Storage layouts for HTAP database must support efficient read and write operations. This is often achieved by separating the data into read- and write-optimized partitions. Data is always added to write-optimized partitions. Update and delete operations invalidate entries in read-optimized partitions. From time to time, data has to be moved from write- to read-optimized partitions.

This transformation may happen by merging data of write-optimized partitions into read-optimized partitions [15, 27]. Merging may require re-encoding of already compressed data. Furthermore, the merge algorithm introduces implementation-specific complexity. For example, modifications to currently merged data have to be handled. In addition, the same data is encoded repeatedly during consecutive merge processes. Last, merge costs increase with the size of involved partitions.

To avoid a merge process in Hyrise2, tables are implicitly divided into *Chunks*, horizontal partitions of a certain size. Optimal chunk sizes are both data- and workload-dependent. A self-driving database system would decide on these autonomously. So far, our experiments showed suitable sizes to be between roughly fifty thousand and a few million records. The optimal chunk size is largely independent of the width of the table, both in terms of data sizes and number of columns in our default setup, where a column-based layout and dictionary encoding are used.

There are two types of chunks, mutable and immutable chunks. Initially, chunks are mutable and append-only containers. Data is added in a plain, unencoded fashion. When a chunk's capacity is reached it becomes immutable. Once this happens, encodings (cf. Section 2.3) can be asynchronously applied. Chunks encapsulate fractions of all of the table's columns, so-called segments.

There are a couple of advantages of the chunk-based approach. First, by implicitly partitioning the data, both multiprocessing (one core processes one chunk) and data placement, e.g., in NUMA environments, are simplified. Chunks can easily be distributed over multiple NUMA nodes, thereby leveraging multiple memory busses and CPUs for simultaneous processing.

Furthermore, auxiliary data structures like indexes and filters can be created on a per-chunk basis. Thus, these data structures are only created for those chunks where they yield a certain benefit. It also offers the flexibility to create different structures, for example, different index types for different chunks. The same can be applied to encodings: Some segments of a column might stay unencoded, others dictionary-encoded, and further segments run length-encoded.

Chunks are implicitly prunable entities. Thereby, in some cases, they can be excluded early from query processing without having to process the contained data. This can be achieved by using approximate membership query properties of filters (cf. Section 2.4) or characteristics of certain encoding types.

Partitioning the data into chunks has some drawbacks that need to be mitigated. First, it introduces the memory cost of storing per-chunk metadata. If, however, chunk sizes are chosen to be hundreds of thousands or millions of rows, this is not an issue as we show in Section 5.2. Second, for some encoding types, chunks may introduce redundant storage of information. For example, chunks encoded using the dictionary encoding store values that occur in all chunks over and over again in every chunk-local dictionary. On the other hand, if the overlap of values across chunks is low, the size of the dictionary can be kept low, and the number of needed bits for the attribute vector is reduced. Thus, choosing the optimal chunk size is a tradeoff between memory overhead and flexibility.

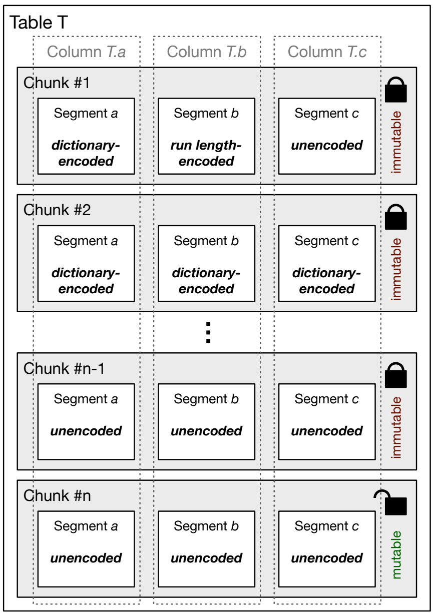

Figure 2: Depiction of Hyrise's storage layout for an exemplary table T with *n* chunks and three attributes.

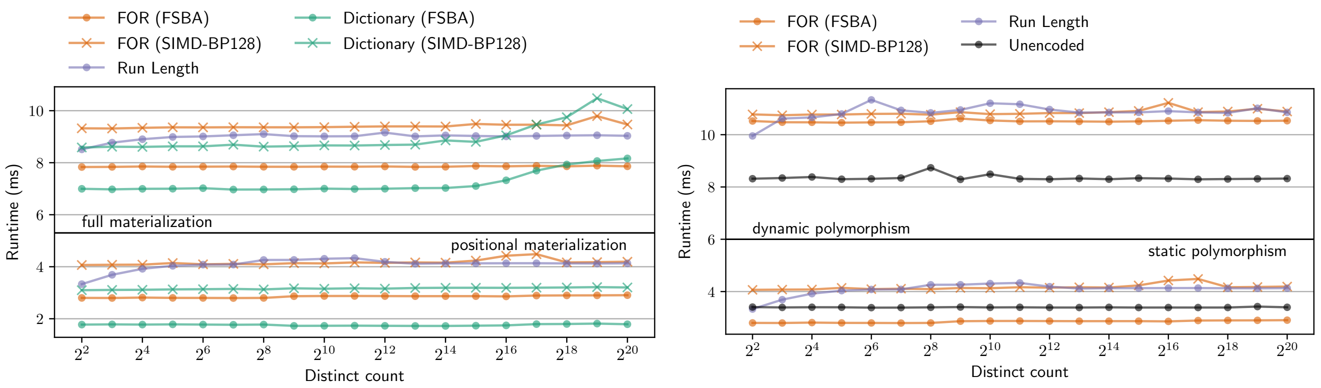
2.3 Segment Encoding

To our best knowledge, all modern columnar and memory-resident databases employ some form of column encoding. This is to (i) compress data and reduce memory consumption, (ii) better utilize the available memory bandwidth by increasing the entropy, and (iii) increase performance since operations on integer-encoded columns can be vectorized and processed by modern CPUs more efficiently. This effect is even stronger when relational operators can operate on encoded data without prior decoding.

Hyrise supports both logical (i.e., mapping input data to an integer representation) and physical (i.e., further compressing integer codes) encoding schemes (cf. [13]). The implemented logical schemes include frame of reference, run length, and order-preserving dictionary encoding. The physical ones include fixed-size byte alignment and SIMD-BP128 for null suppression. Logical and physical encoding schemes can be arbitrarily combined so that existing logical schemes can profit from a new physical encoding without modification.

Hyrise1 includes several encoding and compression schemes, but as mentioned above, no abstraction layer separated the data layout and the execution engine. This caused maintainability and performance issues and led us to formulate the following requirements for an encoding framework in Hyrise2:

- The encoding framework should be an abstraction layer where operators do not need to be implemented for each added encoding type.
- Still, implementing specialized access methods for certain encodings should be possible. For example, scans on dictionary-encoded columns should search for the integer value id, without having to decompress the data.
- Performance should be on par with manually optimized encoding schemes. This means that the compiler should be able to statically resolve the abstractions without having to resort to virtual method calls in hot loops.



(a) Full vs. positional accessing.

(b) Effect of polymorphism.

Figure 3: Runtime comparison for an aggregation accessing 25% of 1M integer values. Left: impact of decoding the full vector upfront vs. positional decoding. Right: impact of static polymorphism via C++ templating vs. dynamic polymorphism as done in the previous version of Hyrise.

- Abstractions should be analyzable by the compiler to the point where auto-vectorization (i.e., the automatic generation of SIMD code) is possible.
- The framework should seamlessly cooperate with our long-term plans on just-in-time query plan compilation.
- Instead of defining encodings per column, it should be possible to have different encodings in different segments.

We fulfill these requirements by heavily relying on static polymorphism, i.e., C++ templates. For each implementation of an encoding type, an *iterable* is implemented. These iterables inherit from a common base class using the curiously recurring template pattern (CRTP). The base class provides the `with_iterators` interface to operators, but instead of implementing this method using virtual inheritance, the CRTP is used to statically call a protected `_on_with_iterators` method. Operators pass a functor (i.e., a lambda or closure) to `with_iterator` as shown in Listing 1. Optionally, `with_iterators` takes a position list, which is used to selectively iterate over the values that, for example, are the result of a previous scan operation.

```
segment_iterable.with_iterators(
  [&](auto left_it, auto left_end) {
    for (; left_it != left_end; ++left_it) {
      const auto left = *left_it;

      if (!left.is_null() && predicate(left.value())) {
        matches.emplace_back(left.chunk_offset());
      }}});
```

Listing 1: Implementation of a vectorizable[1] scan operator using the iterators provided by the encoding framework

Not only the iterators, but also the functors (in the example, the predicate) are resolved at compile time. This allows us to define an adaptable and flexible encoding framework that avoids virtual method calls. Using iterators allows us to hide implementation details of encoded columns, which eases the maintainability of operators. In case query compilation is used, the iterators also provide efficient accesses for tuple-at-a-time processing without incurring virtual method calls. A downside of this approach is that the number of template instantiations grows exponentially. For a scan on a single column, we instantiate $|DataTypes| * |EncodingSchemes| * |Comparators|$ templates, resulting in a compile time of up to five minutes for the most complex operators. To prevent that cost from slowing down our development, the static resolution only takes place for *Release* builds; *Debug* builds use conventional virtual method calls.

The same iterator model can also be used to implement hybrid data layouts. A row-oriented segment type can provide iterators for each included attribute. Because the iterators are resolved at compile-time, accesses to attributes within one tuple would result in contiguous memory accesses.

Figure 3 shows two micro-benchmarks evaluating the performance of our encoding schemes and the encoding framework. As Hyrise is optimized for HTAP workloads, which include frequent positional accesses, random access iterators play an important role. Figure 3a shows the overhead of decoding the encoded vector beforehand (cf. [25]) compared to using positional random access iterators. For most encodings, positional accesses are 2−3× faster, even when decoding large position lists. For typical OLTP queries with short position lists, the advantage is even more pronounced.

The performance advantage of static polymorphism over dynamic polymorphism, i.e., virtual method calls, is shown in Figure 3b. In this benchmark, we aggregated a set of randomly chosen positions (25% of 1M integer values). No matter the encoding type, the cost of static polymorphism is significantly lower, with the biggest improvement being a factor of 3×.

2.4 Indexes and Filters

During execution, two types of secondary data structures are used to reduce the amount of data accessed: (i) secondary indexes and (ii) filters, which are lightweight probabilistic data structures for chunk pruning. Moreover, Hyrise uses these data structures during query optimization for cardinality estimation.

Secondary Indexes. Indexes in Hyrise yield qualifying positions for one or more predicate(s). Three secondary index structures are implemented: (i) adaptive radix trees (ART, cf. [31]), (ii) B-trees[2], and (iii) the group-key index [16]. The group-key index has been developed particularly for Hyrise. It builds on compressed position lists and exploits order-preserving dictionaries.

[1] To enable the compiler's auto-vectorization, it is helpful to first iterate over a constant number of rows at a time. This is not shown in the example for the purpose of brevity.

[2] Google C++ B-tree: https://code.google.com/archive/p/cpp-btree/

Filters. Filters are space-efficient (i.e., significantly smaller than a secondary index) auxiliary data structures, which allow the pruning of chunks (similar to partition elimination) for a given predicate. Hyrise supports min-max filters, counting quotient filters [37], and pruning-optimized histograms, which are comparable to adaptive range filters [3]. The latter two are not only capable of pruning but also support selectivity estimation.

Both indexes and filters are created on a per-chunk basis on immutable chunks and not globally for the whole table so that no maintenance cost is caused by inserts, updates, or deletes. This simplifies the code base and avoids computational overhead in forms of logging or heavy updates of large data structures. However, it is conceptually possible to add, e.g., a B-tree index to mutable chunks when required in OLTP scenarios. As filters and indexes are chunk-local, they can be selectively created for chunks where the estimated performance improvement outweighs the necessary memory space.

An important difference to previous work on filters is that, in Hyrise, they are integrated with the query optimizer, instead of being only used in the execution phase. Doing so enables optimizations that can only be used at query planning time: First, chunk pruning can be propagated through conjunctive predicate chains down to the plan node that initially represents the input table (cf. [6]). That plan node is configured to skip chunks that would later be excluded by one of the predicates. As a result, the number of accessed rows is reduced from the start and not only at the location of the respective predicate. Second, in case chunk pruning has a significant impact on the selectivity of a predicate, this knowledge can be exploited for operator-reordering, which would not be possible when pruning is done later in the execution phase. Similarly, we plan to use indexes not only in the execution phase but also for estimating cardinalities (cf. [32]).

2.5 Networking

Hyrise implements the wire protocol of PostgreSQL [40]. Reusing existing wire protocols is common [41] for new systems for several reasons. First, existing clients and drivers can be reused. This is advantageous for database products as well as for research platforms as it offers the possibility to access Hyrise from many programming languages and makes it accessible to many users. Second, tools such as *Wireshark* can be used to investigate how the sent and received PostgreSQL messages are encapsulated in network packets. As Hyrise is a research platform, we only implement the features needed for receiving SQL queries and returning results, but do not implement features such as user authentication or SSL. This keeps our implementation lean. The wire protocol uses TCP/IP, and our server is implemented using the asynchronous network features of *Boost.Asio*.

2.6 SQL

Figure 4 depicts the different steps in our SQL Pipeline. A dedicated *SQLPipeline* class is the main entry point to everything related to query execution. It takes an SQL string as a parameter and returns one or more tables. Optionally, all intermediary artifacts can be inspected by the developer in their text or graph forms. This was designed based on our experience with other databases where, in some cases, it is difficult to even understand the path that an SQL query takes through the system and which steps are involved. In the following paragraphs, we describe the steps of the SQL pipeline.

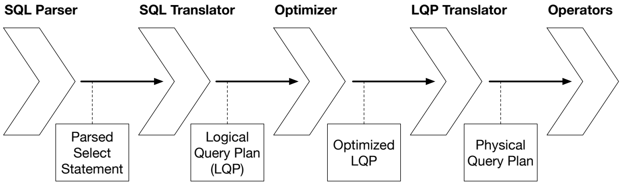


Figure 4: The different steps of the SQL Pipeline, leading from an SQL string to executable operators

Parsing. The SQL parser transforms the SQL query string into data structures that can be accessed and modified programmatically. When we started to add SQL support to Hyrise, we found no easy-to-use component that would transform an SQL string into an Abstract Syntax Tree (AST) that uses C(++) structs. While open-source databases come with their own parser (e.g., PostgreSQL), we found these to be too interwoven with the rest of the database for our purposes. Thus, we built a standalone C++ SQL parser based on Flex and Bison and released it as open source software[3].

SQL-to-LQP Translation. Having parsed the SQL query string into an Abstract Syntax Tree, which still resembles the structure of the SQL Query, we now translate the AST into a *Logical Query Plan (LQP)*, which is based on the relational algebra. Each edge in the LQP represents a table, either a user-defined table that is stored in the central *Storage Manager* or an intermediary table generated by the previous operator. It could also be a user-defined SQL view, which we have stored as its LQP and can embed into the query plan at this point. Operators do not need to perform expensive materializations of intermediary results, but can also pass positional references to the next operator. Having these references avoids expensive materializations. These operators are represented as nodes, which hold information about their input relations and attributes and parameters for their execution. LQP nodes are, however, not executable operators but only form the basis for logical query optimization. They get translated into physical operators only after all optimization steps have been performed. An example of a Logical Query Plan is shown in Figure 5.

Most LQP nodes, such as Predicates, Joins, or Aggregations, are one-to-one representations of their equivalent in the relational algebra. One node type that stands out is the *Projection*, which is our workhorse for most non-trivial column operations. This includes more complex logical operators (nested AND/ORs), string manipulation, but also the execution of subselects: In the initial LQP, all subselects are expressed as sub-LQPs attached to a Projection node close to the point of their first use. As such, subselects are executed as if they were stand-alone queries. For non-correlated subselects, this is done only once. For correlated subselects, the query plan contains placeholders that are replaced with the correlated attributes during the execution. Obviously, this is quite inefficient, which is why the optimizer later rewrites the LQP into a more efficient, join-based version.

Optimization. All optimizations are achieved by rules that are executed on the Logical Query Plan (LQP). Rules are maintained by the optimizer and are part of an optimization pipeline that contains single-pass and multiple-pass rules. While some rules need

[3] Hyrise SQL Parser: https://github.com/hyrise/sql-parser

to be executed only once (e.g., the substitution of constant expressions), others can be re-executed if the LQP has been changed by a different rule or if they themselves improve the resulting LQP in multiple passes. A rule takes an LQP as a modifiable input and returns whether it has modified that LQP. The information on whether a rule modified the LQP is used by the optimizer to decide whether iterative rules should be executed again. At the end of every rule stands a valid LQP. Thus, the optimization process can be skipped or stopped after a certain time, e.g., if the expected runtime of the query is determined to be too low to warrant further optimization efforts.

Out of the eight currently implemented rules, we use three examples to highlight how these rules operate on the LQP: the *Predicate Pushdown Rule*, the *Join-Ordering Rule*, and the *Chunk Pruning Rule*. The Predicate Pushdown Rule is a rule that is almost always applicable: For every LQP, it makes sense to execute cheap filtering predicates as early as possible, that is, before more expensive joins or aggregations. Currently, it is applied to all trivial predicates. Correctly estimating the cost of more complex predicates (such as nested predicates or LIKE expressions) is work in progress. The Join-Ordering Rule is an example, which relies on the statistics component to gather the estimated selectivities of the join predicates and on the cost estimator to estimate the cost of the different joins. These joins are then ordered using DpCcp [34] in what is considered to be the most effective order. Finally, our third example rule, the Chunk Pruning Rule, uses the LQP and the filter information discussed in Section 2.4 to identify chunks that will not contribute to the final result. While the LQP is not structurally changed by this rule, the table nodes at the bottom are augmented with the information of which chunks do not need to be passed to the first operator (cf. Section 2.4).

LQP-to-PQP Translation. Finally, the LQP has to be translated into a PQP. As described above, there are potentially multiple physical implementations of a logical operator. The optimizer has already left hints in the LQP nodes. An example of such a hint is when a logical predicate node contains the information that a secondary index can and should be used. Starting from the bottom, each LQP node is now translated into one of the available physical operators. Because all decisions have already been made by the optimizer, nothing of great interest happens here. This is different for the JIT-Aware LQP Translator, which we describe in Section 2.7.

Prepared Statements and Query Plan Caching. One goal in the design of the previous steps was to keep the SQL Pipeline lean, which is why the cost of query planning is comparably low. Still, commonly reoccurring queries can profit from previously generated query plans. We treat SQL Prepared Statements and Query Plan Caching similarly. In both cases, we store a mapping from an SQL query string to a Physical Query Plan. The only difference is that for Prepared Statements, entries in this mapping are manually maintained, while the query plan cache is limited and automatic eviction takes place. For Prepared Statements, we store placeholders instead of actual values. Before the execution of such a statement, these placeholders are replaced with actual values.

Regular SQL queries are currently cached with all parameters left in place. Automatically replacing these with placeholders would increase the number of cache hits but at the same time introduce further complexity. For example, for skewed workloads, where the reuse of a previously generated query plans may not be safe [5], caching PQPs might not always result in the best

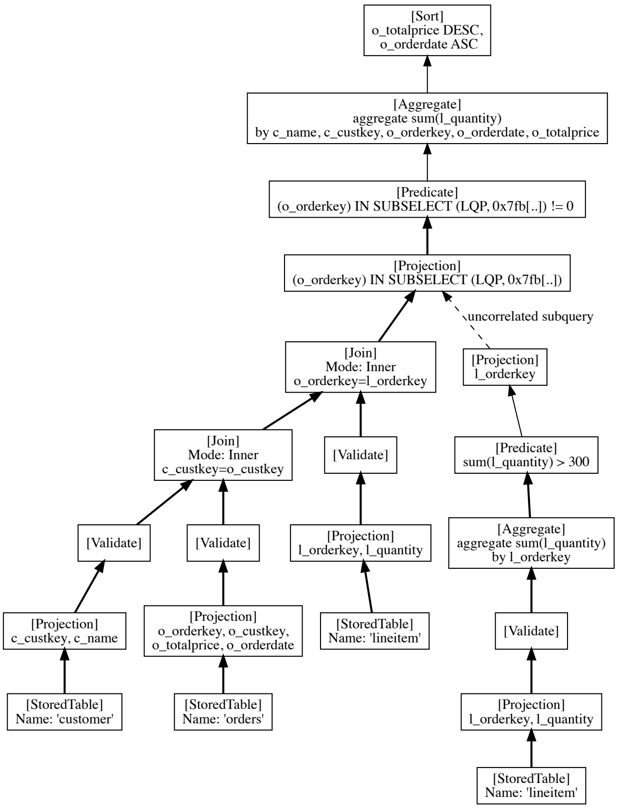

Figure 5: A sample visualization of a Logical Query Plan, here of TPC-H query 18

execution strategy. For these cases, we can easily switch the cache to only cache optimized LQPs, which are then re-optimized once the actual parameters are bound to the placeholders. Because the optimizer has already operated on the cached plan, we can save on optimization time compared to starting the optimization from scratch. Deciding when a PQP is safe to cache and reuse without re-optimization is subject to future work.

2.7 Just-in-Time Compilation

Hyrise's JIT engine is based on three components: The *JIT Repository*, which holds JITtable operators; the *JIT-Aware LQP Translator*, which translates Logical Query Plans into a chain of JITtable operators; and the JIT Code Specializer, which optimizes the operator code and fuses multiple operators into a single loop.

