the design and implementation of BionicDB built on FPGA. We discussed index pipelining and transaction interleaving for index acceleration, and on-chip message-passing for faster communication in partitioned databases. Also, we argued that OLTP requires tightly integrated SW-HW architecture. The experimental results confirmed that transaction processing can be done at substantially lower power cost while providing competitive performance. Possible future directions include scaling up BionicDB on a modern FPGA chip and scaling out over multiple chips and nodes.

Hyrise Re-engineered: An Extensible Database System for Research in Relational In-Memory Data Management

Markus Dreseler, Jan Kossmann, Martin Boissier, Stefan Klauck,
Matthias Uflacker, Hasso Plattner

ABSTRACT

Research in data management profits when the performance evaluation is based not only on individual components in isolation, but uses an actual DBMS end-to-end. Facilitating the integration and benchmarking of new concepts within a DBMS requires a simple setup process, well-documented code, and the possibility to execute both standard and custom benchmarks without tedious preparation. Fulfilling these requirements also makes it easy to reproduce the results later on.

The relational open-source database Hyrise (VLDB, 2010) was presented to make the case for hybrid row- and column-format data storage. Since then, it has evolved from being a single-purpose research DBMS towards becoming a platform for various projects, including research in the areas of indexing, data partitioning, and non-volatile memory. With a growing diversity of topics, we have found that the original code base grew to a point where new experimentation became unnecessarily difficult. Over the last two years, we have re-written Hyrise from scratch and built an extensible multi-purpose research DBMS that can serve as an easy-to-extend platform for a variety of experiments and prototyping in database research.

In this paper, we discuss how our learnings from the previous version of Hyrise have influenced our re-write. We describe the new architecture of Hyrise and highlight the main components. Afterwards, we show how our extensible plugin architecture facilitates research on diverse DBMS-related aspects without compromising the architectural tidiness of the code. In a first performance evaluation, we show that the execution time of most TPC-H queries is competitive to that of other research databases.

1 INTRODUCTION

Hyrise was first presented in 2010 [19] to introduce the concept of hybrid row- and column-based data layouts for in-memory databases. Since then, several other research efforts have used Hyrise as a basis for orthogonal research topics. This includes work on data tiering [7], secondary indexes [16], multi-version concurrency control [42], different replication schemes [43], and non-volatile memories for instant database recovery [44].

Over the years, the uncontrolled growth of code and functionality has become an impediment for future experiments. We have identified four major factors leading to this situation:

- Data layout abstractions were resolved at runtime and incurred costs that sometimes had a disproportional overhead.
- Prototypical components have been implemented to work in isolation, but did not interact well with other components.
- The lack of SQL support required query plans to be written by hand and made executing standard benchmarks tedious.
- Accumulated technical debt made it difficult to understand the code base and to integrate new features.

For these reasons, we have completely re-written Hyrise and incorporated the lessons learned. We redesigned the architecture to provide a stable and easy to use basis for holistic evaluations of new data management concepts. Hyrise now allows researchers to embed new concepts in a proper DBMS and evaluate performance end to end, instead of implementing and benchmarking them in isolation. At the same time, we allow most components to be selectively enabled or disabled. This way, researchers can exclude unrelated components and perform isolated measurements. For example, when developing a new join implementation, they can bypass the network layer or disable concurrency control.

In this paper, we describe the new architecture of Hyrise and how our prior learnings have led to a maintainable and comprehensible database for researching concepts in relational in-memory data management (Section 2). Furthermore, we present a plugin concept that allows testing different optimizations without having to modify the core DBMS (Section 3). We compare Hyrise to other database engines, show which approaches are similar, and highlight key differences (Section 4). Finally, we evaluate the new version and show that its performance is competitive (Section 5).

1.1 Motivation and Lessons Learned

The redesign of Hyrise reflects our past experiences in developing, maintaining, and using a DBMS for research purposes. We motivate three important design decisions.

Decoupling of Operators and Storage Layouts. The previous version of Hyrise was designed with a high level of flexibility in the storage layout model: each table could consist of an arbitrary number of containers, which could either hold data (in uncompressed or compressed, mutable or immutable forms) or other containers with varying horizontal and vertical spans. In consequence, each operator had to be implemented in a way where it could deal with all possible combinations of storage containers. This made the process of adding new operators cumbersome and led to a system where some operators made undocumented assumptions about the data layout (e.g., that all partitions used the same encoding type). Instead of relying on operators to properly process data structures with varying memory layouts, Hyrise now follows an iterator-based approach. By accessing data through iterators, the implementation of new operators is decoupled from the implementation of new data storage concepts without compromising the flexibility. Operators can implement custom specializations for specific iterators, but execution falls back to the default iterator if no implementation exists. The iterator abstraction is explained in Section 2.3.

10.5441/002/edbt.2019.28

Benchmarking. Just as modern software development processes require that fundamental development steps, such as setting up the environment, building the code, and running tests should require only one step each, we believe that the same is true for benchmarks. This might seem obvious, but in our experience, also with other databases, both productive and research, this is almost never the case. In Hyrise, benchmarks are now single binaries that generate their data, run the queries, and print the results. As of writing, the TPC-H benchmark is included in the code base; the alternative data generator JCC-H [8], as well as the TPC-C and Join-Order [30] benchmarks are work-in-progress. Custom benchmarks can be easily added by creating table and query files, which are automatically executed by a generic benchmark runner (cf. Section 2.10). To facilitate reproducibility, all benchmark results contain the parameters relevant to their execution, including the Git commit hash, information about the utilized scheduler, thread count, and more. Benchmarks are executed by the CI process for each commit on the master branch to aid in the identification of performance regressions.

Memory Management & Metaprogramming. When the development of Hyrise started 10 years ago, C++11 was not yet finalized. This meant that memory management had to be done manually using *new/malloc* and *delete/free*, resulting in spurious segmentation faults and considerable debugging efforts. In the new version, Hyrise almost exclusively uses shared or unique smart pointers, which guarantee that objects are only deleted right after there is no remaining pointer to them. The overhead of reference counting for shared pointers seems to be well justified by the noticeable reduction in time spent on debugging memory management issues. Only when these pointers become an actual bottleneck, we look into whether the memory management in that particular component can be made more explicit.

Hyrise employs template metaprogramming to decouple the supported data types, storage layers, encoding types, and operators while at the same time preserving a high degree of compile-time type safety. We use `Boost.Hana` to automatically generate code for the different supported data types and for the resolution of our iterators. Mostly because of this, but also because of other C++17 features that are used all over the code base, Hyrise can only be compiled with current versions of GCC and Clang.

1.2 Building a Database with Students

We believe that the best way to learn about database systems is to program them yourself. Therefore, in addition to our PhD research projects, we use Hyrise in a graduate-level database class in which students develop, integrate, and test new features, such as additional join implementations, optimizer rules, or index structures. Not only does this hands-on experience help their understanding of databases and improve their programming skills; it also raises their interest to research database topics in greater depth, for example as part of their Master's theses. As a result, a considerable fraction of the Hyrise code has been developed together with students as part of their class assignments or thesis work.

Developing a database with students also entails one of the main challenges in the process, which is a relatively short developer turnover time. Even those Master's students who decide to specialize in the field rarely spend more than two years on the project. We address this challenge with strict code reviews, a high degree of test coverage (currently at >85%), and by encouraging new students to highlight existing components that are difficult to understand. On the technical side, we use automatic formatting (clang-format), multiple linting tools (cpplint and clang-tidy), sanitizers (ASan, UBSan, TSan, and Memcheck), and enforce most compiler warnings (`-Wall -Wextra -pedantic -Werror`).

The main criterion for building a maintainable research DBMS is that students without prior database knowledge can be brought up to speed and contribute code in six weeks. The fact that we were able to prove this repeatedly in our database seminars shows us that we are on the right track.

2 SYSTEM ARCHITECTURE

In this section, we give an overview of the new architecture of Hyrise. In places where it improves clarity, we refer to the original Hyrise architecture as *Hyrise1* and to that of the rewritten DBMS *Hyrise2*. After a general description of the high-level architecture, which follows the visualization in Figure 1 and focuses on query execution, we describe major components in their respective subsections, which are also given in the figure.