It is based on a code specialization approach, where, during development, generalized C++ code is written for each operator. This code still contains the virtual method calls for calling the next operator, the switches for different column and encoding types, or checks for null values. At runtime, when this information is available, the JIT compiler replaces these abstractions with their concrete values. This is done using LLVM's ORC (On Request Compilation) interface. For the examples, this means that virtual method calls to the next operator can be inlined, type switches can be removed and replaced with the known type, and checks for null values can be removed if the column is known to be non-nullable. The result of this optimization step is a single binary that represents all logical operators between two pipeline breakers. Because of this, we can optimize across operator boundaries and profit from keeping values in the CPU caches (or even registers) as well as from (auto-)vectorization of the code. We believe that this specialization approach is a better fit for our goals as it does not require developers to write code-generating code. The downside of this approach is a high complexity of the specializer component.

We maintain two execution engines, one with and one without support for just-in-time compilation, for three reasons. First, having two engines allows us to compare their performance and identify bottlenecks. Second, despite all effort to make the development of JIT operators as simple as possible, we consider it to still be more complicated as developing traditional operators. Not only do developers have to understand the JIT model, but they also need to familiarize themselves with our specialization engine in order to be able to debug or profile the resulting binary code. Especially for students who work on the project for just a semester, this becomes a limiting factor. Third, most of the research projects evaluated on Hyrise are orthogonal to the optimizations achieved with JIT. The filter-based access pruning methods presented in Section 2.4, for example, can prune the same number of chunks no matter if the remaining chunks are evaluated using traditional or JITted operators. As such, the relative performance impact is comparable, even if the absolute performance of the JITted queries is better.

In some cases, we can achieve a 22x performance improvement over the traditional, operator-based approach, for example when complex expressions have to be calculated. At the current stage, not all operators are implemented as JIT operators (most notably the different joins) and the JIT-aware LQP Translator automatically falls back to non-JITtable implementations. Also, the encoding-specific optimizations have not made it into the JIT component yet, so table scans on dictionary-encoded segments have to decompress all values. Because of this, the JIT component has to be explicitly enabled.

2.8 Concurrency

As described in Section 2.2, chunks become immutable when they reach their maximum capacity. This makes it easier to efficiently encode them without having to consider future modifications. Updates to these chunks are thus implemented in an insert-only fashion as invalidations and reinsertions. While a table's last chunk is mutable and would theoretically support in-place updates, we keep the architecture simple by following the insert-only approach for that chunk as well. For each chunk, we store three vectors: the (1) *begin* and (2) *end commit ids* of the transactions that inserted or invalidated this row, as well as the *transaction id* of a transaction that currently has this row in its set of modified rows.

When a transaction starts, it is assigned a unique (not necessarily contiguous) transaction id by the transaction manager. Also, it stores the commit id of the last transaction that was committed successfully. We previously called this "last commit id of a transaction" [42] or $lcid_T$, but have since renamed it to snapshot commit id, which we believe communicates its purpose better.

A transaction can identify rows that are visible by comparing the begin commit id with its snapshot id: If it is higher, the row has been inserted after the transaction has started and should not be visible. Similarly, a lower end commit id means that the row has already been deleted by the time the transaction started. Invalidations use the transaction id field for two purposes: First, when checking the visibility of a row, seeing its own transaction id in a row signals to the transaction that it has already modified (i.e., inserted or invalidated) the row. This keeps us from having to maintain a separate list of updated rows. Second, as modifying the transaction id is an atomic compare-and-swap operation, it identifies concurrency conflicts. If two transactions concurrently try to set the transaction id of a single row, only one can succeed and the other has to abort. For more detail on our implementation of MVCC, please refer to our description of transaction processing in Hyrise1 [42].

2.9 Scheduling

Most databases do not leave the task of scheduling their work items to the operating system's scheduler [18]. We, too, have instead implemented a cooperative task-based scheduler that tries to keep the OS scheduling out of the equation. Our unit of work is a *task*, which can be an operator, a subroutine within an operator, a maintenance job, or any other subroutine. The easiest type of task has been modeled after `std::thread` to take a function object or a lambda. This keeps the entry threshold for new developers low. All tasks are stored in a task queue, which is using a lock-free `tbb::concurrent_queue`. Tasks can have dependencies on other tasks and only tasks with fulfilled dependencies get emplaced in the queue by the scheduler. Once a task finishes, it iterates over its list of successors and asks them to check if they are now ready to be scheduled.

Hyrise spawns one active worker thread per CPU core. It polls the queue for new tasks to be executed. Once it has begun executing a task, it continues to do so uninterruptedly until it finishes. A task can also spawn subtasks, which are then emplaced in the scheduling queue and executed in parallel.

On NUMA systems, we use one queue per node. Tasks can specify a preferred node, for example when they should be scheduled close to the data that they are processing. When the queue on one node runs dry, workers on that node perform work stealing and attempt to help other nodes with finishing their queue. To prevent high contention on the queues, workers back off for a fixed time interval (currently 10 milliseconds) if the work stealing was unsuccessful.

In line with our goal to keep the system modular, the scheduler can be entirely disabled so that tasks are executed in the main thread. When `schedule` is called on a task, it is either directly executed or, if it has predecessors, their predecessors are executed first. As a result, when measuring the multi-threaded scalability of our system, there are differences between the measurements for one core with and without scheduler. This allows us to inspect the cost of the scheduler.

2.10 Benchmark Runner

Running standard benchmarks on different databases is often a tedious task. Benchmark tables have to be generated and, in many cases, the generated CSV files need some modifications before they can be loaded. For many research databases, some features of SQL are not supported and queries need to be reformulated accordingly. Finally, many databases have special configuration parameters that users need to be aware of. In our case, this includes the default chunk size and encoding options. Our goal is to provide both developers and new users with a binary that is a one-stop solution for executing such benchmarks.

Currently, Hyrise supports the TPC-H benchmark with the binary `hyriseBenchmarkTPCH`. Support for the alternative data generator JCC-H, as well as the benchmarks TPC-C and Join Order Benchmark are in development. These binaries return a JSON file with the total number of executed queries per second, as well as the individual run times of each query and additional information about the setup. Configuration parameters like default chunk size, encoding, or the number of used threads can optionally be set either via the command line or in a JSON file. Our idea is that by providing a git commit id and optionally a JSON file, results can easily be communicated in a reproducible way. Finally, users can provide their own table and queries in .csv and .sql files, which are then automatically executed. We use this to experiment with enterprise-specific workloads and real-world data that, unfortunately, cannot be published. A tool with a similar goal is OLTP-Bench [14], which we plan to support in the future.

3 PLUGINS

For Hyrise to be a multi-purpose research vehicle, it is important not to clutter the code base with limited-purpose extensions. Often, research concepts and their implementations tackle very distinctive challenges that are not necessary for normal database operation. We believe that these specialized implementations should not necessarily become part of the database core to avoid complicating the process of understanding Hyrise and its source code. Not merging them into the main code base also avoids behavior that is unexpected by other researchers, for example when self-tuning components automatically create new indexes. We see plugins as a solution that allows us to extend the system's functionality beyond that of typical database systems. In this section, we present the plugin interface offered by Hyrise and our plans for its use by a self-driving database.

3.1 Interface

Plugins are dynamic libraries, which can be loaded and unloaded by the user during database runtime. They can access all of Hyrise's components using the respective public interface. This means that, except for the boilerplate code needed to initialize them, the development of plugins is almost indistinguishable from that of the database core. Also, most code can be moved from the core into plugins without modification. The main limitation is that while plugins can call public methods, they cannot modify the code of existing components. For example, no new encoding type can be added via a plugin, as all encoding types have to be known during the compilation of Hyrise.

Plugins are implemented as Singletons to ensure that there is only a single instance in the system. The *Plugin Manager* is responsible for administrative work, such as loading and unloading of plugins via `libdl`. We provide a blueprint for plugins[4] that can be used as a starting point for developing new plugins.

3.2 Self-Driving Database

One prime use case for plugins in Hyrise is the area of self-driving database systems. In contrast to traditional databases, these systems do not rely on human database administrators (DBAs) anymore, but adjust their configuration and tune their physical database design autonomously. Such behavior can be achieved by employing workload-driven optimization and machine learning models. To achieve this efficiently, self-driving components need to access and manipulate database-internal data structures and processes. At the same time, it should still be possible to run Hyrise independently of such a plugin and its dependencies and it should not be necessary for other developers to consider such external components. In addition, components of such a self-driving system should be easily exchangeable to enable experiments with different strategies.

The basic architecture and conceptual ideas for a *Generalized Self-Driving Framework* [26] are currently under development in Hyrise. A couple of typical database configuration and physical design aspects should be adjusted autonomously, e.g., the selection of indexes, data placement in NUMA and in replicated systems, and an automatic selection of efficient encoding and compression schemes per chunk. These are either already part of Hyrise and are going to be transferred to the plugin-based self-driving system or are under development.

4 RELATED WORK

The field of database systems for analytical applications has seen vast progress over the last decade [1]. Amongst the first academic systems were MonetDB [9] and C-Store [46], which are disk- and OLAP-optimized systems. While the first column stores focused solely on analytical workloads, the rise of main memory-optimized databases also led to the use of column stores for mixed workload processing (OLxP or HTAP). Amongst these HTAP-optimized column stores are SAP HANA [15] and Hyper [23]. Other comparable database systems include academic systems like Quickstep [38] and Peloton [39]. In the remainder of this section, we discuss major design decisions of Hyrise and how other systems approached them.

The storage layouts of early column-oriented systems like MonetDB and C-Store closely resemble the *decomposition storage model* (DSM [12]), storing attributes in one large consecutive allocation. In addition to the base attributes, both systems further include additional sort orders (cf. C-Store's projections [46] and MonetDB's cracking [22]). A similar layout is used in SAP HANA with the difference that it tries to minimize the memory footprint and avoids redundant data storage. More recent systems use a different approach that splits columns into several smaller units. With the rising importance of NUMA systems, such a form of an automatic horizontal partitioning in fixed-size blocks eases the equal distribution of data over several nodes [10]. This storage paradigm is used, e.g., in Hyrise, HyPer, and Quickstep. Peloton's *tiles* are a hybrid storage layout and resemble the variable-width containers of the first version of Hyrise.

One of the main challenges for columnar databases is handling a steady stream of modifications in HTAP environments. C-Store introduced the separation into read- and write-optimized stores. A similar concept is used in SAP HANA and has been used in Hyrise1, namely separating each table in a read-optimized main partition and a write-optimized delta partition [27, 29]. In contrast, HyPer and Quickstep have chosen a model that is closer to the chunk concept in Hyrise. While Quickstep is read-optimized, HyPer uses uncompressed small blocks at the beginning and shifts to larger and more compressed blocks over time [17].

Storing aggregated and space-efficient data structures for early pruning of data is done by many database systems. The simplest form is to store the min/max values of each column (e.g., Netezza's zone maps or SAP HANA's synopses [36]) or small materialized aggregates [33]. HyPer uses so-called positional small materialized aggregates, which include scan ranges for multiple value ranges [28]. More sophisticated approaches comparable to Hyrise's filters are adaptive range filters [3] or SuRF [47].

In the area of modern in-memory databases, Hyper has been amongst the first systems that generated data-centric code using

[4] Exemplary plugin for Hyrise: https://github.com/Bensk1/example-plugin

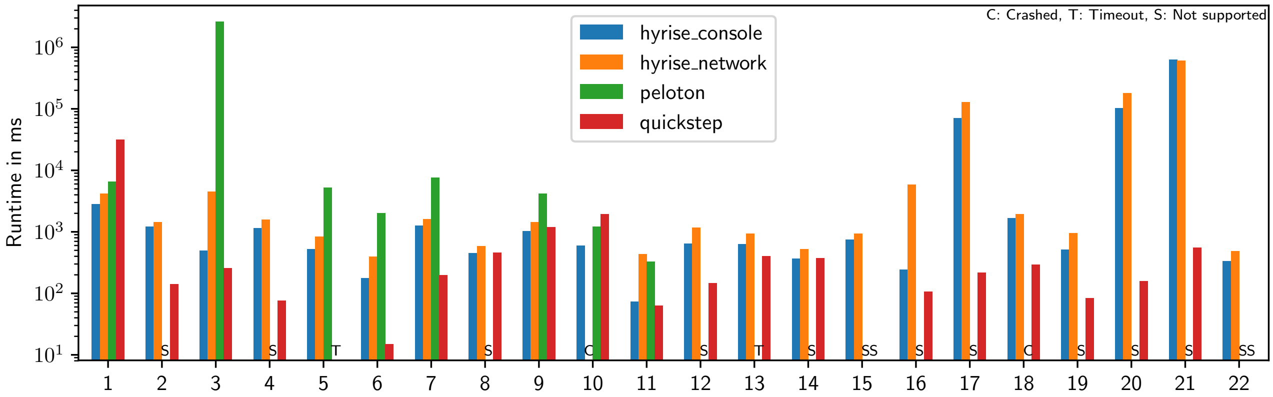

Figure 6: Runtime when executing the TPC-H queries on fresh database instances of Peloton, Quickstep, and Hyrise (SF=1)

LLVM IR [35]. Since then, other database systems, both research and productive, have started to compile queries at runtime, most generating either LLVM IR or C code that is then compiled. Hyrise differs from these approaches in that it does not generate new code but specializes existing code that is stored in LLVM IR and fuses it across operator boundaries. This approach has previously been used by other projects, such as DexterDB [21] or Sharygin et al.'s modifications to PostgreSQL [45]. Hyrise supports both compiled and vectorized queries, allowing for similar evaluations as done by Kersten et al. [24].

The idea of database systems that administrate themselves is almost as old as that of databases itself. Early work [20] dates back to the 1970s where certain aspects of the physical database design were tuned. In later years, vendors of commercial database systems integrated advisors into their products to support human DBAs [11]. Recently, self-driving databases [39] received fresh attention. New systems have a more holistic approach where systems do not rely on human interaction anymore and aim for administrating all aspects of databases instead of certain parts only. With its plugin architecture, Hyrise enables the integration and interplay of self-driving components with reusable components and clearly specified interfaces.

5 EVALUATION

Only recently has the SQL and expression subsystem reached the point where the syntax of all TPC-H queries was supported. Since then, we have constantly been working on improving the optimizer so that it generates better query plans. Although Hyrise still misses some LQP optimizations, which currently limit the performance of a few SQL queries, we can show that Hyrise is already in the same ballpark as other research databases.

5.1 Single Query Comparison

In this section, we compare Hyrise's performance with two other open-source research databases, namely Quickstep [38] and Peloton [39]. All databases were built from source in their release mode[5] using gcc 8.2. Our benchmark system has four Intel Xeon E7-4880 v2 CPUs, a total of 60 cores with 2.5 GHz (up to 3.1 in Turbo Boost Mode), and 2 TB of DRAM. We start the databases using either their network interface and `psql` (Peloton and Hyrise) or by sending queries to the command-line interface using `expect` (Quickstep and Hyrise).

The TPC-H CREATE statements have been slightly modified to reflect the level of data type support in the databases. DECIMAL has been replaced by FLOAT and DATE has been replaced by CHAR(10). While Quickstep seems to offer a date type, using it in comparisons gives us an error. Within the queries, slight modifications have been made to compensate for the lack of date functions. No indexes were created. This evaluation aims at comparing the database performance that researchers can expect when looking at a system for the first time. As such, no additional settings were made. Most importantly, the databases are running with their default number of threads: 1 for Hyrise[6], 120 for Quickstep, and 4 for Peloton. We expect that there are probably better settings for these databases or more advanced code branches that would lead to better results, but limit the evaluation to what is publicly available and what would be a reasonable attempt at generating first numbers.

Results can be found in Figure 6. Considering the mentioned limitations, we can see that for most queries, Hyrise's performance is within an order of magnitude of the other databases. It also shows that there is still optimization potential both within the optimizer and the query execution, but also especially within our network component.

5.2 Chunk Size Evaluation

We discussed Hyrise's storage layout, including the chunk concept, in Section 2.2. In this subsection, we evaluate the performance impact of chunks. The test setup (hardware, compiler, scale factor) remains unchanged from the previous section. Figure 7 depicts the throughput for selected TPC-H queries for chunk capacities varying from one thousand to ten million records per chunk. The throughput is shown relative to a setup without any form of chunking. In the figure, TPC-H queries for which the performance is only marginally impacted by the chunk capacity are combined into "Avg. of other queries". This experiment demonstrates that the chosen chunk capacity influences the throughput to a large extent. Compared to a chunk capacity of 10 000 000 rows, which effectively results in a single chunk for the given scale factor, a chunk capacity of 100 000 improves the throughput by a factor of 26 for TPC-H query 21. At the same time, chunks containing only 1 000 records diminish the throughput by 97% for TPC-H query 22.

[5] Git-Hashes for Hyrise: 9a60098b, Peloton: 3bc6d461, Quickstep: 5cbaa7ef

[6] In the default configuration, the scheduler is currently disabled as we are investigating a performance regression.

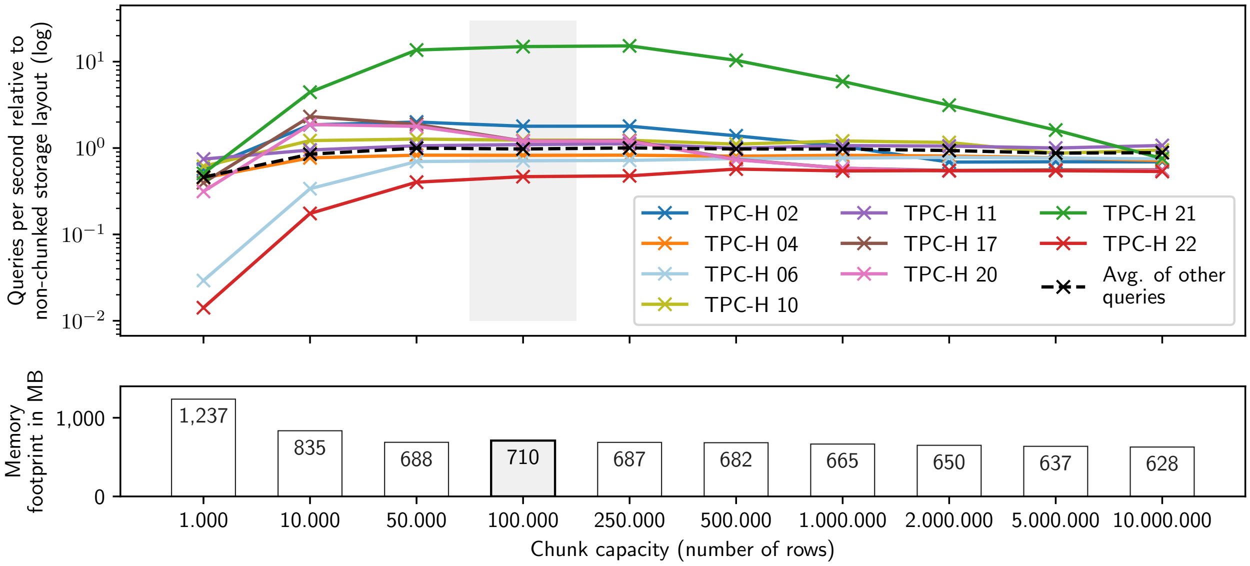

Figure 7: Performance impact and memory consumption of varying chunk capacities (the highlighted chunk capacity of 100 000 is Hyrise's default setting).

As stated earlier, chunks can influence the performance in different ways. First, chunks provide inherent partitions that can be used to distribute the workload. In the results above, however, multithreading was disabled and we see a second effect: Because chunks enable pruning, they can sometimes help in avoiding the access to large parts of the data. Whether pruning is possible depends on the underlying data. If pruning cannot be applied, queries might see drawbacks when too small chunks are used. Queries 6 and 22 with a chunk capacity of 1 000 are an example for this: pruning cannot be applied and many small chunks introduce a significant overhead. Overall, the best throughput is achieved with chunk sizes around 100 000. Compared to a non-chunked layout in Hyrise, the performance increases by 146%.

In addition, the chunk size affects a table's memory footprint as stated in Section 2.2. The lower half of Figure 7 shows the memory footprint for different chunk sizes of all TPC-H tables for a scale factor of 1 when applying dictionary encoding. The configuration that is best for throughput consumes roughly 10% more memory than the most space-efficient configuration. Fine-tuning this parameter on a per-table basis instead of setting it globally is subject to future work. Depending on the encoding scheme, a smaller chunk size can also reduce the footprint in edge cases, for example when a lower number of dictionary entries enables the use of fewer bits for their encoded representation.

6 SUMMARY

In this paper, we have presented how our research database Hyrise was re-engineered and rewritten to be a platform for future research projects. Our new architecture was built around the goals of being easy to understand and extend, enabling end-to-end benchmarking, and delivering high performance even in the presence of multiple abstraction layers. We have described which prior experiences with Hyrise1 have influenced the development, both from an architectural, and from a processual perspective.

Most components that are relevant to our query execution have been explained, including storage and encoding, auxiliary data structures, networking, the SQL pipeline, JIT compilation, multi-threading, and benchmarking. Furthermore, we have described our plugin interface and the self-driving plugin as an example for its use. Finally, we have evaluated chunks as the main storage concept of Hyrise, have shown how pruning can reduce the number of accessed rows during execution, and have compared Hyrise to other research databases.

Future work has been discussed for the separate components. From a high-level perspective, we will focus on implementing the missing LQP optimizations that are current bottlenecks to our performance, will implement more benchmarks, and improve the performance of the system by making better use of modern hardware components.

We invite the reader to experiment with Hyrise by following our first steps guide[7], which not only contains instructions on how to setup Hyrise and run first benchmarks within minutes, but also examples on how to run queries, and visualize them.

ACKNOWLEDGEMENTS

Hyrise is partly developed during Master's seminars and theses. The presented improvements would not have been possible without the contributions and ideas of over 60 students in the last two years. We would like to thank all of them for their dedication. The work of Moritz Eyssen has not only brought Hyrise its current degree of SQL support but, through his immensely helpful feedback on pull requests, also greatly contributed to the overall quality of the code base.

ABSTRACT

Core decomposition is a popular tool for analyzing the structure of network graphs. For probabilistic graphs the computation comes with several challenges and the state-of-the-art approach is not scalable to large graphs. One of the challenges is to compute tail probabilities of vertex degrees in probabilistic graphs. To address this we employ a special version of the Central Limit Theorem (CLT) to obtain the tail probabilities efficiently. Based on our CLT methodology we propose a peeling algorithm to compute the core decomposition of a probabilistic graph that scales to very large graphs and is orders of magnitude faster than the state-of-the-art. Next, we propose a second algorithm that can handle graphs not fitting in memory by processing them sequentially one vertex at a time. This algorithm has the desirable property that it can produce close approximations to true core numbers of vertices in only a fraction of iterations needed for full completion. The graphs in our study are orders of magnitude larger than those considered in the literature. Our extensive experimental results confirm the scalability and efficiency of our algorithms; the largest graph we can process has more than 40 million nodes and 1.5 billion edges and we are able to compute its core decomposition on a commodity machine in about two and half hours.

1 INTRODUCTION

Probabilistic graphs are graphs in which each edge has a probability of existence (cf. [6–8, 19, 21, 43]). Mining probabilistic graphs has become the focus of interest in analyzing many real-world datasets, such as social, trust, communication, and biological networks due to the intrinsic uncertainty present in them. For instance, influence between users (cf. [7, 17, 21]) in a social network can be modeled as a probabilistic graph with probabilities on the edges representing the likelihood that some action of one user will be adopted by another. In terms of trust inference, probabilistic models with trust values as edge probabilities can be used to compute trust associated with a social relationship [27, 28]. In protein-protein networks (cf. [9]) interactions between proteins are obtained through laboratory experiments that are prone to measurement errors resulting in edges labeled with confidence levels that can also be interpreted as probabilities [14, 15, 41].

Discovering dense components is of great importance in analyzing network graphs [29]. A popular way to find such components is core decomposition which has been shown to have a wide variety of applications (cf. [1, 24, 30, 44, 46]). For instance, it can be used in measuring structural diversity is social contagion [44], describing biological functions of proteins in protein-protein interaction networks [30], analyzing network structure's properties to explore collaboration in software teams [46], and also as a metric for sentence selection in text summarization [1]. Probabilistic core decomposition naturally extends all the applications of deterministic core decomposition to probabilistic graphs. Other applications, showcased in [6], are facilitating influence maximization and task-driven team formation in probabilistic graphs.

In k-core computation the goal is to find the maximal subgraph in which each vertex has at least k neighbors within that subgraph. The set of all k-cores of a graph, for various k, forms the core decomposition of that graph [40]. Core decomposition in deterministic graphs has been thoroughly studied in literature [3, 11, 24, 35], and can be computed in $O(m)$ time, where m is the number of the edges in the input graph. However, in the probabilistic context, computing core decomposition is much more challenging.

Here we use the probabilistic (k, η)-core notion introduced by Bonchi, Gullo, Kaltenbrunner, and Volkovich in [6]. In (k, η)-core computation the goal is to find the maximal subgraph in which each vertex has at least k neighbors within that subgraph with probability no less than $\eta \in [0, 1]$. Threshold η is given by the user and defines the desired level of certainty of the output cores. A fundamental notion needed to compute the (k, η)-core is the η-degree of a vertex v. It is the maximum degree such that the probability for v to have that degree is no less than η.

Challenges and contributions. A significant initial challenge is computing η-degrees of graph vertices. In [6], the η-degree of each vertex v is computed using dynamic programming (DP) which has a complexity of $O(d_v^2)$, where d_v is the number of edges incident to v. Unfortunately, in many real social and web networks, d_v can be in the millions and a quadratic algorithm such as DP is impractical.

Our first contribution is the design of an efficient method for computing η-degrees. Our method is based on Lyapunov's special version of the Central Limit Theorem [25, 34] and we show its output to be virtually indistinguishable from exact computation for vertices with a high number of incident edges.

While solving the challenge of computing η-degrees is an important step forward, we still need efficient algorithms to compute core decomposition for large probabilistic graphs. We propose two efficient algorithms to solve this problem.

The first one, which we call the "peeling algorithm" (PA), recursively deletes (peels-off) the vertex of the smallest degree. Our contribution here is in designing efficient arrays for storing important bookkeeping information. Handling these arrays becomes challenging because, differently from the deterministic case, the process of keeping the vertices sorted based on their changing η-degrees is more complicated and we need to shuffle information carefully in order to keep the arrays up to date. Notably, our PA algorithm scales to datasets two orders of magnitude bigger than those that the state-of-the-art algorithm [6] can handle.

For the case when the input graph does not fit in memory, we propose a sequential algorithm (SA) based on the vertex-centric model of computation. The main idea of the SA algorithm is to

10.5441/002/edbt.2019.29

maintain an upper-bound, called vertex value, on the core number of each vertex. This upper-bound is initialized to be the η-degree of each vertex, and after each iteration of the algorithm it is tightened further until it reaches the exact core value. While being moderately slower than PA, there are two notable advantages associated with this algorithm. First, the SA algorithm has a memory footprint of $O(n)$ as opposed to $O(m)$ for PA, where n and m are the number of vertices and edges, respectively. This amounts to SA requiring 30 to 40 times lower memory for social and web network graphs in practice. Second, as shown in Section 6, after only a fraction of iterations of the algorithm, we can obtain an approximation very close to the true core numbers of vertices.

In summary, our contributions are as follows.

- We introduce an efficient approach to compute η-degrees using Lyapunov's central limit theorem which gives very accurate approximations on the probability that a vertex can have a certain degree. We prove the accuracy of the approach and show that this method of computing probabilistic degree is numerically stable.
- We propose a peeling algorithm (PA) based on recursive vertex deletions which, by using carefully engineered array structures, is able to scale to graphs two orders of magnitude larger than what the state-of-the-art algorithm can handle.
- For the case when the input graph does not fit into memory, we propose a sequential algorithm (SA) to produce the core decomposition in probabilistic graphs with a low memory footprint. This algorithm can also produce accurate approximations after only a fraction of total iterations, a useful feature to have in applications when exact core numbers are not necessary.

2 BACKGROUND

Cores of deterministic graphs. Let $G = (V, E)$ be an undirected graph, where V is a set of n vertices, and E is a set of m edges. For vertex $v \in V$, let $N_G(v)$ be the set of v's neighbors: $N_G(v) = \{u : (u, v) \in E\}$. The (deterministic) degree of v in G, is equal to $|N_G(v)|$.

Given $V' \subseteq V$, and $E_{V'} = \{(u, v) \in E : u, v \in V'\}$, graph $H = (V', E_{V'})$ is called the subgraph of G induced by V'. Let $k \in [0, d_{\max}(G)]$, where $d_{\max}(G)$ is the maximum vertex degree in G. The k-core of G is defined as the maximal induced subgraph $C_k(G) = (V', E_{V'})$ in which each vertex $v \in V'$ has degree of at least k. The set of all k-cores forms the core decomposition of G. Core decomposition of G is unique and it satisfies the following relation [40]: $G = C_0(G) \supseteq \cdots \supseteq C_{d_{\max}(G)-1} \supseteq C_{d_{\max}(G)}$. The coreness (or core number) of a vertex is defined as the maximum value of k such that the corresponding $C_k(G)$ contains v.

Probabilistic graphs. A probabilistic graph is a triple $\mathcal{G} = (V, E, p)$, where V and E are as before and $p : E \to (0, 1]$ is a function that maps each edge $e \in E$ to its existence probability p_e. For each vertex $v \in V$, the set of edges incident to v is denoted by $\mathcal{N}_v$. $d_v = |\mathcal{N}_v|$ is the number of all edges incident to v which is equal to the deterministic degree of v. In the most common probabilistic graph model (cf. [6, 19, 21]), the existence probability of each edge is assumed to be independent of other edges.

In order to analyze probabilistic graphs, we use the concept of *possible worlds* that are deterministic graph instances of $\mathcal{G}$ in which only a subset of edges appears. The probability of a possible world $G \sqsubseteq \mathcal{G}$ is obtained as follows: $\Pr(G) = \prod_{e \in E_G} p_e \prod_{e \in E \setminus E_G} (1 - p_e)$.

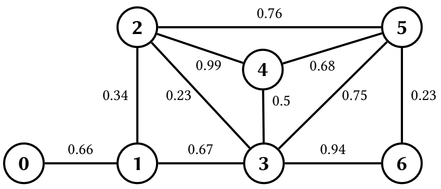

Figure 1: A probabilistic graph.

In a probabilistic graph $\mathcal{G}$, the notion of *η-degree*, where $\eta \in [0, 1]$, denoted by *η-deg*(v), of a vertex v is defined in [6] as the maximum k for which $\Pr_{G \sqsubseteq \mathcal{G}}[d_G(v) \geq k] \geq \eta$, where $k = 0, \ldots, d_v$, and the probability is taken over all the possible worlds $G \sqsubseteq \mathcal{G}$.

For instance, consider Figure 1. When $\eta = 0.5$, vertex 6 has degree at least 2 with probability $0.94 \cdot 0.23 = 0.2162$ (product of probabilities that each of the two edges is in a possible world), and it has degree at least 1 with the probability $1 - ((1 - 0.94) \cdot (1 - 0.23)) = 0.9538$ (complementary probability that none of the two edges is in a possible world) which is greater than the threshold. Thus, the η-degree of vertex 6 is 1.

In the rest of the paper, we use $\Pr[d(v) \geq k]$ to denote $\Pr_{G \sqsubseteq \mathcal{G}}[d_G(v) \geq k]$. The value of $\Pr[d(v) \geq k]$ decreases with the increase of k. Note that d_v is different from $d(v)$; the former is constant, whereas the latter is a random variable.

Cores of probabilistic graphs. In order to extend k-core decomposition to probabilistic graphs, the notion of *(k, η)-core* is defined in [6]:

Definition 1. *Given a probabilistic graph $\mathcal{G} = (V, E, p)$, and a threshold $\eta \in [0, 1]$, (k, η)-core is the maximal induced subgraph $C_{(k,\eta)}(\mathcal{G}) = (V', E_{V'}, p)$ in which the η-degree of each vertex $v \in V'$ is at least k. The set of all (k, η)-cores forms the core decomposition of $\mathcal{G}$.*

The core decomposition in probabilistic graphs is unique, and the (k, η)-cores are nested into each other similar to the deterministic case. The highest value of k for which v belongs to a (k, η)-core is called *η-core* number or probabilistic coreness of v.

Computing η-degrees using Dynamic Programming. We have that $\Pr[d(v) \geq k] = 1 - \sum_{i=0}^{k-1} \Pr[d(v) = i]$. One way of computing $\Pr[d(v) = i]$ is to use dynamic programming as proposed in [6]. However, this method of computing the η-degree has complexity of $O(d_v^2)$ for a vertex v of deterministic degree d_v. This is not practical when d_v is big, say over 20 thousand, which occurs often in all our datasets. In fact, DP cannot finish in reasonable time even for one such vertex. In addition, web-scale graphs normally have millions of nodes with moderate-high degree (e.g., a thousand or more), and if DP is applied to every such node, the total processing time increases considerably. In the next section we introduce an alternative way for fast computation of the η-degree of a vertex v using Lyapunov central limit theorem.

3 COMPUTING η-DEGREES USING CENTRAL LIMIT THEOREM

In this section, we first show how a special version of Central Limit Theorem (CLT) can be applied to accurately estimate $\Pr\big[d(v) \geq k\big]$. Then, we show theoretical bounds on the accuracy of this approximation. Specifically, we show that CLT can produce a very accurate approximation to tail probabilities of the vertex degree.

CLT, one of the most important theorems in statistics, states that given a set of random variables, their properly scaled sum converges to a normal distribution under certain conditions. There are different versions of CLT, with the most common one focusing on independent identically distributed (i.i.d.) random variables. In this paper, we consider a variant called Lyapunov CLT [33, 34] that can be applied when random variables are independent, but not necessarily identically distributed. The Lyapunov's condition imposes a limit on the growth of the third absolute central moment of each random variable in the given sequence ensuring the convergence of the normalized sum of that sequence to standard normal distribution. Formally, we have

Theorem 3.1. ***Lyapunov CLT [25].*** *Let $\xi_1, \xi_2, \cdots, \xi_n$ be a sequence of independent, but non-identically distributed random variables, each with finite expected value μ_k and variance σ_k. Let*

$$s_n^2 = \sum_{k=1}^{n} \sigma_k^2, \tag{1}$$

Lyapunov CLT states that if

$$\lim_{n\to\infty} \frac{1}{s_n^{2+\delta}} \sum_{k=1}^{n} \mathrm{E}[|\xi_k - \mu_k|^{2+\delta}] = 0, \tag{2}$$

for some $\delta > 0$, then $\frac{1}{s_n}\sum_{k=1}^{n}(\xi_k - \mu_k)$ converges in distribution to a standard normal random variable.

Equation (2) is called Lyapunov's condition which in practice is usually tested for the special case $\delta = 1$. The proof for this theorem can be found in [4, 13].

Computing η-degrees using Lyapunov CLT. In what follows, we show how Lyapunov CLT can help compute $\Pr[d(v) \geq k]$, for each vertex v of the input probabilistic graph $\mathcal{G}$.

Recall that for each vertex v we have a set of edges incident to v denoted by $\mathcal{N}_v$. Each e_i in $\mathcal{N}_v$ has existence probability p_i, which is independent of the other edge probabilities in $\mathcal{G}$. Corresponding to each edge e_i in $\mathcal{N}_v$, we define a Bernoulli random variable X_i which takes on 1 with probability p_i, and 0 with probability $(1 - p_i)$. Formally,

$$X_i = \begin{cases} 1 & \text{if edge } e_i \text{ incident to } v \text{ exists in the graph} \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

Since X_i is a Bernoulli random variable, we know that $\mathrm{E}[X_i] = \mu_i = p_i$ and $\mathrm{Var}[X_i] = p_i(1 - p_i)$. Using the fact that $d(v) = \sum_{i=1}^{d_v} X_i$, we have:

$$\Pr[d(v) \geq k] = \Pr\left[\sum_{i=1}^{d_v} X_i \geq k\right]. \tag{4}$$

According to Equation (4), finding the probability that a vertex v is of the degree at least k is equivalent to computing the probability that the sum of X_i's for v is at least k. In addition, Bernoulli random variables X_i's are independent, but not identically distributed. Thus, if condition (2) is satisfied and if d_v is large enough, we can conclude that $\frac{1}{s_{d_v}}\sum_{i=1}^{d_v}(X_i - \mu_i)$ has standard normal distribution, where $s_{d_v} = \sqrt{\sum_{i=1}^{d_v} p_i(1 - p_i)}$. To compute $\Pr[\sum_{i=1}^{d_v} X_i \geq k]$, we can subtract $\sum_{i=1}^{d_v}\mu_i$ from both sides of the inequality, and then divide by s_{d_v} which results in:

$$\Pr\Big[\sum_{i=1}^{d_v} X_i \geq k\Big] = \Pr\Big[\frac{1}{s_{d_v}}\sum_{i=1}^{d_v}(X_i - \mu_i) \geq \frac{1}{s_{d_v}}(k - \sum_{i=1}^{d_v}\mu_i)\Big]. \tag{5}$$

Using Lyapunov CLT, and setting

$$Z = \frac{1}{s_{d_v}}\sum_{i=1}^{d_v}(X_i - \mu_i), \tag{6}$$

we can say that Z has standard normal distribution. Thus

$$\Pr[d(v) \geq k] \cong \Pr[Z \geq z], \tag{7}$$

where $z = \frac{1}{s_{d_v}}(k - \sum_{i=1}^{d_v}\mu_i)$. In fact, since Z in Equation (6) has standard normal distribution, using the complementary cumulative distribution function [56], we can efficiently evaluate the right hand side of Equation (7). To find the η-degree we start with $k = 1$, and approximate $\Pr[d(v) \geq k]$ using Lyapunov CLT, finding the maximum k for which the probability is above threshold η.

We can apply Theorem 3.1 provided that Lyapunov's condition is satisfied. By setting $\delta = 1$ in Equation (2) we show that this condition holds for a sequence of non-identically distributed Bernoulli random variables.

Theorem 3.2. *Given a sequence of random variables $X_i \sim$ Bernoulli(p_i), for $i \in [1, n]$, the Lyapunov's condition (2) for $\delta = 1$ is satisfied whenever $s_n^2 = \sum_{k=1}^{n} p_k(1 - p_k) \to \infty$.*

Proof. For each Bernoulli random variable X_i we know that $\sigma_i^2 = p_i(1 - p_i)$, and $\mu_i = p_i$. Therefore, $s_n^2 = \sum_{k=1}^{n} p_k(1 - p_k)$ according to the equation (1). On the other hand, when $\delta = 1$, $\mathrm{E}[|X_k - \mu_k|^3]$ is computed as follows:

$$\begin{aligned} \mathrm{E}[|X_k - \mu_k|^3] &= p_k(1 - p_k)^3 + (1 - p_k)p_k^3, \\ &= p_k(1 - p_k)[(1 - p_k)^2 + p_k^2] \leq \sigma_k^2, \end{aligned} \tag{8}$$

where in inequality (8) we have used the fact that $(1-p_k)^2 + p_k^2 \leq 1$. Thus, $\sum_{k=1}^{n}\mathrm{E}[|X_k - \mu_k|^3] \leq s_n^2$. Substituting this in the Lyapunov's condition (2) for $\delta = 1$, we conclude that the condition is satisfied whenever $s_n^2/s_n^3 \to 0$ as $n \to \infty$ which means that s_n should go to infinity as n increases. This is equivalent to $s_n^2 = \sum_{k=1}^{n} p_k(1 - p_k) \to \infty$, and as a result the theorem follows. In other words, since we have

$$s_n^2 = \sum_{k=1}^{n} p_k(1 - p_k) = \sum_{k=1}^{n}\sigma_k^2 \geq n\sigma_{\min}^2, \tag{9}$$

for large n and as long as $\sigma_{\min}^2 = \min_k\{\sigma_k^2\}$ is away from zero, $n\sigma_{\min}^2 \to \infty$ which results in $s_n^2 \to \infty$ as n approaches infinity. □

Accuracy of the Approximation. In order to show the accuracy of the approximation, we refer to the Berry–Esseen theorem [57]: For a given sequence $Y_1, Y_2, \ldots$ of non identically distributed and independent random variables with $E(Y_i) = 0$, $E(Y_i^2) = \sigma_i^2$, and $E(|Y_i^3|) = \rho_i < \infty$, there exists a constant C_0 such that the following inequality is satisfied for all n:

$$\sup_{x\in\mathbb{R}} |F_n(x) - \Phi(x)| \leq C_0 \cdot \psi_0, \tag{10}$$

where F_n is the cumulative distribution of $S_n = \frac{Y_1+Y_2+\cdots+Y_n}{\sqrt{\sigma_1^2+\sigma_2^2+\cdots+\sigma_n^2}}$, which is the sum of Y_i's standardized by the variances, and Φ is the cumulative distribution of the standard normal distribution. In the above inequality ψ_0 is a function given by

$$\psi_0 = \psi_0(\vec{\sigma}, \vec{\rho}) = \left(\sum_{i=1}^{n}\sigma_i^2\right)^{-3/2} \cdot \sum_{i=1}^{n}\rho_i. \tag{11}$$

where $\vec{\sigma} = (\sigma_1, \cdots, \sigma_n)$, and $\vec{\rho} = (\rho_1, \cdots, \rho_n)$ are the vectors of σ_i's and ρ_i's respectively. It should be noted that the best upper-bound obtained so far for C_0 is 0.56 [42].

Based on the Berry–Esseen theorem, the more the number of edges incident to a vertex, the better the accuracy of the results. In the following corollary, we show how to obtain an upper-bound on the maximal error while approximating the true distribution of the sum of X_i's with the normal distribution.

Corollary 1. *For each vertex v in the probabilistic graph $\mathcal{G}$ with X_i's being Bernoulli random variables as defined in (3), where $i = 1, \dots, d_v$, the error bound on the approximation of the right-hand side of Equation (7) to the standard normal distribution is given as follows:*

$$\sup_{x\in\mathbb{R}} \left|F_{d_v}(x) - \Phi(x)\right| \le \frac{0.56}{\sqrt{p_1(1-p_1) + \cdots + p_{d_v}(1-p_{d_v})}}$$

Proof. Setting $Y_i = X_i - p_i$ in equation (6), we can apply the Berry–Essen theorem for random variables $Y_1, Y_2, \cdots, Y_{d_v}$, since for each Y_i, $\mathrm{E}[Y_i] = 0$. In addition,

$$\begin{aligned}\mathrm{E}[Y_i^2] &= \mathrm{E}[(X_i - p_i)^2] = \mathrm{Var}[X_i] = \sigma_i^2 = p_i(1-p_i),\\ \mathrm{E}[|Y_i^3|] &= \mathrm{E}[|X_i - p_i|^3] = \rho_i = (1-p_i)^3 p_i + p_i^3(1-p_i)\\ &= p_i(1-p_i)[(1-p_i)^2 + p_i^2] < \infty. \end{aligned} \tag{12}$$

It should be noted that the random variable

$$S_{d_v} = \frac{(X_1 - p_1) + (X_2 - p_2) + \cdots + (X_{d_v} - p_{d_v})}{\sqrt{\sigma_1^2 + \sigma_2^2 + \cdots + \sigma_{d_v}^2}} \tag{13}$$

in the Berry–Essen theorem is the same as the random variable Z in Equation (6).