We decided to make as much functionality and as many components optional as reasonably possible. This decision is based on a learning from Hyrise1, where we found it difficult to isolate the root of performance issues because of the number of involved components. In Hyrise2, even core concepts, such as optimization, concurrency control, or scheduling, can be disabled. Without an optimizer, queries get executed close to how they are defined in SQL; for example, joins are only identified if `JOIN ... ON ...` is used. If MVCC is turned off, all tables are read-only, do not store information with regards to transactions or concurrency, and validation operators are not inserted into the query plan. If the scheduler is turned off, tasks are immediately executed in the same thread (while still guaranteeing progress). Similarly, Hyrise2 can be benchmarked with and without the just-in-time compiler, the network interface, or logging.

2.1 General Overview

Figure 1 shows the core components of Hyrise. We discuss them by following the process of answering a user-provided SQL query. Users have three options to submit queries to Hyrise. As a first option, we provide a command line interface, which can not only be used to submit queries, but also offers convenience functions for generating TPC-C or TPC-H benchmark tables, visualizing query plans, and toggling optional Hyrise components. As a second option of interacting with the database, Hyrise has an integrated TCP/IP server implementing the wire protocol of PostgreSQL. Users can send queries using PostgreSQL's interactive terminal *psql* or existing drivers for PostgreSQL. More details on how this interface is designed and implemented can be found in Section 2.5. Lastly, the third option is the SQL-C++ interface, which is used by our benchmark binaries (cf. Section 2.10) and also enables hand-written optimization of query plans. Currently, the benchmark binaries use the SQL-C++ interface. We are working on a benchmark implementation that utilizes the network interface.

All of the three entry points hand the user's SQL string to Hyrise's SQL Pipeline (cf. Section 2.6), which consists of multiple steps that transform the provided SQL string to an efficient query plan. The *SQL Parser* translates the SQL string to an abstract syntax tree expressed as C++ data structures. Next, the *SQL to LQP Translator* changes the abstraction level by creating a logical query plan (*LQP*), which is a directed acyclic graph (DAG) whose nodes loosely resemble the operations of the relational algebra. Finally, the *Optimizer* applies a series of rules to the LQP, which