Substituting σ_i^2 and ρ_i in Equation (11), we obtain:

$$\begin{aligned}\psi_0 &= \psi_0(\overrightarrow{\sigma}, \overrightarrow{\rho})\\ &= \left(\sum_{i=1}^{d_v} p_i(1-p_i)\right)^{-3/2} \cdot \left(\sum_{i=1}^{d_v} p_i(1-p_i)[(1-p_i)^2 + p_i^2]\right),\end{aligned} \tag{14}$$

Using the fact that $1 = (1-p_i+p_i)^2 = (1-p_i)^2 + p_i^2 + 2p_i(1-p_i) \ge (1-p_i)^2 + p_i^2$, we can simplify (14) to have:

$$\begin{aligned}\psi_0 &\le \left(\sum_{i=1}^{d_v} p_i(1-p_i)\right)^{-3/2} \cdot \left(\sum_{i=1}^{d_v} p_i(1-p_i)\right)\\ &= \left(\sum_{i=1}^{d_v} p_i(1-p_i)\right)^{-1/2} = \frac{1}{\sqrt{p_1(1-p_1) + \cdots + p_{d_v}(1-p_{d_v})}},\end{aligned} \tag{15}$$

Substituting (15) in (10) the stated claim follows. □

4 PEELING ALGORITHM (PA)

In this section we propose a graph peeling algorithm (PA). Graph peeling, that is, (1) recursively deleting the vertex v of smallest degree (2) setting v's coreness to be equal to its degree at the time of deletion, and (3) updating the degrees of v's neighbors while keeping them sorted, is a general idea that has been used broadly in core decomposition of deterministic graphs (cf. [3, 24]). However, it requires substantial algorithmic engineering in order to achieve high scalability when applied to probabilistic graphs. This is because when a vertex v is deleted in the peeling process, updating the η-degrees of v's neighbors and maintaining the data structures up to date are non-trivial. In order to tackle these challenges, we use efficient *array structures* and *lazy updates*, which delay updating the η-degrees of v's neighbors for as long as possible.

Computing and updating η-degrees. An expensive step in the peel-off process is computing initial η-degrees and updating them for those vertices that lose neighbors in a peel-off step. We will depart from the feature of the deterministic case of having vertices sorted at all times based on their current degrees and allow instead the vertices to not be on their precise order as long as at the time of their removal we can fix things up using the key functions and data structures that we define.

More specifically, the computation and update of η-degrees is delayed as much as possible by using easy to compute lower-bounds on η-degrees instead of exact values. It is only when a vertex is candidate for removal that we compute its exact η-degree. At that time the remaining graph is typically much smaller and the computation becomes significantly faster.

Based on Corollary 1, we know that Lyapunov CLT gives a very good approximation on tail probabilities of vertex degrees. We use the values produced by CLT (decremented by a small epsilon) in order to obtain lower-bounds on η-degrees. For simplicity of exposition, we refer to the lower-bound values simply as *values*.

One important difference between the core decomposition of probabilistic and deterministic graphs is that the η-degree of a vertex can decrease by *at most one* when a neighbor is removed (according to Lemma 2 in [6]) as opposed to *exactly one* in deterministic graphs. An array **A** stores, for each value in the input graph, the set of vertices with that value. In the PA algorithm at each iteration, we decrease the value of a vertex v by one if a v's neighbor is removed. When v's turn comes to be removed and processed, we compute its η-degree and if it is the same as its current value we remove v. Otherwise, we repeatedly swap v to the proper place in **A**. There could be several neighbor removals that did not change the η-degree of v, thus the proper place of v in **A** could be far from the next block of vertices, and therefore we might need to perform several swaps.

PA algorithm description. The PA algorithm is given in Algorithm 1. There we have arrays **d**, **b**, **p**, and **A**. For an example see Figure 1 and Table 1. Vertices in the PA algorithm are assumed to be labeled by numbers 0 to $n-1$. Array **d** initially stores for each vertex the lower-bound on the η-degree of that vertex. For instance, vertex 1 has a lower-bound of 1 in Table 1, so **d**[1] = 1. Initially, vertices are stored in **A** in ascending order of their lower-bounds. We have colored **A** in shades of green in Table 1. The first block in **A** contains all the vertices with a lower-bound equal to 0; the second block contains vertices with lower-bound equal to 1, and so on. In order to determine the index boundaries of such blocks in **A**, we define array **b** which stores the index boundaries of the vertex blocks in **A**. In Table 1 we have for instance **b**[1] = 2 and **b**[2] = 6. In order to handle swapping efficiently we define an array **p** which stores the position of each vertex in **A**. For instance, vertex 6 is at position 2 in **A**, therefore **p**[6] = 2.

There are two additional arrays as well; **gone** and **valid**. Since we do not remove vertices physically from the graph, we use array **gone** to keep track of the removed vertices at each step of the algorithm. Array **valid** tells for each vertex v if the η-degree of v is the same as the value **d**[v]. The array **gone** is initially set to false for all the vertices, because none of the vertices has been removed yet. Array **valid** is set to all-false vector because all the vertices are on their lower-bound at the beginning of the algorithm. For instance, in Table 1, we have **valid**[4] = false

which indicates that vertex 4 is on its lower-bound and its η-degree should eventually be computed.

We illustrate a few steps of the PA algorithm on the graph in Figure 1. We set $\eta = 0.5$. The PA algorithm starts with the first vertex v in array **A**, checking whether v is on its lower-bound or its η-degree is available. As can be seen in Table 1, vertex 0 is the first vertex in **A**. Since **valid**$[0] = false$, the vertex 0 is on its lower-bound, and its η-degree might be higher. Therefore, it might not be its turn to be removed. As such, the compute_swap function is called (line 19, Algorithm 1) to compute the η-degree, and then do the required number of swaps to the right, using Algorithm 3, to place the vertex in the proper block of **A**. *Thus, unlike deterministic case we do need to perform several swaps to the right.* The compute_swap function (Algorithm 4) computes the η-degree of vertex 0, which turns out to be 1. Thus, the vertex only needs one swap to the right in **A** to be placed in the block containing all the vertices with degree 1. In order to do each swap in constant time (using Algorithm 3), we swap vertex 0 with the last vertex in the same block which is 6. As a result, the positions of vertices 0 and 6 should be swapped as well: $\mathbf{p}[0] = 2, \mathbf{p}[6] = 1$. Vertex 0 becomes the last element of its current block (the block of vertices with degree 0). In order to make vertex 0 become an element of the next block, the index of the block of vertices with degree 1, **b**[1], is decremented by one to include vertex 0 as its first element. We have $\mathbf{b}[1] = 1$, and vertex 0 becomes the first element of the block of vertices with degree 1.

Table 2 shows the current status of arrays after swapping vertex 0 with 6. The updated values are shown in red color. As can be seen, **valid**$[0] = true$ because now the η-degree of vertex 0 is available. Now, vertex 6 is the first vertex in **A** and the algorithm processes it. The summary of the results is shown in Table 3. Since **valid**$[6] = true$ we can safely remove vertex 6. The corresponding index in array **gone** is set to true, and the coreness of vertex 6 is set to **d**[6], which is 1.

When a vertex v is removed, we process those neighbors u of v with a higher degree (lower-bound or exact) than v's (see lines 14-16), and decrement their degrees by one. Therefore, these neighbors should be moved one block to the left in **A**. This is done in constant time using the swap_left function (line 15) which is shown in Algorithm 2. For instance, vertex 3 is a neighbor of vertex 6 with degree 2, which is decremented by one, from 2 to 1, when vertex 6 is removed. Therefore, vertex 3 should be swapped to the block in the left in **A**, which contains vertices of degree 1. The process is similar to swapping to the right. However, when swapping to the left, vertex u is swapped with the first vertex, w in the same block in **A**. In addition, the positions of u and w are swapped in **p**. Then, the block index in **b** is incremented by one (line 7, Algorithm 2), making u the last element of the previous block.

Correctness of the algorithm. For every $v \in V$, and $C \subseteq V$, a vertex property function [3] is a function $\phi(v, C) : V \times 2^V \to \mathbb{R}$, and it is monotonic if $\forall C_1, C_2 \subseteq V : C_1 \subseteq C_2$ implies that $\phi(v, C_1) \leq \phi(v, C_2)$. According to the result by Batagelj and Zaversnik [3], for a monotonic vertex property function $\phi(v, C)$, the algorithm that repeatedly removes the vertex with smallest ϕ value gives the core decomposition. Since η-degree of a vertex is a monotonic vertex property function [6], then our peeling algorithm, which removes the vertex with smallest η-degree at each iteration of the algorithm, computes the desired core decomposition. Also, it should be noted that, the algorithm scans the next vertex in array **A** only when the η-degree of the previous vertex has been set. In addition, the lower-bounds never surpass the value of η-degrees. Thus, we conclude that the PA algorithm computes the desired core decomposition in probabilistic graphs.

Running time of the PA algorithm. The compute_swap function is dominated by two parts: **(1)** computing η-degrees takes $O(\eta\text{-deg}(u))$ for each vertex u **(2)** swapping a vertex to the proper block; each swap is done in constant time, and the maximum number of swaps required for a vertex u is $O(\eta\text{-deg}(u))$. However, as reported above, initially the difference between the lower-bounds obtained by Lyapunov CLT and the η-degrees is no more than one. Hence, either one or no swap is required initially. Thus, the compute_swap function takes in total

$$O\left(\sum_{v\in V}\;\sum_{u:(u,v)\in\mathcal{N}_v} \eta\text{-deg}(u)\right) = O\left(\sum_{v\in V} d_v\delta'\right) = O(m\delta'),$$

where m is the number of edges, and δ' is the maximum η-degree over all vertices at the time of their removal. The swap_left function swaps each vertex one block to the left in **A** in constant time. Therefore, the main cycle (Algorithm 1, line 6-19) takes $O(m\delta')$. In conclusion, the running time of the PA algorithm is $O(m\delta')$.

5 SEQUENTIAL ALGORITHM (SA)

In this section we present a sequential algorithm (SA) which processes the vertices one-by-one, and as such, does not require the graph to be fully loaded into memory but rather one vertex at a time. Furthermore, as shown in Section 6, after only a fraction of iterations, SA is able to produce high quality results.

SA maintains bookkeeping information for each vertex and has a memory footprint of $O(n)$ as opposed to $O(m)$ for PA. More

Algorithm 1 PA k-core computation function

```
function K_CoreCompute(Graph $\mathcal{G}$, $\eta$)
    initialize($\mathbf{d}, \mathbf{b}, \mathbf{p}, \mathbf{A}, \mathcal{G}$)
    gone ← False                                    ▷ all-false vector
    valid ← False                                   ▷ all-false vector
    $i \leftarrow 1$
    while $i < n$ do
        $v \leftarrow \mathbf{A}[i]$
        if valid[$v$] = true then
            gone[$v$] ← true
            for all $u : (u, v) \in \mathcal{N}_v$ do
                if $\mathbf{d}[u] = \mathbf{d}[v]$ then
                    if valid[$u$] = false then
                        compute_swap($\mathbf{d}, \mathbf{p}, \mathbf{b}, \mathbf{A}, u$, valid)
                if $\mathbf{d}[u] > \mathbf{d}[v]$ then
                    swap_left($\mathbf{d}, \mathbf{p}, \mathbf{b}, \mathbf{A}, u$)
                    valid[$u$] ← false
            $i++$
        else
            compute_swap($\mathbf{d}, \mathbf{p}, \mathbf{b}, \mathbf{A}, v$, valid)
    return d
```

Algorithm 2 PA swap to left function

```
function SWAP_LEFT($\mathbf{d}, \mathbf{p}, \mathbf{b}, \mathbf{A}, u$)
    $du \leftarrow \mathbf{d}[u], pu \leftarrow \mathbf{p}[u]$
    $pw \leftarrow \mathbf{b}[du]$ , $w \leftarrow \mathbf{A}[pw]$
    if $u \neq w$ then
        $\mathbf{A}[pu] \leftarrow w, \mathbf{A}[pw] \leftarrow u$
        $\mathbf{p}[u] \leftarrow pw, \mathbf{p}[w] \leftarrow pu$
    $\mathbf{b}[du]++, \mathbf{d}[u]--$
```

Algorithm 3 PA swap to right function

```
function SWAP_RIGHT($\mathbf{d}, \mathbf{p}, \mathbf{b}, \mathbf{A}, u$)
    $du \leftarrow \mathbf{d}[u], pu \leftarrow \mathbf{p}[u]$
    $pw \leftarrow \mathbf{b}[du + 1] - 1$ , $w \leftarrow \mathbf{A}[pw]$
    if $u \neq w$ then
        $\mathbf{A}[pu] \leftarrow w, \mathbf{A}[pw] \leftarrow u$
        $\mathbf{p}[u] \leftarrow pw, \mathbf{p}[w] \leftarrow pu$
    $\mathbf{b}[du + 1]--, \mathbf{d}[u]++$
```

Algorithm 4 η-degree computation and swap function

```
function COMPUTE_SWAP($\mathbf{d}, \mathbf{p}, \mathbf{b}, \mathbf{A}, u$, valid)
    $\eta\_deg$ ← compute $\eta$-deg($u$)
    valid[$u$] ← true
    $diff \leftarrow \eta\_deg - \mathbf{d}[u]$
    for $j \leftarrow 1$ to $diff$ do
        swap_right($\mathbf{d}, \mathbf{p}, \mathbf{b}, \mathbf{A}, u$)
```

specifically, SA adopts the "semi-external" model of computation, which assumes that for each vertex we can fit a small constant amount of information in main memory while the edges of the graph are stored on disk. As other works have shown, this model is practical for a large number of real-world, web-scale graphs, and widely adopted to handle other graph problems [32, 45, 50, 51].

Algorithms that are sequential and semi-external do exist for deterministic core-decomposition (see [24, 35, 45]). They are based on the idea of maintaining an upper-bound on each vertex's coreness. This upper-bound is initialized to the degree of each vertex, and after each iteration of the algorithm it is tightened further using a simple *locality property* until it reaches the exact core value. The locality property is as follows. The coreness of a vertex v can at most be the largest value k such that v has at least k neighbors with a value greater or equal to k. Locality-based tightening (LBT) lowers the bound of a vertex to be the number k described above.

Unfortunately, this idea does not work for probabilistic core decomposition. LBT does not necessarily converge to true core values of vertices. For an example, consider Figure 1, $\eta = 0.5$, and Table 4. We initialize the upper-bounds to the η-degree of each vertex. Then, we execute a round of LBT. The bound for vertex 3 is tightened to 2. This is because the largest k for which vertex 3 has at least k neighbors with a value at least k is 2. These neighbors are 1, 2, 4, and 5 with a bound equal to 2. Running one more iteration of LBT does not produce any further tightening. However, the true core number of vertex 3 is 1 not 2 (see Table 4, last column). In the following, we tackle the problem with a new procedure we call *probabilistic bound tightening* (PBT). PBT takes into consideration the edge probability values and uses an optimized version of dynamic programming to gradually tighten the upper bounds of vertices to the true coreness. While PBT by itself can be used to compute coreness, we combine PBT with LBT in order to speed up the convergence, since LBT is faster than PBT.

First we show that the obtained values at the end of LBT are always an upper-bound to the true coreness values.

Proposition 1. *Let $\mathcal{G} = (V, E, p)$ be a probabilistic graph. Also, for each vertex $v \in V$, let k_v be the true coreness of v, and $\bar{k}_v$ be the value assigned to v at the end of the LBT phase. Then, $\bar{k}_v \geq k_v$.*

Proof. Once a LBT phase terminates, and the coreness of v is fixed to $\bar{k}_v$; then there should be a subset $V_{\bar{k}_v}$ of neighbors of v with the size at least $\bar{k}_v$, and $\forall u \in V_{\bar{k}_v} : \bar{k}(u) \geq \bar{k}_v$, where $\bar{k}(u)$ is the coreness assigned to u by LBT. However, considering the existence probability of edges incident to v, the value for $\Pr[d_{\mathcal{G}(V_{\bar{k}_v})}(v) \geq \bar{k}_v]$ can be less than η, where $\mathcal{G}(V_{\bar{k}_v})$ is the induced subgraph by $V_{\bar{k}_v}$. On the other hand, since $\Pr[d(v) \geq k]$ is monotonically non-increasing with the value of k, the true coreness of v should be in the interval $[0, \bar{k}_v]$ such that $\Pr[d_{\mathcal{G}(V_{\bar{k}_v})}(v) \geq k] \geq \eta > \Pr[d_{\mathcal{G}(V_{\bar{k}_v})}(v) \geq \bar{k}_v]$. Thus, $\bar{k}_v \geq k_v$. □

Once a LBT phase terminates, PBT starts to check whether the obtained value for each vertex is the true coreness of the vertex or not. If not, the gap is tightened further. We run LBT and PBT repeatedly, one after the other, until the core value for each vertex reaches a fixed point.

Before formally giving the algorithm, we present an example to illustrate how the SA algorithm works. We consider the probabilistic graph in Figure 1 and $\eta = 0.5$. LBT for this example was discussed earlier and the vertex values at the end of it are given in Table 4, third column. As can be seen, there are some vertices whose bounds are different from their true coreness (e.g. vertices 1 and 3). Therefore, the SA algorithm starts PBT to close this gap by checking for exactness of each bound to the true coreness of the vertex. For instance, consider vertex 1. We should check whether the coreness of it can be equal to 2 or not. In probabilistic core decomposition, a vertex v has coreness k if

$\Pr[d_{\mathcal{H}}(v) \geq k] \geq \eta$, where $\mathcal{H}$ is a maximal subgraph in which each vertex has degree of at least k. Checking $\Pr[d_{\mathcal{H}}(1) \geq 2]$, we see that this probability does not pass threshold $\eta = 0.5$, and therefore vertex 1 cannot have coreness of 2 in subgraph $\mathcal{H}$ which contains the neighbors 2 and 3. We perform the check of $\Pr[d_{\mathcal{H}}(v) \geq k]$ using an optimized version of dynamic programming explained later. Vertex 0 cannot belong to the subgraph because its bound is less than 2. For vertex 1, the maximum value, for which the probability passes the threshold, is equal to 1. As a result, the bound on the coreness of vertex 1 is updated to 1. The same process is done for vertex 3. The values obtained at the end of PBT are shown in the fourth column of Table 4, which contains exactly the true core value of each vertex.

v	η-degree	LBT-Round 1	PBT-Round 1	Coreness
0	1	1	1	1
1	2	2	1	1
2	2	2	2	2
3	3	2	1	1
4	2	2	2	2
5	2	2	2	2
6	1	1	1	1

Table 4: Upper-bounds obtained at LBT and PBT phase of SA. $\eta = 0.5$ for the example. LBT and PBT correspond to locality-based and probability bound tightening, respectively.

SA algorithm description. The main cycle of SA is given in Algorithm 5. We define two Boolean variables, *PBT_phase* and *etadegree_change*. Variable *PBT_phase* is used to determine whether a PBT phase has been started or not. The variable *etadegree_change* is used to record whether there is some vertex (in PBT phase) with its η-degree changed or not. Initially both of them are set to *false*. Then, we invoke LBT. Once this process terminates (line 4), the vertex value (upper-bound) of all the vertices should be checked for the possibility of gap between the current vertex value and its true coreness. In fact, for each vertex v it should be investigated whether the degree of v can be greater than or equal to its current vertex value with probability no less than η or not. If so, the current vertex value should be the same as its η-deg(v). Checking whether a vertex should be processed (in PBT) or not is done using the Boolean array *check* which contains a flag for each vertex. If the flag is set to *true*, its vertex value needs to be checked, using the *PBT* function (see line 10). Then, the algorithm enters a PBT phase (lines 8-10). We make a clone, *checkNow*, of *check*; then we reinitialize *check* to the all-false vector (lines 8-9). The clone is needed to be used in the *for* loop in the *PBT* function (line 3, Algorithm 6). If after a PBT phase terminates there is some vertex with its η-degree not equal to its current vertex value, a new LBT phase is started again (line 15) and this process continues until a fixed point is obtained for all the vertices (lines 11-12).

PBT is given in Algorithm 6. The implementation iterates over each vertex v, and checks if there is a gap between v's value and its true coreness; if so, that vertex should be processed. In this process, only the neighbors of v whose current values are greater or equal to v's value are considered because it is only them that can contribute to v's coreness. We compute $\Pr[d(v) \geq C[v]]$ and check whether it passes threshold η or not. If $\Pr[d(v) \geq C[v]] < \eta$, then, since we know that $\Pr[d(v) \geq k]$ is non-increasing with k, the maximum k for which the probability passes the threshold is returned and stored in variable *localValue* (line 5). In this case, all the values from $(C[v] - 1)$ down to *localValue* should be checked as candidate values for the coreness of v and the maximum value (variable *max* in line 16), is chosen as the new value of v. This way we make sure that the algorithm does not go below the real coreness value at each PBT step (lines 8-15). For each value j in the *for* loop (line 8) we check whether $\Pr[d(v) \geq j] \geq \eta$ (line 9). If so, *max* is set to j (line 10) and the vertex value is updated to *max* (line 16). Otherwise, the value for which the probability passes the threshold is stored in variable *value* (line 13), and if it is greater than *max*, the latter is updated to the former (lines 14-15).

It should be noted that in the *for* loop, similar to what we do in lines 4-5 of Algorithm 6, we should compute $\Pr[d(v) \geq j]$ and check if it passes the threshold or not. For this, we use an optimized dynamic programming process as follows. Variable j starts from $C[v] - 1$ and goes down to *localValue*. In order to avoid computing these probabilities from scratch, once we compute $\Pr[d_{\mathcal{H}}(v) \geq C[v]]$, we cache the following probabilities $\Pr[d_{\mathcal{H}}(v) = 0], \cdots, \Pr[d_{\mathcal{H}}(v) = C[v]]$, where $\mathcal{H}$ contains all the neighbors of v whose upper-bound is at least $C[v]$. Then, since for $j = C[v] - 1$, $\mathcal{H}'$ contains all the neighbors whose upper-bound is exactly equal to j (we denote this set by V_j) and higher, we can have $\mathcal{H}' = V_j \cup \mathcal{H}$. Therefore, to compute $\Pr[d_{\mathcal{H}'}(v) \geq j]$ we use the computed probabilities in $\mathcal{H}$ and only consider vertices in V_j. This way we optimize DP to compute the probabilities very fast since V_j is typically small (e.g., about 100 in our later evaluated large-scale graphs). For the next iteration, we store all the probabilities computed in the previous iteration and use them to compute new probabilities. In the following we describe our DP process in more detail.

Let assume that we have computed $\Pr[d_{\mathcal{H}}(v) = k]$, where $k = 0, 1, ..., j$, and $\mathcal{H}$ is a subgraph of the input probabilistic graph in which each vertex has core value at least j. Also, let V_{j-1} contain all the vertices (including the neighbours of v) whose core value is exactly $j-1$. Thus, $\mathcal{H}' = \mathcal{H} \cup V_{j-1}$ is the subgraph whose vertices have core value at least $j - 1$. We denote $\{e_1, ..., e_x\}$ to be the set of edges incident to v such that for each $e_i = (u_i, v)$, $u_i \in V_{j-1}$, where $i = 1, ..., x$. In order to evaluate $\Pr[d_{\mathcal{H}'}(v) = k']$, where $0 \leq k' \leq k$, and avoid from scratch computation, we denote the degree of v in the subgraph $\mathcal{H}'$ by $d(v \mid (\mathcal{H} \cup \{e_1, ..., e_x\}))$. Then, it holds that:

$$\begin{aligned} &\Pr[d(v \mid (\mathcal{H} \cup \{e_1, ..., e_x\})) = k'] = \\ &= p_{e_x} \Pr[d(v \mid (\mathcal{H} \cup \{e_1, ..., e_{x-1}\})) = k' - 1] + \\ &+ (1 - p_{e_x}) \Pr[d(v \mid (\mathcal{H} \cup \{e_1, ..., e_{x-1}\})) = k']. \end{aligned} \tag{16}$$

Letting $T(x, k') = \Pr[d(v \mid (\mathcal{H} \cup \{e_1, ..., e_x\})) = k']$, we have the following recursive formula:

$$T(x, k') = p_{e_x} T(x - 1, k' - 1) + (1 - p_{e_x}) T(x - 1, k') \tag{17}$$

with the following base cases:

$$\begin{cases} T(0, k') = \Pr[d_{\mathcal{H}}(v) = k'], & 0 \leq k' \leq k \\ T(x, -1) = 0, \end{cases} \tag{18}$$

As can be seen, in the base case of the recursive formula, we are using the previously computed probabilities to compute the probabilistic degree of vertex v in the new subgraph, which results in saving time significantly.

Since the vertex value of v is updated, all its neighbors with value at least the vertex value of v should be checked for validity of their vertex value. We show in the following that the PBT estimate of the coreness eventually equals the true coreness for each vertex.

Algorithm 5 SA k-core computation function

```
function SA_CORE_COMPUTATION(Graph $\mathcal{G}$)
    $PBT\_phase \leftarrow false$
    $C \leftarrow \mathbf{0}$                          ▷ array of core values
    LBT()
    $check \leftarrow$ True                            ▷ all-true vector
    $etadegree\_change \leftarrow false$
    while true do
        $checkNow \leftarrow check.clone()$
        $check \leftarrow$ False                       ▷ all-false vector
        PBT($\mathcal{G}, checkNow$)
        if $etadegree\_change = false$ then
            break
        else
            $PBT\_phase = true$
            LBT()
            $etadegree\_change \leftarrow false$
    return $cores$
```

Algorithm 6 SA probabilistic bound tightening function

```

15:                             $max \leftarrow value$
16:                 $C[v] \leftarrow max$
17:                 $etadegree\_change \leftarrow true$
18:                 for all $u : (u, v) \in \mathcal{N}_v$ do
19:                     if $C[u] \geq C[v]$ then
20:                         $check[u] \leftarrow true$
```

Correctness of the SA algorithm. We prove this by contradiction. Suppose that after the last PBT phase, there is vertex u_1 such that $k(u_1) = k_1$ (real coreness) and $core[u_1] = k' > k_1$, where $core$ is the coreness assigned to u_1 after PBT phase. Since $k(u_1) = k_1$, k_1 is the maximum value such that $\Pr[d_{\mathcal{H}}(u_1) \geq k_1] \geq \eta$, and $\Pr[d_{\mathcal{H}'}(u_1) \geq i] < \eta$ for all $i > k_1$, where $\mathcal{H}$ and $\mathcal{H}'$ are the maximal induced subgraphs in which each vertex has degree at least k_1 and i, respectively, with probability no less than η. Based on the properties of cores of a graph, we know that $\mathcal{H}' \subseteq \mathcal{H}$. If all the neighbors of u_1 in $\mathcal{H}$ have coreness k_1, then u_1 will not have any neighbors with coreness greater than k_1 in $\mathcal{H}'$, so u_1 eventually sets $core[u_1]$ equal to k_1, which is a contradiction. The similar argument holds if all the neighbors of u_1 in $\mathcal{H}$ have coreness greater than k_1. Since $k(u_1) = k_1$ and $core[u_1] = k' > k_1$, there should exist a neighbor u_2 with $k(u_2) = k_1$ and $core[u_2] > k_1$ such that $\Pr[deg_{\mathcal{H}' \cup \{u_2\}}(u_1) \geq k'] \geq \eta$, because otherwise $\Pr[d_{\mathcal{H}'}(u_1) \geq k'] < \eta$. In fact, the existence of this neighbor will contribute to the assigned coreness of u_1 to be greater than k_1.

Now by reasoning similar to [35], we can build a sequence of vertices $S = \{u_i, u_{i+1}, u_{i+2}, ..., u_j = u_i\}$ connected to each other with $k(u_i) = k_1$ and $core[u_i] > k_1$. For each vertex u_i in S, let V_i be the set of all neighbors of u_i in $\mathcal{H}'$. Now, we can define a set $U = S \cup \bigcup_{u_i \in S} V_i$. The corresponding induced subgraph $\mathcal{G}(U)$ is a k'-core, because all the vertices in V_i have coreness at least k' with probability greater than or equal to η. Also, since for each vertex u_i in S, $\Pr[d_{V_i \cup \{u_{i+1}\}}(u_i) \geq k'] \geq \eta$, we have that $\mathcal{G}(U)$ is a k'-core where $k' > k_1$. Hence, we find a subgraph whose vertices have coreness $k' > k_1$ which is a contradiction because we assumed that each vertex in S has coreness k_1. Therefore, k_1 is not a maximal (i.e. true) coreness.

Running time of the SA algorithm. The time complexity of the algorithm is dominated by time complexity of the PBT because LBT has a time complexity of $O(N - K + 1)$ [35], where K is the number of vertices with minimal degree (in probabilistic graphs it refers to η-degree). To analyze the time complexity of a PBT step (Algorithm 6), let Δ be the maximum upper-bound on the η-degree over all the vertices in all the probabilistic bound tightening steps. Lines 4 and 5 (η-degree computation) are done simultaneously, and take time $O(d_v C[v])$ for each vertex v, where $C[v]$ is the upper-bound on the η-degree of v. In practice this computation is fast because the η-degree computation is performed on the subgraph $\mathcal{H}$ which contains only those neighbors of v whose upper-bound is at least $C[v]$ (not all the d_v vertices). In the worst case the inner loop is repeated $C[v]$ times, and each time the η-degree computation and the checking of the probability threshold (lines 9 and 13) are performed similarly to what explained above. Therefore, the time complexity of this part is: $\sum_{j=1}^{C[v]} O(jd_v)$. It should be noted that at each iteration in the for loop, we use the previously computed probabilities to avoid computing η-degrees from scratch. However, here we consider the worst case analysis of the algorithm. The time complexity of lines 18-20 is $O(d_v)$. As a result, each PBT iteration takes $\sum_{v \in V} \left(O(C[v]d_v) + \sum_{j=1}^{C[v]} O(jd_v) + O(d_v) \right) = \sum_{v \in V} \left(O(\Delta d_v) + O(\theta d_v) + O(d_v) \right)$, where $\theta = \Delta^2$. Therefore, the time complexity of each PBT round is $O(m\theta)$, where m is the total number of edges. In the worst case, we assume that at each PBT round, the difference between the actual coreness of a vertex and its initial estimate (the initial η-degree) decreases by one unit. Thus, in the worst case $\Gamma = \sum_{v \in V} \eta$-deg$(v)$ PBT steps are required. Therefore, the total running time can be expressed as: $O(\Lambda m)$, where $\Lambda = \Gamma\theta$.

As in [35], the complexity upper bounds for such iterative algorithms are not representative of practical performance. In practice, LBT and PBT are fast, and the number of iterations is only a handful, thus SA is an efficient algorithm for large datasets while requiring only $O(n)$ memory footprint.

6 EXPERIMENTS

In this section, we present our experimental results. Our implementations are in Java and the experiments are conducted on a commodity machine with Intel i7, 2.2Ghz CPU, and 12Gb RAM, running Ubuntu 14.03. The hard disk is Seagate Barracuda ST31000524AS 2TB 7200 RPM.

The statistics for all of the datasets we consider are shown in Table 5. We obtained flicker, dblp, and biomine from the authors of [6], and the rest of the datasets from Laboratory of Web Algorithmics.[1] The datasets are divided by horizontal lines according to their size, small (S), medium (M), large (L), and extra large (XL).

[1] http://law.di.unimi.it/datasets.php

We use the Webgraph framework [5] to store these datasets. The flickr, dblp, and biomine datasets already contained probability values. For the other datasets we generated probability values uniformly distributed in [0, 1].

We evaluate our algorithms in three important aspects. First is numerical stability. As [6] points out, using probability values may lead to numerical instability. We discuss this in Subsection 6.1. Second is the quality of our η-degree lower-bounds using Lyapunov CLT. We evaluate and discuss this in Subsection 6.2. Third is the efficiency of our proposed algorithms. We show our performance results in Subsection 6.3.

6.1 Numerical Stability

For evaluating numerical stability we refer to the results of η-degree computations shown in Table 6. The table contains results for $\eta = 0$, $\eta = 10^{-9}$ and $d_v = 100$, $d_v = 1000$. For each combination of η and d_v we compute η-degrees for 1000 randomly selected vertices. We show results for twitter-2010, but any of the other datasets above can be used for this experiment to obtain similar results.

Using the BigDecimal class in Java we adjust the numerical precision to different levels when using DP for computing η-degrees. We compare numerical results of DP using different precision levels in Java, where DPU (DP with unlimited precision) is the highest level of precision and thus the gold standard. The DP128 and DP256 columns in the table correspond to computing η-degrees using DP by setting precision to 128 bit and 256 bit, respectively. We observe that the more we increase the level of precision, the longer it takes to perform the computation. For example, when executing the DP algorithm for computing η-degrees for vertices with $d_v = 1000$, it takes more than 7000 times longer to perform the computation using unlimited precision than using the default (plain) number computation in Java.

Following [6], we start by setting $\eta = 0$ (top two parts). For this η the (k, η)-core decomposition of a probabilistic graph should coincide with the core decomposition of the deterministic graph derived by ignoring probabilities. The accuracy can thus be measured by comparing, for each vertex, the $(k, 0)$-core number with the core number obtained on the deterministic version of the graph.

We can see that for $\eta = 0$, we need a lot of precision (bits) to achieve error free computation. For example, when $d_v = 100$, we need at least 256-bit precision, whereas when the degree is 1000, we need DP with unlimited precision.

The DPLog2 column of the table shows the results if we operate in logarithmic space[2]. We can see that DP operating in logarithmic space is very stable and never produces any error at all, while being much faster than the DP variants operating with specified precision.

We test $\eta = 0$ to compare our results to previous work [6]. However, the situation changes significantly if η is greater than zero even by a very small amount. If we set $\eta = 10^{-9}$ (one billionth) or higher, we never get an error even for plain DP which is much faster than any other DP variant including the one in log space (see the two bottom parts). We tested with η in $[10^{-9}, 0.5]$ and obtained similar results.

The last column of Table 6 shows the accuracy of η-degree computation when using Lyapunov CLT instead of DP. For $\eta = 0$, computing η-degrees using CLT is error-free. More interesting are the bottom two parts for η greater than zero. For vertices with $d_v = 100$, CLT makes errors in computation (on 43% of the vertices), however, those errors are small; only 1% on average of the η-degree value.

When considering vertices with $d_v = 1000$, the computation using CLT is error-free and furthermore it is orders of magnitude faster than the variants of DP. Again, we also tested with a variety of η levels and obtained similar results. Guided by the above, in our algorithms, we set the threshold on d_v to start using Lyapunov CLT for computing η-degrees at 1500. Recall that the η-degree computation is needed in PA when a vertex becomes candidate for removal, while in SA it is needed when initializing vertex values.

In summary, regarding numerical stability, our contribution is to show that DP is sensitive to the setting of η value and becomes error-free once η is greater than zero even by a small amount. This was not investigated thoroughly before. On the other hand, CLT is resilient to different η values (even $\eta = 0$). With respect to efficiency in computing η-degrees, when $d_v \geq 1000$, CLT can be used to produce error-free computations orders of magnitude faster than all the DP variants.

6.2 Accuracy of CLT as a lower-bound

Here we investigate the quality of the lower-bounds on η-degrees obtained using CLT. Namely, we compare CLT with another method for deriving lower-bounds used in [6], which utilizes a

Table 7: Maximum error of CLT and regularized beta function for selected datasets.

formula based on the regularized beta function.[3] We computed initial η-degrees for biomine, cnr-2000, and ljournal-2008 with $\eta = 0.1$ using DP, Lyapunov CLT, and regularized beta function. Then, we computed the maximum error for CLT and regularized beta function. We report the results in Table 7. As can be seen, the maximum error for CLT for all the datasets is one which means that the difference between the values obtained by CLT and the true values is either zero or at most one. On the other hand the max error for the regularized beta function is big, in the order of thousands.

The small value of error for CLT is of great importance in the main cycle of the PA algorithm where each vertex is processed based on its lower-bound before its true η-degree is computed. To summarize, since the difference between each vertex's lower-bound (computed by CLT) and its true η-degree is small, we only need to do a small number of swaps to place a vertex in the proper place in the array **A** resulting in significant savings in running time.

6.3 Efficiency of the Proposed Algorithms

Table 8 shows the running times of the PA (left) and SA (right) algorithms on the selected datasets. For twitter-2010 we report the results for different values of η ranging from 0.1 to 0.5. For the other datasets, we only show results for $\eta = 0.1$ and omit results for $\eta = 0.2, \ldots, 0.5$, since they are similar to those for $\eta = 0.1$ and their nature is the similar to what we see for twitter-2010.

For the small and medium datasets, PA produced the results in about 2 sec for the small and 4 to 6 sec for the medium datasets. PA also performed well on the large datasets; biomine and ljournal-2008, computing the core decomposition of these two graphs on average in only 40 sec and 2 min, respectively. Notably, for biomine for instance, our algorithm is 32 times faster than the algorithm of [6] (see also Table 10 which we discuss later).

The running time of PA is good on the very large datasets as well. On uk-2005 and arabic-2005, PA completed in about 28 min and 42 min, respectively; less than one hour; in contrast the state-of-art [6] was not able to complete for these datasets in our machine after one day. For twitter-2010, which is much larger than uk-2005 and arabic-2005, with a maximum η-degree of $1,500,282$, our PA algorithm completed in around two hours, which is impressive for processing such a big dataset on our consumer-grade machine.

The running times of SA are shown in Table 8 (right part). For the small and medium datasets the total running times of SA were similar to those of PA. For the large datasets, SA needed more time, 2-3 times more, than PA. However, we recall that SA has a much smaller memory footprint than PA, namely $O(n)$ as opposed to $O(m)$ for PA. As such we are trading time for space when using SA over PA, a beneficial feature to have when using low-cost, cloud-server machines.

Another benefit of using SA is that it can produce good approximate results after only a small fraction of total iterations. We discuss this more later in this section.

Effect of η values. We observe that the total running time does not change much as the value of η increases. This is because when η increases, the η-degree of a vertex might not change or slightly decrease and as such this does not have a significant effect on the total running time of the algorithms. This is also evident in

[3] http://mathworld.wolfram.com/RegularizedBetaFunction.html

Table 9 where the average coreness (kavg) and the maximum coreness (kmax) decrease only slightly as η increases. As before, we report the average coreness, the maximum coreness, and the maximum η-degree for twitter-2010 for $\eta = 0.1, \ldots, 0.5$, whereas for the other datasets we only show the values for $\eta = 0.1$.

Comparing with the algorithm of [6]. We also compared the running times of our algorithms, PA and SA, to that of the algorithm of [6] (which we call BGKV[4]), for $\eta = 0.1$. We considered the (k, η)-core implementation made available to us by the authors of [6] with numbers represented by using BigDecimal in Java. From this, we also created a second version, which we call BGKV-2, where we replaced the computations using BigDecimal with plain computations in Java. This is because as shown in Subsection 6.1, for η greater than 0, the use of BigDecimal for DP is not warranted.

Table 10 summarizes the running times on three datasets, flickr, dblp and biomine. For biomine, which is a large dataset, we were only able to use up to 64 precision bits. We can see that both PA and SA are significantly faster than BGKV. For example, for biomine our algorithms are more than 32 times faster than BGKV.

BGKV-2 is faster than BGKV. For the small datasets, flickr and dblp, it is even faster than PA and SA. This can be attributed to the fact that since the memory footprint is small, the benefit of using our algorithms is outweighed by the overhead of using the Webgraph compression structures in PA and SA.

The situation changes significantly as the size of the datasets grows. For biomine, BGKV-2 is about twice slower than PA and SA. For the rest of the datasets that are bigger than biomine, BGKV-2 cannot run to completion in our machine after one day. For those datasets, our algorithms, PA and SA, are the only algorithms that can produce results in a matter of minutes or few hours (for twitter-2010), Table 8.

Convergence speed of SA. To further investigate the execution of SA as it unfolds with time, we look at average error and maximum difference (max error) from the true core value over the sequence of iterations (see Figure 2). As shown by the plots in the top part of the figure, the average error sharply decreases for all the datasets which we consider, except for uk-2005 and arabic-2005 whose average errors decrease more gradually.

Similar to the average error, the maximum difference from the true core value (shown in the plots in the bottom part) drops quickly, becoming 1 in only a fraction of the total number of iterations. Furthermore, as the value of η increases, the total number of iterations required decreases.

These results show that SA produces approximate results of good quality in only a fraction of iterations needed for completion. For instance, for arabic-2005 with $\eta = 0.1$, the average error drops below 0.01 at iteration 200, only one third of the total number of required iterations (about 600, see the end of the curve). Depending on the application domain this can be a desirable property during data analysis.

Dataset	η	PA-Running Time	SA-Running Time
flickr	0.1	2.05	1.88

SA		1.88	9.57	40

Table 10: Running time (sec) of the algorithm in [6] with BigDecimal (BGKV), and without (BGKV-2) versus PA and SA. "pr" is the precision (bits) used. BGKV cannot run for biomine to completion after one day (we use N.P. for "Not Possible"). BGKV-2 is faster for the small datasets, flickr and dblp, but twice slower for biomine than PA and SA. For the rest of the datasets that are bigger than biomine, both BGKV and BGKV-2 cannot run to completion in our machine after one day. Our algorithms PA and SA can produce results for every dataset, see Table 8.

7 RELATED WORK

Among different notions of cohesive subgraphs, k-core is one of the most popular (cf. [1, 24, 30, 44, 46]. Other definitions of dense subgraphs such as maximal cliques can also be computed using k-core decomposition [16]. In deterministic graphs, the computation of k-core has been well studied. Batagelj and Zaversnik [3] give an efficient peeling algorithm for deterministic core decomposition. Montresor et al. [35] give a distributed algorithm for deterministic core decomposition and introduce the concept of locality-based bound tightening. Wen et al. [45] propose I/O efficient core decomposition algorithms which only allow node information to be loaded in memory. Khaouid et al. [24] consider deterministic core decomposition of large networks on a single PC. Sariyuce et al. [39] propose incremental k-core decomposition algorithms for dynamic graph data, in which edges are added/deleted on a regular basis. In a similar setting, a distributed k-core decomposition and maintenance algorithms are proposed in [2]. Core decomposition in large temporal graphs is addressed in [47].