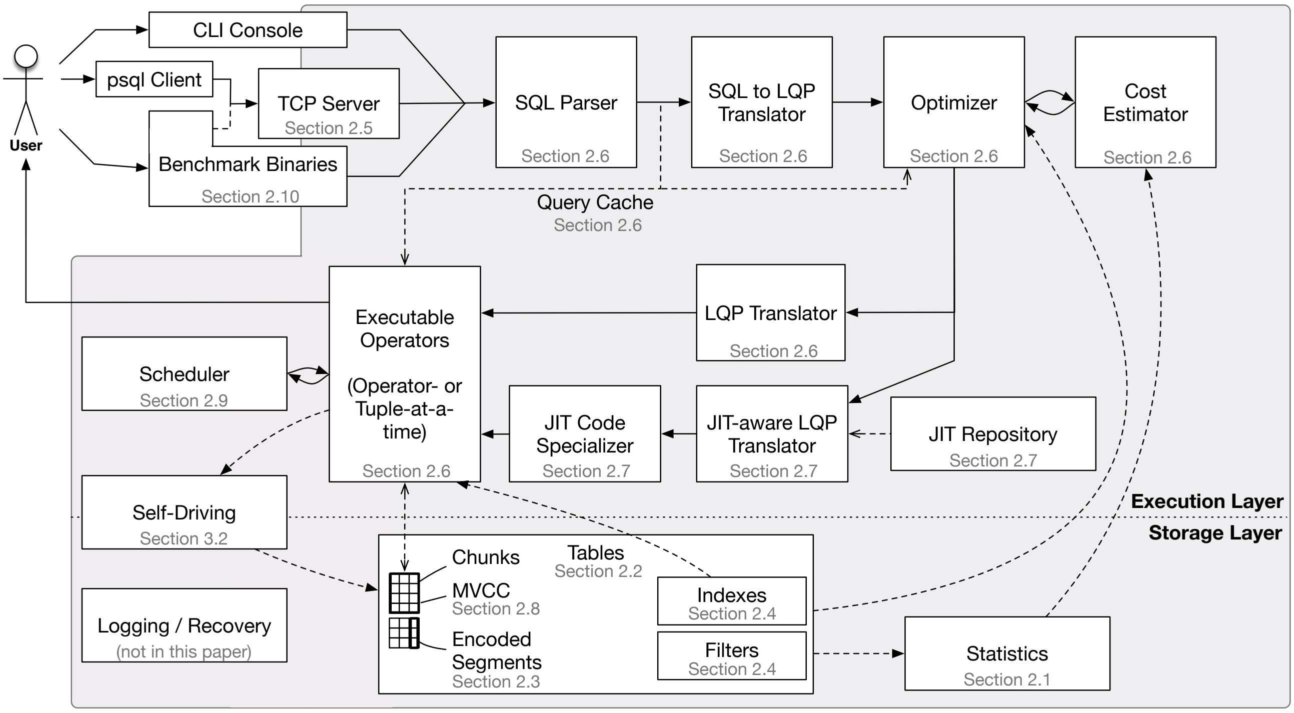

Figure 1: Hyrise Architecture Overview.

transform it into a more efficient, semantically equivalent version of the query. Some rules work by simply applying logical properties of the query plan (e.g., single-table predicates should almost always be pushed below joins), while others utilize information about the referenced tables that is only known at runtime. This information is collected from auxiliary data structures, such as general *statistics*, *indexes*, and *filters* (cf. Section 2.4). At the time of writing, statistics rely on histograms (equal height, equal width, equal distinct count) and other simpler metrics, e.g., the number of distinct values. Filters are probabilistic data structures that support approximate membership queries and allow the pruning of chunks (i.e., logically ruling out the necessity to access a chunk for a given predicate), whereas indexes return qualifying positions for a certain predicate directly without scanning through the data.

Hyrise implements a query plan cache, which can store both logical and physical query plans. Thereby, translation and optimization can be skipped to avoid doing these steps repeatedly for the same queries. While the cache does not yet auto-parameterize incoming queries, users can use prepared statements for queries with varying parameters. Both implicitly cached queries and prepared statements use the same caching data structures and shortcuts shown in the figure.

After optimization, the LQP is passed to the *LQP Translator*, which translates logical operators (such as predicates, joins, and sorts) to physical operators. Physical operators are concrete implementations of the logical concepts and more than one implementation might exist for a logical operator. For example, we implement joins as either sort-merge joins (cf. [2]), hash joins (cf. [4]), or nested-loop joins. Based on the optimizer's hints, one of these implementations is chosen for each logical operator. The result of the LQP Translator is another DAG, which we call Physical Query Plan (*PQP*). If the just-in-time compiler (cf. Section 2.7) is enabled, the LQP is not passed to the LQP translator, but to a *JIT-aware LQP Translator*, which creates JIT operators whose code is specialized using runtime information.

In both cases, the resulting PQP is then handed to the scheduler, which takes care of executing the translated operators. Once all operators have been executed, the resulting table is returned to the user.

Having looked at the entities that make executing a query possible, we now go over the data structures that are accessed for this. During execution, the primary table data as well as secondary data structures such as *indexes* are accessed by the operators. Tables are horizontally partitioned into *chunks*. Within a chunk, we have vertical partitions called *segments* where the segments across all chunks constitute the columns. Data within a segment might be encoded (cf. Section 2.3), for example using dictionary or run-length encoding. Additionally, chunks hold the data needed for multi-version concurrency control (MVCC, cf. Section 2.8). For more information on our storage layout refer to Section 2.2.

There are two more components shown in Figure 1: Self-Driving and Logging / Recovery. We envision future database systems to be self-driving [26], meaning that they autonomously adjust their configurations. Therefore, a *self-driving* component that assesses the database's current workload and tunes the configuration accordingly is part of Hyrise as well. This component is explained in more detail in Section 3.2. *Logging and recovery* are currently work-in-progress and are not described in this paper.

2.2 Storage Layout

Hyrise1 offers hybrid layouts, providing a maximum of flexibility with regards to storage layouts. This flexibility causes increased system complexity as well as runtime overhead by introduced abstractions. While the underlying system architecture of Hyrise2 supports hybrid layouts, we focus on columnar-oriented data for now. Figure 2 depicts the storage layout for an example table.