[4] Abbreviation using the first letters of the authors' names.

For probabilistic graphs, the generalization of k-core is the notion of (k, η)-core introduced by Bonchi et al. [6], which we discussed in detail throughout the paper. Other notions of cohesive subgraphs are studied in probabilistic setting [18, 36, 55]. [36, 53] focus on the problem of finding k vertex sets with the largest maximal-clique probabilities. Truss decomposition as another notion of a cohesive subgraph has been studied in [18, 55].

Significant research has been done in mining and querying probabilistic graphs. Reachability is addressed in [12, 20, 22, 23]. Shortest paths are studied in [38, 48] and frequent subgraph mining in [10, 37, 52, 54]. Clustering analysis is investigated in [26, 31] and subgraph similarity in [49].

8 CONCLUSIONS

We presented two efficient algorithms, PA and SA, for computing the core decomposition of probabilistic graphs at web scale. An important contribution of this work is the use of Lyapunov Central Limit Theorem in these algorithms to compute tail probabilities for η-degrees. We evaluated our algorithms, and showed that they are efficient and numerically stable. Our algorithms were considerably faster than the-state-of-the-art for large datasets. For datasets larger than biomine, our algorithms PA and SA, were the only algorithms able to run to completion on a consumer grade machine. In particular, PA was able to compute probabilistic core decomposition for uk-2005, arabic-2005, and twitter-2010 in 28 min, 42 min and 2.2 hours, respectively, which is impressive for such large datasets. SA has smaller memory footprint and can produce approximate results of high quality in only a fraction of iterations needed for full completion.

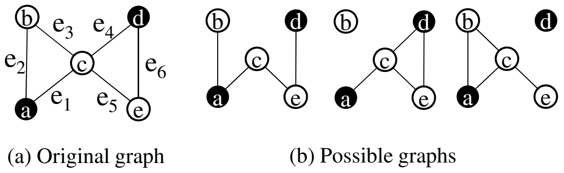
ABSTRACT

Network reliability is an important metric to evaluate the connectivity among given vertices in uncertain graphs. Since the network reliability problem is known as #P-complete, existing studies have used approximation techniques. In this paper, we propose a new sampling-based approach that efficiently and accurately approximates network reliability. Our approach improves efficiency by reducing the number of samples based on the *stratified sampling*. We theoretically guarantee that our approach improves the accuracy of approximation by using lower and upper bounds of network reliability, even though it reduces the number of samples. To efficiently compute the bounds, we develop an extended BDD, called *S^2BDD*. During constructing the S^2BDD, our approach employs dynamic programming for efficiently sampling possible graphs. Our experiment with real datasets demonstrates that our approach is up to 51.2 times faster than existing sampling-based approach with a higher accuracy.

1 INTRODUCTION

To understand and design our world, we need to model and analyze relationships between objects. Objects and relationships can be modeled by a graph, whose vertices and edges represent the objects and the relationships, respectively. Graph analysis is widely used in many domains, and the *reachability* [8, 34, 37] and *network reliability* [5, 10, 33] are the fundamental research topics in graph analysis. Reachability techniques compute whether there are paths between two *terminals* (i.e., given vertices). On the other hand, network reliability techniques compute a probability that all pairs of terminals are connected in *uncertain graphs*. In an uncertain graph, each edge is associated with an *edge existence probability* to quantify the likelihood that the edge exists in the graph. Network reliability is more generalized than reachability in terms of two aspects (1) a probabilistic value (the reachability is binary) and (2) the number of terminals. Thus, network reliability techniques have two benefits over reachability techniques. First, we can handle the inherent *uncertainty* of relationships in the real-world by modeling the uncertainty as the edge existence probability [1, 23]. Second, we can flexibly specify arbitrary numbers of terminals. From the above two benefits, the network reliability can be widely used for the uncertain graph analysis [6, 36] and many practical applications [20]. For example, protein-protein interaction networks can be modeled by uncertain graphs since protein interactions are not always established due to the sensitivity to conditions [4, 17]. In such protein-protein interaction networks, analysts evaluate the network reliability among several proteins as the strengths of the relationships to elucidate the functions of proteins. The network reliability is also used in many domains such as communication networks [5, 29] and urban planning [13].



(a) Original graph (b) Possible graphs

Figure 1: Uncertain graph

Unfortunately, the computation cost of the network reliability is significantly large because it is #P-complete problem [33]. The high complexity of #P-complete is caused by the fact that the computation of the network reliability inherently requires to enumerate all *possible graphs* which have the same set of vertices and an arbitrary subset of the edges without their probabilities. Each possible graph has its probability computed from the existence probabilities of its edges. A set of possible graphs is logically equivalent with its original uncertain graph. To compute the network reliability, we sum up the probabilities of all possible graphs in which all the terminals are connected.

We explain an example of computation of the network reliability by using Figure 1. This figure shows an original uncertain graph and three examples of its possible graphs. The black vertices represent terminals. Let us assume that each edge has 0.7 as its existence probability. Since these possible graphs have four existent and two non-existent edges, their probabilities are 0.0216 (i.e., $0.7^4 \cdot (1 - 0.7)^2$). All these terminals are connected only in the left and middle possible graphs. Thus, their probabilities are added to the network reliability.

Problem Definition and Technical Overview

We approximate the network reliability since the computation cost of the network reliability is significantly large due to #P-complete problem. In this paper, we consider the problem of computing the approximate network reliability by sampling. We formally define the problem as follows.

Problem definition: **(Approximate network reliability)**. Given an uncertain graph $\mathcal{G}$, a set of terminals $\mathbb{T}$, and the number of samples s, we efficiently compute the approximate network reliability $\hat{R}[\mathcal{G}, \mathbb{T}]$.

The computation cost of sampling becomes considerable as the number of samples increases. To efficiently approximate the network reliability, we reduce the number of samples with keeping a high accuracy. Our challenges are (1) how to reduce the number of samples with a theoretical guarantee of the accuracy and (2) how to practically achieve the theoretical results from the first challenge. As for the first challenge, we extend the *stratified sampling* [32], which increases the accuracy of an estimated value by using the lower and upper bounds of the value. We first prove a theorem that we reduce the number of samples without sacrificing the accuracy of approximation.

We can reduce the number of samples in accordance with the theoretical results. The theoretical results have two requirements; (1) to efficiently compute the approximate network reliability, we need to efficiently obtain the tight lower and upper bounds of the network reliability and (2) to guarantee the approximation of accuracy, we need to sample possible graphs from the set of possible graphs that are not used to compute the bounds. There are no trivial techniques to effectively achieve them. Therefore, we develop an extended *binary decision diagram*, which we call *scalable and sampling BDD* (*S^2BDD* for short). The S^2BDD enables preferentially searching for possible graphs in which terminals are connected/disconnected. The connected and disconnected possible graphs are used for computing the lower and upper bounds. Our approach employs dynamic programming during constructing the S^2BDD for efficiently sampling the possible graphs. It enables avoiding sampling possible graphs from the set of possible graphs that are used to compute the bounds.

Furthermore, our approach becomes more efficient by reducing the size of graphs. Thus, we propose an extension technique of our approach which uses 2-edge connected components [7]. The extension technique prunes vertices and edges that do not affect the network reliability, decomposes the graph to several subgraphs, and transforms the subgraphs into a smaller graphs. It efficiently reduces the vertices and edges involved in the computation while preserving the network reliability.

Contributions and Organization

To the best of our knowledge, our approach is the first solution to achieve both high efficiency and accuracy to compute the network reliability. Our approach has the following attractive characteristic.

- Our approach improves the efficiency to compute an approximate network reliability by reducing the number of samples. The extension technique effectively reduces the size of graphs while preserving the network reliability.
- Our approach outputs more accurate network reliability than the existing approaches. We theoretically guarantee that our approach improves the accuracy of approximation, even though it reduces the number of samples.
- Our approach computes the exact answer for small-scale graphs due to the S^2BDD though the existing sampling-based approach cannot compute the exact answer.
- Our approach can be used to improve the performances on uncertain graph analyses [6, 18, 22] in terms of both accuracy and efficiency because many algorithms compute the network reliability by sampling techniques.

The remainder of this paper is organized as follows. Section 2 introduces related work. Section 3 then describes the preliminaries. Sections 4 and 5 present our approach and an extension technique for our approach, respectively. Section 6 describes algorithms of our approach with the extension. Section 7 shows the results obtained from the experiments, and Section 8 concludes the paper.

2 RELATED WORK

Querying and mining uncertain graphs have recently attracted much attention in the database and data mining research communities. We review some relevant works related to the network reliability problem.

Network reliability: For computing the network reliability, several approaches have been proposed such as cut-based approach and BDD-based approach. The cut-based [3, 15, 25] approach enumerates all cuts which are divides the terminals and then computes the network reliability by using the set of cuts. Harris and Srinivasan [15] proposed theoretical result to obtain the lower bound of network relaibility based on cuts. However, they do not mention how to efficiently obtain the cuts. The BDD-based approach is more efficient than the cut-based approach. The BDD-based approach [14, 26, 35] effectively avoids enumerating all possible graphs without sacrificing the exactness of the network reliability. However, it cannot be applicable to large graphs due to the large memory usage. The BDD-based approach first constructs a BDD, and then obtains the possible graphs in which terminals are connected by traversing the BDD. Recent work has shown that the BDD-based approach can be applied only to graphs with 100–200 edges because of limitations of memory space [14, 26]. The state-of-the-art library TdZDD[1] also can only be applied to very small-scale graphs. Herrmann and Soh [16] proposed a memory-efficient BDD that computes the network reliability by constructing a BDD and deleting unnecessary parts of it during the process. We partially adopt their idea to reduce the memory usage. There are several preprocessing and indexing techniques to efficiently compute the network reliability (and similar problems) [12, 24]. These techniques remove redundant parts of graphs, which have similar idea of our extension technique. However, these techniques cannot directly apply to k-terminal reliability. To the best of our knowledge, there has been no prior work on approximating the network reliability with BDD.

Reachability query in uncertain graphs: The reachability in uncertain graphs is a special type of network reliability (called s-t network reliability) [2]. Jin et al. [19] proposed a distance-constraint reachability query in uncertain graphs, which answers the probability that the distance from one vertex to another is less than or equal to a threshold. They proposed approximate algorithms as solutions to this problem. The approximate algorithms use unequal sampling techniques [31], and achieves higher accuracy than Monte Carlo sampling. Cheng et al. [9] proposed an algorithm to compute the reachability in distributed environments. The algorithm reduces the size of graphs without sacrificing the exactness of the result before computing the reachability. It divides the graph into several subgraphs and computes probabilities of the subgraphs in distributed environments. The algorithm is only applicable to directed acyclic graphs. While these algorithms [9, 19] deal with uncertain graphs, their objective is to compute reachability and their algorihms cannot be applied to computing the network reliability.

Other problems with uncertain graphs: Many existing works in uncertain graphs use the network reliability as the metric to evaluate the connectivity among vertices. The efficiency and accuracy of their algorithms depend on those of the sampling techniques. Although they use the sampling technique to compute the network reliability, they have not proposed efficient sampling techniques. Jin et al. [18] proposed an algorithm for finding reliable subgraphs in which the vertices are connected with a higher probability than a given threshold. Ceccarello et al. [6] proposed clustering techniques for uncertain graphs. The technique uses the network reliabilities between vertices as distances between them. Khan et al. [22] proposed a reliability search

Table 1: Notations

Symbol	Meaning
$\mathcal{G}$	Uncertain graph
$\mathbb{V}$	Set of vertices
$\mathbb{E}$	Set of edges $e = (v, v')$
$p(e)$	Edge existence probability of e
G_p	Possible graph
$\mathbb{E}_p$	Set of edges in G_p
$Pr[G_p]$	Existence probability of G_p
$\mathcal{G}_{\mathbb{E}}$	Intermediate graph
$\mathbb{E}_\exists$	Set of existent edges in $\mathcal{G}_{\mathbb{E}}$
$\mathbb{E}_\neg$	Set of non-existent edges in $\mathcal{G}_{\mathbb{E}}$
$Pr[\mathcal{G}_{\mathbb{E}}]$	Existence probability of $\mathcal{G}_{\mathbb{E}}$
$\mathbb{T}$	Set of terminals
$R[\mathcal{G}, \mathbb{T}]$	Network reliability of $\mathcal{G}$ for $\mathbb{T}$
$\hat{R}[\mathcal{G}, \mathbb{T}]$	Approximate network reliability of $\mathcal{G}$ for $\mathbb{T}$
k	The number of terminals
w	Maximum size of BDD
$\mathbb{F}_l$	Set of frontiers at layer l
$\lvert \cdot \rvert$	The number of elements in a set

that returns a set of vertices that are connected from given vertices with a higher probability than the threshold. These studies have different purposes, but they use the Monte Carlo sampling to compute the network reliability. Our approach can be used to improve their performances in terms of both accuracy and efficiency instead of using the Monte Carlo sampling.

3 PRELIMINARIES

As preliminaries of our approach, we explain uncertain graph and network reliability. Table 1 summarizes the notations.

3.1 Uncertain graph

Let $\mathcal{G} = (\mathbb{V}, \mathbb{E}, p)$ be a connected and undirected uncertain graph, where $\mathbb{V}$ is a set of vertices, $\mathbb{E} \subseteq \mathbb{V} \times \mathbb{V}$ is a set of *uncertain* edges, and $p : \mathbb{E} \longrightarrow (0, 1]$ is a function that determines the edge existence probability $p(e)$ of uncertain edge $e \in \mathbb{E}$ in the graph. We denote edge $e \in \mathbb{E}$ between v and v' as $e = (v, v')$. A state of uncertain edge e is *existent* with a probability $p(e)$ or *non-existent* with a probability $(1-p(e))$. We assume that edge existence probabilities of different edges are independent of one another [6, 19].

A *possible graph* $G_p = (\mathbb{V}, \mathbb{E}_p)$ is a graph that contains a set of vertices and a subset of edges of $\mathcal{G}$ without their edge existence probabilities. Edges in $\mathbb{E} \backslash \mathbb{E}_p$ are non-existent in the possible graph. Although edges in possible graphs have no probabilities, the possible graphs themselves have existent probabilities. The existent probability $Pr[G_p]$ of possible graph G_p is as follows:

$$Pr[G_p] = \prod_{e \in \mathbb{E}_p} p(e) \cdot \prod_{e \in \mathbb{E} \backslash \mathbb{E}_p} (1 - p(e)).$$

The total number of the possible graphs of $\mathcal{G}$ is $2^{|\mathbb{E}|}$ because each edge is either existent or non-existent. We define $\mathbb{W}^{\mathcal{G}}$ as all possible graphs obtained from $\mathcal{G}$.

We define an *intermediate graph* $\mathcal{G}_{\mathbb{E}}(\mathbb{E}_\exists, \mathbb{E}_\neg)$, which is an uncertain graph with the set of existent edges $\mathbb{E}_\exists$, the set of non-existent edges $\mathbb{E}_\neg$, and the set of uncertain edges $\mathbb{E} \backslash (\mathbb{E}_\exists \cup \mathbb{E}_\neg)$. The existent probability $Pr[\mathcal{G}_{\mathbb{E}}(\mathbb{E}_\exists, \mathbb{E}_\neg)]$ of the intermediate graph $\mathcal{G}_{\mathbb{E}}(\mathbb{E}_\exists, \mathbb{E}_\neg)$ is as follows:

$$Pr[\mathcal{G}_{\mathbb{E}}(\mathbb{E}_\exists, \mathbb{E}_\neg)] = \prod_{e \in \mathbb{E}_\exists} p(e) \cdot \prod_{e \in \mathbb{E}_\neg} (1 - p(e)).$$

We simply use $Pr[\mathcal{G}_{\mathbb{E}}]$ as $Pr[\mathcal{G}_{\mathbb{E}}(\mathbb{E}_\exists, \mathbb{E}_\neg)]$. We define $\mathbb{W}^{\mathcal{G}_{\mathbb{E}}}$ as all possible graphs obtained from $\mathcal{G}_{\mathbb{E}}$. The total number of the possible graphs of $\mathcal{G}_{\mathbb{E}}(\mathbb{E}_\exists, \mathbb{E}_\neg)$ is $2^{|\mathbb{E} \backslash (\mathbb{E}_\exists \cup \mathbb{E}_\neg)|}$. We define that vertices are connected in intermediate graphs if there are paths among the vertices by existent edges, and vertices are disconnected if there are no paths among the vertices by existent and uncertain edges. Note that it is unsure to be connected or disconnected even if there are paths among the vertices by uncertain edges.

3.2 Network reliability

The network reliability is computed by summing up the probabilities of all possible graphs in which all terminals (a subset of vertices) are connected. The definition is as follows:

Definition 1 (Network reliability). *Given a set of k terminals $\mathbb{T}$ and an uncertain graph $\mathcal{G}$, the network reliability $R[\mathcal{G}, \mathbb{T}]$ is*

$$R[\mathcal{G}, \mathbb{T}] = \textstyle\sum_{G_p \in \mathbb{W}^{\mathcal{G}}} I(G_p, \mathbb{T}) \cdot Pr[G_p], \qquad (1)$$

where G_p denotes a possible graph, and $I(G_p, \mathbb{T})$ is an indicator function that returns one if all terminals in $\mathbb{T}$ are connected in G_p, and returns zero, otherwise.

We denote by $\hat{R}[\mathcal{G}, \mathbb{T}]$ the approximate network reliability. We simply use R and $\hat{R}$ as $R[\mathcal{G}, \mathbb{T}]$ and $\hat{R}[\mathcal{G}, \mathbb{T}]$ for the given uncertain graph and terminals, respectively.

The network reliability with k terminals is called the *k-terminal reliability*, and it is known as the most generalized network reliability [14]. The network reliability problem is #P-complete [33]. Planar graphs can be more efficiently solved than general graphs, but it is also #P-complete [30]. Therefore, it has no polynomial time algorithm unless $P = NP$.

BDD [14] and sampling [19] are main techniques to compute the network reliability. BDD-based approach can compute the exact answer in small-scale graphs, while sampling-based appraoch can compute approximate answers in large-scale graphs.

3.2.1 Binary decision diagram. A BDD $\mathcal{D} = (\mathbb{N}, \mathbb{A})$ is a directed acyclic graph with sets of nodes $\mathbb{N}$ and arcs $\mathbb{A}$[2]. Figure 2(a) shows the BDD to compute the network reliability of the original graph in Figure 1. Nodes in the BDD correspond to intermediate graphs, and arcs in the BDD correspond to existent/non-existent edges. The BDD has a single node that has no incoming arcs, called the *root node* (node G_1 in Figure 2(a)). Each node has two outgoing arcs, called the *0-arc* and *1-arc* (represented by dashed and solid arrows in Figure 2(a), respectively). 0-arcs and 1-arcs indicate that edges are non-existent and existent in the uncertain graph, respectively. Each arc is associated with a *weight* that represents the existent or non-existent probability of the edge. We define *layer* l (≥ 1) as the depth from the root node. The nodes at layer l of the BDD correspond to the intermediate graphs whose edges $e_1, \ldots, e_{l-1}$ are existent/non-existent and the other edges $e_l, \ldots, e_{|\mathbb{E}|}$ are uncertain. The BDD has special nodes that have no outgoing arcs, called *sink nodes*. The sink nodes are of two types, called *1-sink* and *0-sink* (represented by rectangles with labels 1 and 0 in Figure 2(a), respectively). If the terminals in the intermediate graph are connected and disconnected, the arcs point at the 1-sink and 0-sink, respectively. We can obtain intermediate graphs in which terminals are connected by traversing the BDD from the root node to the 1-sink.

[2] To avoid confusion, we use the terms "vertex" and "edge" to refer to a vertex and an edge in an uncertain graph, respectively, and "node" and "arc" to refer to a vertex and an edge in a BDD, respectively.

(a) BDD (b) Intermediate graphs at layer 3

Figure 2: BDD for the original graph on Figure 1(a).

To construct the BDD, the *frontier-based method* is a common procedure [21, 26]. This method first orders edges $(e_1, \ldots, e_{|\mathbb{E}|})$. It generates the nodes on layer $l + 1$ by setting the states of e_l when a BDD is already constructed until layer l. In the frontier-based method, a vertex that has both existent/non-existent and uncertain edges are called a *frontier* f, and we denote by $\mathbb{F}_l$ the set of frontiers at layer l. Figure 2(b) shows intermediate graphs after processing e_1 and e_2, where solid black, dashed black, and dashed gray lines denote existent, non-existent, and uncertain edges, respectively. These intermediate graphs correspond to G_4, G_5, and G_6 in the BDD from the top, respectively. Vertices b and c are frontiers because they have both existent/non-existent and uncertain edges. Note that nodes at the same layer l have the same set of frontiers $\mathbb{F}_l$. The frontier-based method maintains several attributes on only the frontiers (e.g., the number of uncertain edges and the number of terminals connected to the frontiers). It merges the nodes if the attributes are the same. Thus, the frontier-based method can effectively reduce the number of nodes.

The size of the BDD is defined by the number of nodes in the BDD [14]. Generally, it exponentially increases as the number of edges in the uncertain graphs increases. As the size of the BDD increases, both of the computation cost and the memory usage increase. Thus, it is hard to compute the exact network reliability.

3.2.2 Sampling. Sampling is a basic approach for computing the approximate network reliability [9, 18, 19]. Given the number of samples s, the sampling-based approach repeats the following procedures s times: (1) picking a possible graph of $\mathcal{G}$ as a sample, G_{p_i} $(1 \leq i \leq s)$ according to the probabilities $Pr[G_{p_i}]$ from $\mathbb{W}^{\mathcal{G}}$ and then (2) computing whether all the terminals are connected or not in G_{p_i}. The time complexity of the sampling-based approach is $O(s \cdot (|\mathbb{V}| + |\mathbb{E}|))$. This is because it requires $O(|\mathbb{E}|)$ time to determine the states of all edges and $O(|\mathbb{V}| + |\mathbb{E}|)$ time to compute the connectivity by a depth first search for each sample.

The accuracy of the sampling-based approach is evaluated by its variance. Since the sampling-based approach is a randomized algorithm [28], the average network reliability is most likely to be closest to the exact network reliability. A small variance indicates a small rate of error (i.e., high accuracy). Note that *unbiased sampling* is necessary that samples possible graphs according to their probabilities for guaranteeing the theoretical variance. As the number of samples increases, the variance decreases but the computation cost increases. Therefore, there is a trade-off between the accuracy and the computation cost.

The *stratified sampling* is known as a successful method in the field of statistics [32]. The stratified sampling divides the population into subgroups and individually picks samples from each subgroup. The variance of the estimated value for the whole population are the sum of the variances of the estimated values for individual subgroups. Let L be the number of subgroups and R_i be the estimated total probabilities of possible graphs for subgroup i. The estimated network reliability is computed by summing up the total probabilities for the subgroups as follows:

$$\hat{R} = \textstyle\sum_{i=1}^{L} \hat{R}_i.$$

The variance is the sum of the individual variances for the subgroups as follows:

$$Var[\hat{R}] = \textstyle\sum_{i=1}^{L} Var[\hat{R}_i].$$

When we compute the exact values for the subgroups, the variances of the estimated network reliability for the subgroup become zero. Thus, when we compute the exact values for the subgroups, the variance of the estimated network reliability for the whole population decreases.

4 OUR APPROACH

In this paper, we solve the problem of the approximate network reliability. Section 4.1 provides an overview of our approach. Section 4.2 explains how to reduce the number of samples. Section 4.3 presents our extended BDD S^{2}BDD.

4.1 Overview

Our approach efficiently and accurately computes the approximate network reliability. We achieve high efficiency and accuracy with the following ideas:

- **Reduction of the number of samples**: Our approach significantly reduces the number of samples with keeping a high accuracy of approximation by using the lower and upper bounds of the network reliability.
- **Efficient computation of the bounds of network reliability**: We develop the S^{2}BDD to efficiently compute the bounds of the network reliability.
- **Dynamic programming**: During constructing S^{2}BDD, we employ dynamic programming for efficiently sampling possible graphs.

Our approach reduces the number of samples in accordance with the stratified sampling. We theoretically guarantee that the number of samples becomes small as the lower and upper bounds become tight without sacrificing the accuracy of approximation. We prove it in two representative estimators; Monte Carlo and Horvitz-Thompson estimators [32].

For achieving the theoretical result, we compute the lower and upper bounds by constructing the S^{2}BDD. We specify the maximum size w of S^{2}BDD for avoiding a large cost to construct the S^{2}BDD. Our approach deletes nodes on the S^{2}BDD when its size exceeds w. To effectively delete nodes, we define a heuristic function for preferentially keeping *high-priority* nodes in the S^{2}BDD; the priorities are computed from the possibilities of improving the bounds. The S^{2}BDD enables efficiently computing the bounds because nodes preferentially point at sink nodes.

For efficiently sampling possible graphs, our approach employs dynamic programming during constructing the S^{2}BDD. We can straightforwardly employ dynamic programming for sampling because sampling possible graphs from intermediate graphs is a sub problem of sampling possible graphs from the original uncertain graph. We also use the *stratified random sampling* for determining the number of samples for each sub problem. The stratified random sampling divides the set of possible graphs into subgroups and samples possible graphs from each subgroup.

4.2 Reducing the number of samples

In this section, we theoretically prove that our approach reduces the number of samples while keeping a high accuracy in accordance with the stratified sampling [11, 27]. As we mentioned in Section 4.3.3, the accuracy of sampling is evaluated by the variance of the estimated network reliability. Since the stratified sampling reduces the variance of the estimated network reliability, we can reduce the number of samples without sacrificing the accuracy of approximation.

To apply the stratified sampling, we divide the set $\mathbb{W}^{\mathcal{G}}$ of possible graphs into three subgroups $\mathbb{W}_c^{\mathcal{G}}$, $\mathbb{W}_d^{\mathcal{G}}$, and $\mathbb{W}_u^{\mathcal{G}}$. $\mathbb{W}_c^{\mathcal{G}}$ and $\mathbb{W}_d^{\mathcal{G}}$ include the sets of only possible graphs in which terminals are connected and disconnected, respectively. $\mathbb{W}_u^{\mathcal{G}}$ includes the set of possible graphs that are not included in $\mathbb{W}_c^{\mathcal{G}}$ and $\mathbb{W}_d^{\mathcal{G}}$. Let p_c and p_d be the sum of the probabilities of possible graphs in $\mathbb{W}_c^{\mathcal{G}}$ and $\mathbb{W}_d^{\mathcal{G}}$, respectively. Hence, from Definition 1, the upper and lower bounds are given as follows:

$$\begin{aligned} R &= \textstyle\sum_{G_p \in \mathbb{W}_c^{\mathcal{G}}} Pr[G_p] + \sum_{G_p \in \mathbb{W}_u^{\mathcal{G}}} I(G_p, \mathbb{T}) Pr[G_p] \\ &= p_c + \textstyle\sum_{G_p \in \mathbb{W}_u^{\mathcal{G}}} I(G_p, \mathbb{T}) Pr[G_p] \\ &\geq p_c. \\ R &= 1 - \textstyle\sum_{G_p \in \mathbb{W}_d^{\mathcal{G}}} Pr[G_p] - \sum_{G_p \in \mathbb{W}_u^{\mathcal{G}}} (Pr[G_p] - I(G_p, \mathbb{T}) Pr[G_p]) \\ &= 1 - p_d - \textstyle\sum_{G_p \in \mathbb{W}_u^{\mathcal{G}}} (Pr[G_p] - I(G_p, \mathbb{T}) Pr[G_p]) \\ &\leq 1 - p_d. \end{aligned}$$

Consequently, we have $p_c \leq R \leq 1 - p_d$. We reduce the number of sample by using the lower bound p_c and upper bound $1 - p_d$.

The variance also depends on estimators. In our approach, we exploit two representative estimators; Monte Carlo estimator and Horvitz-Thompson estimator. The Monte Carlo estimator is a basic technique for computing the average values of the samples. On the other hand, the Horvitz-Thompson estimator is unequal probability estimator, which provides smaller variance than the Monte Carlo estimator under sampling without replacement. We explain how to reduce the number of samples in the two estimators with keeping a high accuracy.

Monte Carlo estimator: The Monte Carlo estimator for R is:

$$\hat{R} = \frac{\sum_{i=1}^{s} I(G_{p_i}, \mathbb{T})}{s}.$$

The variance is computed by the following equation [11]:

$$Var[\hat{R}] = \frac{R(1-R)}{s}.$$

Because the random sampling is unbiased, i.e., $E(\hat{R}) = R$, the variance can be simply written as follows [27]:

$$Var[\hat{R}] = \frac{R(1-R)}{s} \approx \frac{\hat{R}(1-\hat{R})}{s}. \tag{2}$$

Let $Var[\hat{R}]'$ be the variance using the upper and lower bounds. $Var[\hat{R}]'$ is computed in accordance with the stratified sampling as follows [11, 27]:

$$Var[\hat{R}]' = \frac{(\hat{R}-p_c)(1-p_d-\hat{R})}{s}. \tag{3}$$

From Equations (2) and (3), we obtain the following equation:

$$\frac{\hat{R}(1-\hat{R})}{s} \geq \frac{(\hat{R}-p_c)(1-p_d-\hat{R})}{s}. \tag{4}$$

Therefore, we have $Var[\hat{R}] \geq Var[\hat{R}]'$. From Equation (4), we obtain the following theorem:

Theorem 1. *Given the number of samples s, the lower bound p_c, and the upper bound $1 - p_d$, the variance of network reliability by using Monte Carlo estimator with s' ($\leq s$) samples is less than and equal to that with s samples if s' is computed by the following equations:*

$$s' = \begin{cases} \lfloor s(1-p_d) \rfloor. & (p_c = 0) \\ \lfloor s(1-p_c) \rfloor. & (p_d = 0) \\ \lfloor s(1 - 4 \cdot p_c(1-p_c)) \rfloor. & (p_c = p_d) \\ \lfloor s(1 - 4 \cdot p_c(1-p_d)) \rfloor. & (p_c < p_d) \\ \lfloor s(1 - \min(4p_c(1-p_c), & \\ \quad 4(p_c(1-p_d) + (p_d - p_c))) \rfloor. & (p_c > p_d) \end{cases}$$

Proof: From Equation (4), we have the following equation such that the variance with s samples is equal to that with s' samples by using the lower and upper bounds:

$$\frac{(p_c-\hat{R})(1-p_d-\hat{R})}{s'} = \frac{\hat{R}(1-\hat{R})}{s}$$

Then, s' is computed as follows:

$$\begin{aligned} s' &= s \cdot \frac{(\hat{R}-p_c)(1-p_d-\hat{R})}{\hat{R}(1-\hat{R})} \\ &= s \cdot \left(1 - \frac{p_c(1-\hat{R}) + p_d(\hat{R}-p_c)}{\hat{R}(1-\hat{R})}\right) \end{aligned} \tag{5}$$

However, we cannot compute $\hat{R}$ before sampling s possible graphs. Therefore, we remove $\hat{R}$ from Equation (5) by dividing the patterns of p_c and p_d. First, if $p_c = 0$, s' is computed as follows:

$$s\left(1 - \frac{p_d \hat{R}}{\hat{R}(1-\hat{R})}\right) \leq s(1-p_d).$$
$$s' = \lfloor s(1-p_d) \rfloor.$$

Second, if $p_d = 0$, s' is computed as follows:

$$s\left(1 - \frac{p_c(1-\hat{R})}{\hat{R}(1-\hat{R})}\right) \leq s(1-p_c).$$
$$s' = \lfloor s(1-p_c) \rfloor.$$

Third, if $p_c = p_d$, s' is computed as follows:

$$s\left(1 - \frac{p_c(1-\hat{R}) + p_c(\hat{R}-p_c)}{\hat{R}(1-\hat{R})}\right) \leq s(1 - 4p_c(1-p_c)). \tag{6}$$
$$s' = \lfloor s(1 - 4p_c(1-p_c)) \rfloor.$$

In Equation (6), the maximum value of $\hat{R}(1-\hat{R})$ is 0.25. Thus, we substitute 0.25 for $\hat{R}(1-\hat{R})$ in the denominator. Fourth, if $p_c < p_d$, s' is computed as follows:

$$s\left(1 - \frac{p_c(1-\hat{R}) + p_d(\hat{R}-p_c)}{\hat{R}(1-\hat{R})}\right) \leq s(1 - 4p_c(1-p_d)).$$
$$s' = \lfloor s(1 - 4p_c(1-p_d)) \rfloor.$$

Finally, if $p_c > p_d$, s' is computed as follows:

$$s\left(1 - \frac{p_c(1-\hat{R}) + p_d(\hat{R}-p_c)}{\hat{R}(1-\hat{R})}\right) \leq s(1 - 4p_c(1-p_c)).$$
$$s\left(1 - \frac{p_c(1-\hat{R}) + p_d(\hat{R}-p_c)}{\hat{R}(1-\hat{R})}\right) \leq s(1 - 4(p_c(1-p_c) + (p_d - p_c)).$$
$$s' = \lfloor s(1 - \min(4p_c(1-p_c), 4(p_c(1-p_d) + (p_d - p_c)))) \rfloor. \tag{7}$$

In Equation (7), the minimum s' depends on the values of p_c and p_d. Consequently, we have that $s' \leq s$ for all patterns of p_c and p_d. □

Horvitz-Thompson estimator: The Horvitz-Thompson estimator for R is:

$$\hat{R} = \frac{\sum_{i=1}^{s} Pr[G_{p_i}] \cdot I(G_{p_i}, \mathbb{T})}{\pi_i},$$

where $\pi_i = 1 - (1 - Pr[G_{p_i}])^s$. The variance is:

$$Var[\hat{R}] = \sum_{i=1}^{s} \left(\frac{1-\pi_i}{\pi_i}\right) I(G_{p_i}, \mathbb{T}) Pr[G_{p_i}]^2$$
$$+ \sum_{i}^{s} \sum_{j, i \neq j}^{s} \left(\frac{\pi_{ij} - \pi_i \pi_j}{\pi_i \pi_j}\right) I(G_{p_i}, \mathbb{T}) I(G_{p_j}, \mathbb{T}) Pr[G_{p_i}] Pr[G_{p_j}],$$

where $\pi_{ij} = 1 - (1 - Pr[G_{p_i}])^s - (1 - Pr[G_{p_j}])^2 + (1 - Pr[G_{p_i}] - Pr[G_{p_j}])^s$. The variance is simplified as follows [19]:

$$Var[\hat{R}] = \frac{R(1-R)}{s} - \frac{\sum_{i=1}^{s}(s-1)I(G_{p_i}, \mathbb{T})Pr[G_{p_i}]^2}{2s}. \tag{8}$$

The variance using the lower and upper bounds is computed in accordance with the stratified sampling as follows:

$$Var[\hat{R}]' = \frac{(\hat{R}-p_c)(1-p_d-\hat{R})}{s} - \frac{\sum_{i=1}^{s}(s-1)I(G_{p_i}, \mathbb{T})Pr[G_{p_i}]^2}{2s}. \tag{9}$$

Theorem 2. *Given the number of samples s, the lower bound p_c, and the upper bound $1 - p_d$, the variance of network reliability by using Horvits-Thompson estimator with s' ($\leq s$) samples is less than and equal to that with s samples where s' is equal to the number of samples in Monte Carlo estimator in 1.*

Proof: From Equations (8) and (9), we have the following equation:

$$\frac{(\hat{R}-p_c)(1-p_d-\hat{R})}{s'} - \frac{\sum_{i=1}^{s}(s'-1)I(G_{p_i}, \mathbb{T})Pr[G_{p_i}]^2}{2s'}$$
$$= \frac{\hat{R}(1-\hat{R})}{s} - \frac{\sum_{i=1}^{s}(s-1)I(G_{p_i}, \mathbb{T})Pr[G_{p_i}]^2}{2s}.$$

The values of the right are the same because the estimator is unbiased. The proof for this follows Theorem 1. □

Our approach reduces the number of samples in accordance with Theorems 1 and 2. As a result, our approach is more efficient than the existing sampling-based approach.

4.3 Scalable and Sampling BDD: S^{2}BDD

We can reduce the number of samples by using the lower and upper bounds of network reliability. To efficiently obtain the bounds, we develop the S^{2}BDD. We efficiently search for the possible graphs in which terminal are connected and disconnected with high probabilities by constructing the S^{2}BDD. Furthermore, during constructing the S^{2}BDD, we sample possible graphs that are not used to compute the bounds, which is the requirement of stratified sampling. Our approach uses S^{2}BDD for both computing the bounds of network reliability and sampling possible graphs.

We design the S^{2}BDD to effectively reduce its size. The S^{2}BDD keeps a single layer and sink nodes while ordinary BDD contains all layers. This idea is based on the observation that the layer $l - 1$ is unnecessary after constructing the next layer l to both construct the layer $l + 1$ and obtain the bounds. We first define the S^{2}BDD and then explain how to construct it.

Definition 2. *Let $\mathbb{N}_l$ be a set of nodes at layer l. S^{2}BDD consists $\mathbb{N}_l$, the 1-sink, and the 0-sink. The S^{2}BDD maintains the following attributes on node $n \in \mathbb{N}$:*

- *p_n: the probability of the intermediate graph corresponding to node n.*
- *$\{c_{n,f}\}$ for all $f \in \mathbb{F}_l$: an identifier of connected component. If frontiers f and $f' \in \mathbb{F}_l$ are connected by existent edges, $c_{n,f}$ and $c_{n,f'}$ share the same identifier.*
- *$\{d_{n,f}\}$ for all $f \in \mathbb{F}_l$: the sum of the numbers of uncertain edges connected to the frontiers such that $\{f' \in \mathbb{F}_l | c_{n,f} = c_{n,f'}\}$.*
- *$\{t_{n,f}\}$ for all $f \in \mathbb{F}_l$: the number of the terminals that are connected to f by existent edges.*

The 1-sink and 0-sink maintain the probabilities p_c and p_d that terminals are connected and disconnected, respectively.

For example, in Figure 2, S^{2}BDD contains third and sink layers but does not contains first and second layers.

To construct an S^{2}BDD, we process edge e_l and generate the set of nodes $\mathbb{N}_{next}$ at layer $l + 1$. The construction method comprises four procedures; *generating*, *merging*, *deleting*, and *sampling*. The following sections explain these procedures in details.

4.3.1 Generating and Merging Procedures. The BDD-based approach uses the generating and merging procedures to construct the BDD. We extend these procedures to effectively compute the bounds without sacrificing the exactness of the network reliability. For extending the generating and merging procedures, we capture the feature of computing the network reliability such that we can skip the computation of nodes when we obtain the probabilities p_c and p_d exactly.

We first explain the generating procedure. The generating procedure sets the state of edge e_l (recall that arcs at layer l in the BDD corresponding to e_l) and then generates the set of new nodes $\mathbb{N}_{next}$ at layer $l + 1$. As the same as the traditional procedure, we generate two new nodes at layer $l + 1$ from every node at layer l according to the state of e_l. We set the attributes on the new nodes (i.e., p_n, $\{c_{n,f}\}$, $\{d_{n,f}\}$, and $\{t_{n,f}\}$). More specifically, p_n is set as $p_n \cdot p(e_l)$ when e_l is existent and set as $p_n \cdot (1 - p(e_l))$ when e_l is non-existent. $\{c_{n,f}\}$, $\{d_{n,f}\}$, and $\{t_{n,f}\}$ are computed from attributes of frontiers on nodes at layer l by merging attributes of frontiers and creating new frontiers. If all the terminals in the intermediate graph are connected, we add its probability to p_c, and if they are disconnected, we add its probability to p_d.

If we determine whether or not terminals are connected/disconnected with processing a smaller number of edges, we can obtain the tight bounds of the network reliability earlier. Let n, n', $\mathbb{F}$, and $\mathbb{F}'$ be the new node at layer $l + 1$, the node before setting e_l of n at layer l, the sets of frontier at layers $l + 1$ and l, respectively. We determine whether or not terminals are connected/disconnected based on following lemmas:

Lemma 4.1. *All the terminals $t \in \mathbb{T}$ are connected if the attributes of the frontiers satisfy one of the following conditions:*
Condition 1: *edge $e_l = (v, v')$ is existent, for $t_{n,f} = k$, $\exists f \in \mathbb{F}$.*
Condition 2: *edge $e_l = (v, v')$ is existent, for (1) $v \in \mathbb{F}'$, (2) $v' \notin \mathbb{F}' \cup \mathbb{F}$, (3) $t_{n',v} = k - 1$, and (4) $v \in \mathbb{T}$ (similarly, replacing v with v' and vice versa).*
Condition 3: *edge $e_l = (v, v')$ is existent, for (1) $v, v' \in \mathbb{F}$, (2) $c_{n',v} \neq c_{n',v'}$, and (3) $t_{n',v} + t_{n',v'} = k$.*

Proof: This is an immediate consequence of the definitions because all the terminals are connected. □

Lemma 4.2. *The terminals are disconnected if the attributes of the frontiers satisfy one of the following conditions:*
Condition 1: *edge $e_l = (v, v')$ is non-existent, for (1) $v \notin \mathbb{F}' \cup \mathbb{F}$, and (2) $v \in \mathbb{T}$ (similarly, for v').*
Condition 2: *edge $e_l = (v, v')$ is non-existent, for (1) $v \in \mathbb{F}'$, (2) $t_{n',v} > 0$, and (3) $d_{n',v} = 1$ (similarly, for v').*
Condition 3: *edge $e_l = (v, v')$ is existent or non-existent, for (1) $v, v' \in \mathbb{F}' \backslash \mathbb{F}$ and (2) ($t_{n',v} > 0$ or $t_{n',v'} > 0$).*

Proof: This is an immediate consequence of the definitions because the terminals are disconnected. □

Note that the state-of-the-art construction of the BDD uses only the condition 1 on Lemmas 1 and 2. As a result, the S^{2}BDD can more effectively tighten the bounds of network reliability.

We next explain the merging procedure. Since each intermediate graph on S^{2}BDD has different existent and non-existent edges, the attributes on each frontier are different (in general). The merging procedure merges the nodes that make a transition to the same sink nodes based on the following lemma:

Lemma 4.3. *Given nodes n_1 and n_2 at layer l, if we have for $\forall f \in \mathbb{F}_l$ (1) $c_{n_1,f} = c_{n_2,f}$ and (2) ($t_{n_1,f} = 0$ and $t_{n_2,f} = 0$) or ($t_{n_1,f} > 0$ and $t_{n_2,f} > 0$), then nodes derived from n_1 and n_2 with the same states of edges $e_{l+1}, \dots, e_{|\mathbb{E}|}$ make a transition to the same sink nodes.*

Proof: If n_1 and n_2 have (1) $\{c_{n_1,f}\} = \{c_{n_2,f}\}$ for all f in $\mathbb{F}_l$, the connected frontiers are the same in the intermediate graphs corresponding to n_1 and n_2. New nodes n'_1 and n'_2 derived from n_1 and n_2 are the same $\{c_{n'_1,f}\} = \{c_{n'_2,f}\}$ if they have the same states of edges $e_{l+1}, \dots, e_{|\mathbb{E}|}$. Thus, $\{c_{n_1,f}\}$ and $\{c_{n_2,f}\}$ for all f in $\mathbb{F}_l$ are the same until they make a transition to the sink nodes. Since the same $\{c_{n_1,f}\}$ and $\{c_{n_2,f}\}$ share the same connected components, each frontier has the same $\{d_{n_1,f}\}$ and $\{d_{n_2,f}\}$. In addition, frontiers f and f' must be connected if they connect to at least one terminals (i.e., $t_{n_1,f} > 0$ and $t_{n_2,f} > 0$). If (1) $\{c_{n_1,f}\} = \{c_{n_2,f}\}$ and (2) ($t_{n_1,f} = 0$ and $t_{n_2,f} = 0$) or ($t_{n_1,f} > 0$ and $t_{n_2,f} > 0$) for all f in $\mathbb{F}_l$, nodes derived from n_1 and n_2 with the same states of edges $e_{l+1}, \dots, e_{|\mathbb{E}|}$ have the same attributes on the frontiers, and thus they make a transition to the same sink nodes. □

The probabilities of the merged nodes are aggregated to one node. The probabilities p_c and p_d are consistent, regardless of whether or not the nodes are merged. These procedures do not sacrifice the exactness of the network reliability.

4.3.2 Deleting Procedure. The size of the S^{2}BDD increases exponentially as the size of the graph increases. If the size of S^{2}BDD increases, the computation cost increases to obtain the lower and upper bounds of the network reliability because it takes a large time to construct the S^{2}BDD. Hence, we control the size of S^{2}BDD by specifying the maximum size w. The deleting procedure deletes the nodes so that the size of an S^{2}BDD is not larger than w. One of major difficulties in designing this procedure pertains to which nodes should be kept in the S^{2}BDD for achieving higher efficiency and accuracy. According to Theorems 1 and 2, the number of samples effectively decreases as the probabilities p_c and p_d increase. We identify intermediate graphs in which terminals are highly likely connected or disconnected after processing a small number of edges. We make the following key observations in terms of the connectivity of terminals:

Observation 1 The terminals in the intermediate graph corresponding to node n are highly likely connected if $t_{n,f}$ is large for $\exists f \in \mathbb{F}_l$.

Observation 2 The terminals in the intermediate graph corresponding to node n are highly likely disconnected if $d_{n,f}$ is small and $t_{n,f} > 0$ for $\exists f \in \mathbb{F}_l$.

Furthermore, if the probability of node p_n is high and node n makes a transition to sink nodes, p_c and p_d increase considerably. Based on these observations, we define a heuristic function based on our observations. We compute the priorities of nodes from their attributes by the heuristic function and preferentially keep high-priority nodes. The heuristic function h to compute the priority of node n is as follows:

$$h(n) = p_n \cdot \max\nolimits_{f \in \mathbb{F}} \left(\frac{t_{n,f}}{k}, \frac{1}{d_{n,f}} \right) \text{ if } t_{n,f} > 0. \tag{10}$$

This function outputs larger value when (1) a frontier is connected to at least one terminals and (2) the frontier is connected to a large number of terminals or (3) the frontier has a small number of uncertain edges. In the former case, the terminals are likely connected, and in the latter case, the terminals are likely disconnected. Low-priority nodes (i.e., n with small $h(n)$) are then deleted from an S^{2}BDD.

4.3.3 Sampling procedure. Our approach samples possible graphs so that it avoids sampling the possible graphs that are used to compute the lower and upper bounds of network reliability, for satisfying the requirements of the stratified sampling. We sample the possible graphs from the set of possible graphs that in which terminals are not connected/disconnected yet. We denote by $\mathbb{W}_u^{\mathcal{G}}$ such set of possible graphs, and the set is obtained from intermediate graphs corresponding to the deleted nodes and nodes in the S^{2}BDD. We employ dynamic programming for efficiently sampling possible graphs from $\mathbb{W}_u^{\mathcal{G}}$. In addition, we use the idea of the *stratified random sampling* [32] for determining the number of samples for subgroups that are partial $\mathbb{W}_u^{\mathcal{G}}$.

We first divide $\mathbb{W}_u^{\mathcal{G}}$ into subgroups and then randomly sample possible graphs from each subgroup. The number of samples for each subgroup is taken in proportion to the sum of the probabilities of the intermediate graphs in the subgroup. We here explain only how to divide the deleted nodes and how to decide the number of samples for them. As for the nodes in S^{2}BDD, each subgroup is the set of possible graphs obtained from the intermediate graph corresponding to the node, and the number of samples is computed from its probabilities.

We divide the set of intermediate graphs for deleted nodes into subgroups according to original BDD layers instead of the node itself. This is because probabilities of deleted nodes are typically quite small to decide the number of samples. $\mathbb{W}_u^{\mathcal{G}_l}$ and s_l are the set of intermediate graphs corresponding to the deleted nodes at layer l and the number of samples at layer l, respectively. s_l is computed by multiplying s and the total probabilities $\hat{p_{s_l}}$ of deleted nodes at layer l. We compute $\hat{p_{s_l}}$ from the attributes maintained by the S^{2}BDD by the following equation:

$$\hat{p_{s_l}} = 1 - \textstyle\sum_{i=1}^{l-1} p_{s_i} - p_{\mathbb{N}_{next}} - p_c - p_d, \tag{11}$$

where $p_{\mathbb{N}_{next}}$ denotes the sum of probabilities of $n \in \mathbb{N}_{next}$. $\hat{p_{s_l}}$ is the expected sum of probabilities of deleted nodes. This is because $\hat{p_{s_l}}$ indicates the sum of probabilities in $\mathbb{N}_l$ when the number of nodes at layer $l+1$ reaches the maximum size. The number of samples s_l at layer l becomes $s \cdot \hat{p_{s_l}}$. The dynamic programming and stratified random sampling improve the efficiency of sampling while keeping the unbiased sampling.

4.4 Complexity

We explain the time and space complexities of our approach.

Theorem 3. *Given the uncertain graph $\mathcal{G}$, the updated number of samples s', and the maximum width of S^{2}BDD w, the time and space complexities of our approach are $O(w^2 \log w + s'(|\mathbb{V}| + |\mathbb{E}|))$ and $O(w \log w + |\mathbb{V}| + |\mathbb{E}|)$, respectively.*

Proof: The time complexity of our approach is divided into two parts; constructing S^{2}BDD and sampling. To construct S^{2}BDD, our construction method compares attributes on each node each other for generating and merging procedures. The number of attributes on each node increases in proportion to the number of frontiers. The number of frontiers is $O(\log w)$ because the number of existent/non-existent edges is at most $\log w$. Thus, the time complexity for constructing S^{2}BDD is $O(w^2 \log w)$. The time complexity of sampling is $O(s'(|\mathbb{V}| + |\mathbb{E}|))$. Therefore, the time complexity of our approach is $O(w^2 \log w + s'(|\mathbb{V}| + |\mathbb{E}|))$.

The space complexity depends on the size of S^{2}BDD and the uncertain graphs. The size of S^{2}BDD is the number of nodes multiplied by the number of attributes on each node. Therefore, the space complexity is $O(w \log w + |\mathbb{V}| + |\mathbb{E}|)$. □

5 EXTENSION

The computation cost of our approach depends on the size of the uncertain graphs as well as the number of samples. The computation cost decreases as the size of the uncertain graphs decreases. Therefore, we propose an extension technique to efficiently reduce the size of graphs while preserving the accuracy. The extension technique preprocesses the uncertain graphs before sampling possible graphs and constructing an S^{2}BDD. It not only improves the efficiency but also improves the accuracy of the approximation. The extension technique uses *2-edge-connected components* for reducting the size of uncertain graphs [7].

Definition 3 (2-edge-connected component). *Given a graph $G = (\mathbb{V}, \mathbb{E})$, an edge is called a bridge if G is disconnected after the removal of the edge from $\mathbb{E}$. Vertices that are connected by bridges are called articulation points. A subgraph $C = (\mathbb{V}_C, \mathbb{E}_C)$ of G is a 2-edge connected component if C is still connected after the removal of any edges from $\mathbb{E}_C$. We denote the sets of bridges, articulation points, and 2-edge connected components by $\mathbb{B}$, $\mathbb{A}$, and $\mathbb{C}$, respectively*

The 2-edge-connected components, bridges, and articulation points provide sets of edges (and vertices) such that the uncertain graph is disconnected or still connected when the edges (and vertices) are deleted. Because we can compute 2-edge connected components only by using the network topology of a given uncertain graph, we precompute them as an index.

The extension technique consists of three phases; (1) pruning, (2) decomposing, and (3) transforming. In the pruning phase, we first compute $\mathcal{G}'$ such that $R[\mathcal{G}] = R[\mathcal{G}']$. The number of edges in $\mathcal{G}'$ is smaller than that in $\mathcal{G}$ by pruning edges and vertices that do not affect computing the network reliability. Next, in the decomposing phase, we compute the subgraphs $\mathcal{G}_1, \ldots, \mathcal{G}_m$ where $R[\mathcal{G}'] = \Pi_{i=1}^{m} R[\mathcal{G}_i]$. Finally, in the transforming phase, we compute $\mathcal{G}_i'$ such that $R[\mathcal{G}_i] = R[\mathcal{G}_i']$ for all $1 \leq i \leq m$. Since we transform the graph into a smaller graph, the number of edges in $\mathcal{G}_i'$ is smaller than that in $\mathcal{G}_i$.

Prune: We prune vertices and edges that do not affect the network reliability. A vertex (or an edge) is unnecessary if the graph is partitioned after the removal of the vertex (or edge) from $\mathcal{G}$ and one of the partitioned graphs does not include terminals. A naive approach deletes each articulation point and bridge, and then checks whether partitioned graphs include terminals or not. This approach incurs $O((|\mathbb{B}| + |\mathbb{A}|)(|\mathbb{V}| + |\mathbb{E}|))$ time complexity. To improve the efficiency, we reconstruct the uncertain graph based on the 2-edge connected components. To do so, we first unite the set of vertices and edges included in $C \in \mathbb{C}$ to form a single vertex v_c. We then set every articulation point included in C as vertex v_a and set edges between v_a and v_c. The other vertices and edges that are not included in $\mathbb{C}$ are still in the reconstructed graphs. Therefore, the vertices of the reconstructed graph indicate $\mathbb{C}$, $\mathbb{A}$, and the vertices that are not included in $\mathbb{C}$. If any vertex in C except for articulation points is a terminal, v_c is also a terminal. The reconstructed graph is structured as a tree structure because the 2-edge connected components are connected to the other components by a single edge. To compute the necessary vertices and edges, we compute the minimum Steiner tree for terminals in the reconstructed graph. The minimum Steiner tree includes only the necessary vertices and edges to compute the network reliability because it includes only the edges and vertices that all the terminals are connected. Its computation cost is $O(|\mathbb{V}|)$, because the minimum Steiner tree in a tree structure is computed by a depth first search from a terminal.

Decompose: We decompose the graph because the time complexity for computing the network reliability on decomposed graphs becomes smaller than that on that original uncertain graph. The decomposed graph has fewer edges than the original uncertain graph. We decompose the graph according to the following lemma:

Lemma 5.1. *Given an uncertain graph and a set of bridges, we obtain $R[\mathcal{G}, \mathbb{T}] = p_b \cdot \prod_{i=1}^{m} R[\mathcal{G}_i, \mathbb{T}_i]$, where $p_b = \prod_{e_b \in \mathbb{B}} p(e_b)$ and $\mathbb{T}_i$ is the set of terminals for $\mathcal{G}_i$.*

Proof: Given intermediate graph $\mathcal{G}_{\mathbb{E}}(\mathbb{E}_\exists, \mathbb{E}_\neg)$ and edge $e \in \mathbb{E} \backslash (\mathbb{E}_\exists \cup \mathbb{E}_\neg)$, the network reliability is computed using the Factoring Theorem [10]:

$$\begin{aligned} R[\mathcal{G}_{\mathbb{E}}(\mathbb{E}_\exists, \mathbb{E}_\neg)] \quad = \quad & p(e) \cdot R[\mathcal{G}_{\mathbb{E}}(\mathbb{E}_\exists \cup e, \mathbb{E}_\neg)] \\ & + (1 - p(e)) \cdot R[\mathcal{G}_{\mathbb{E}}(\mathbb{E}_\exists, \mathbb{E}_\neg \cup e)]. \quad (12) \end{aligned}$$

If we select bridge $e_b = (v, v') \in \mathbb{B}$ as e in Equation (12), $R[\mathcal{G}_{\mathbb{E}}(\mathbb{E}_\exists, \mathbb{E}_\neg \cup e)]$ is zero because terminals in $\mathcal{G}_{\mathbb{E}}(\mathbb{E}_\exists, \mathbb{E}_\neg \cup e)$ are disconnected. Therefore, we obtain the following equation:

$$R[\mathcal{G}_{\mathbb{E}}(\mathbb{E}_\exists, \mathbb{E}_\neg)] = p(e_b) \cdot R[\mathcal{G}_{\mathbb{E}}(\mathbb{E}_\exists \cup e_b, \mathbb{E}_\neg)]. \quad (13)$$

For connecting all the terminals, e_b must be existent, and thus we can decompose the intermediate graph $\mathcal{G}_{\mathbb{E}}$ into two graphs $\mathcal{G}_{\mathbb{E}_1}$ and $\mathcal{G}_{\mathbb{E}_2}$. We also divide the terminals $\mathbb{T}$ into $\mathbb{T}_1$ and $\mathbb{T}_2$ for $\mathcal{G}_{\mathbb{E}_1}$ and $\mathcal{G}_{\mathbb{E}_2}$, respectively; $\mathbb{T}_1$ includes $\{t \in \mathbb{T}, v, v' | t, v, v' \in \mathbb{V}_1\}$ (similarly, $\mathbb{T}_2$). Thus, $R[\mathcal{G}_{\mathbb{E}}] = p(e_b) \cdot R[\mathcal{G}_{\mathbb{E}_1}] R[\mathcal{G}_{\mathbb{E}_2}]$. $\mathcal{G}_{\mathbb{E}_1}$ and $\mathcal{G}_{\mathbb{E}_2}$ are decomposed in the same manner. Then, we obtain $R[\mathcal{G}] = p_b \cdot \prod_{i=1}^{m} R[\mathcal{G}_i, \mathbb{T}_i]$. □

We decompose the uncertain graph into several subgraphs based on the above lemma. Its computation cost is $O(|\mathbb{B}||\mathbb{V}|)$ because we check whether decomposed graphs include terminals or not for each bridge.

Transform: We transform the graph to reduce its size. We delete and add the following edges and vertices without sacrificing the exactness of the network reliability:

- Sequential edges ($e = (v, v'), e' = (v, v'')$): Delete v, e and e', and add a new edge with probability $p(e) \cdot p(e')$ between v' and v'', provided that v is not a terminal and its degree is two.
- Parallel edges ($e = (v, v'), e' = (v, v')$): Delete e and e', and add a new edge with probability $(1-(1-p(e) \cdot (1-p(e'))$ between v and v'.
- Loop : Delete the loop because loops do not contribute to the network reliability. Note that transforming sequential and parallel edges can generate loops.

We iteratively repeat this process until the graph does not change. The computation cost is $O(\gamma \cdot |\mathbb{V}| \cdot {d_{avg}}^2)$ where γ and d_{avg} are the number of repetitions and the average degree of the vertices, respectively.

Consequently, the extension technique effectively reduces the computation cost for computing the network reliability with a small preprocessing time. Furthermore, it improves the accuracy of the sampling technique.

Algorithm 1: Computing the approximate network reliability

```
input  : Uncertain graph $\mathcal{G}$, terminals $\mathbb{T}$, maximum BDD size $w$, size of
         samples $s$, 2-edge connected components $\mathbb{C}$, bridges $\mathbb{B}$, articulation
         points $\mathbb{A}$
output : Approximate network reliability $\hat{R}$
1  procedure our approach
2  set $\mathbb{T}$ to $\mathcal{G}$;
3  $\hat{R}$, $\mathcal{S}_{\mathcal{G}} \leftarrow$ Preprocess($\mathcal{G}, \mathbb{T}, \mathbb{C}, \mathbb{B}, \mathbb{A}$);
4  for $\mathcal{G}_i \in \mathcal{S}_{\mathcal{G}}$ do
5      $r \leftarrow$ Construction($\mathcal{G}_i, w, s$);
6      $\hat{R} \leftarrow \hat{R} \cdot r$;
7  return $\hat{R}$;
8  end procedure
```

Algorithm 2: Constructing S^{2}BDD

```
input  : Uncertain graph $\mathcal{G}$, maximum size $w$, number of samples $s$
output : Approximate network reliability $\hat{R}$
1  procedure Construction($\mathcal{G}, w, s$)
2  Ordering($\mathbb{E}$);
3  $p_c, p_d, \hat{p_{s_l}}, c \leftarrow 0$;        /* initialize probabilities and sampling
     count */
4  $s' \leftarrow s$;
5  $\mathbb{N} \leftarrow$ CreateRoot; $\mathbb{F} \leftarrow null$;
6  for $l$ for 1, . . . , $|\mathbb{E}|$ do
7      $p_{\mathbb{N}}, p_{s_i} \leftarrow 0$;
8      $\mathbb{F}' \leftarrow \mathbb{F}$; compute $\mathbb{F}$ based on $e_l$;
9      while $\mathbb{N}$ is empty do
10         $n \leftarrow \mathbb{N}.pop$;
11         for state $\in$ { non-existent, existent} do
12             set($n, \mathbb{F}', \mathbb{F}$, state, $\mathcal{G}, e_l$);
13             if $n$ is 0-sink then $p_d \leftarrow p_d + p_n$;
14             else if $n$ is 1-sink then $p_c \leftarrow p_c + p_n$;
15             else
16                 if hashmap[$n$] is not null then
17                     $p_{hashmap[n]} \leftarrow p_{hashmap[n]} + p_n$;
18                 else
19                     if $|\mathbb{N}_{next}| \leq w$ then
20                         $h_n \leftarrow h(n)$;
21                         $\mathbb{N}_{next}$.add($n$); hashmap[$n$] $\leftarrow n$;
                           $p_{\mathbb{N}_{next}} \leftarrow p_{\mathbb{N}_{next}} + p_n$;
22                     else
23                         $p_{s_i} \leftarrow p_{s_i} + p_n$;
24                         for $i$ for
                             1, . . . , $\lfloor s' \cdot (1 - \hat{p_{s_l}} - p_{\mathbb{N}_{next}} - p_c - p_d) \rfloor$
                             do
25                             if Sampling($\mathcal{G}, n$) then $c \leftarrow c + 1$;
26         if $c + \lfloor s' \cdot p_{\mathbb{N}_{next}} \rfloor \geq s'$ then
27             for $n \in \mathbb{N}$ do
28                 for $i$ for 1, . . . , $\lfloor s' \cdot p_{\mathbb{N}_{next}} \rfloor$ do
29                     if Sampling($\mathcal{G}, n$) then $c \leftarrow c + 1$;
30             break;
31         if $\mathbb{N}_n$ is empty then
32             break;
33         $\mathbb{N} \leftarrow \mathbb{N}_{next}$;
34         sort $\mathbb{N}$ in descending order of $h(n)$;
35         $\hat{p_{s_l}} \leftarrow \hat{p_{s_l}} + p_{s_i}$; compute $s'$; clear $\mathbb{N}_{next}$; clear hashmap;
36 compute $\hat{R}$ based on the sampling;
37 return $\hat{R}$;
38 end procedure
```

Theorem 4. *Given* $\mathcal{G}_1, \ldots, \mathcal{G}_m$ *such that* $R[\mathcal{G}] = p_b \cdot \Pi_{i=1}^{m} R[\mathcal{G}_i]$*, the variance of the network reliability decreases for* $0 < \hat{R} < 1$ *and* $0 < p_b < 1$.

Proof: The network reliability is denoted by $\hat{R} = p_b \cdot \Pi_{i=1}^{m} \hat{R}[\mathcal{G}_i]$. The valiance is computed as follows:

Algorithm 3: Extension technique

```
input  : Uncertain graph $\mathcal{G}$, terminals $\mathbb{T}$, 2-edge connected components $\mathbb{C}$,
         bridges $\mathbb{B}$, articulation points $\mathbb{A}$
output : Probability $p_b$, the set of decomposed graphs $\mathcal{S}_{\mathcal{G}}$
procedure Preprocess($\mathcal{G}, \mathbb{C}, \mathbb{B}, \mathbb{A}$)

Note that $Var[p_b] = 0$. $Var[\hat{R}]$ is smaller than the variance of the network reliability of the original graph. □

6 ALGORITHM OF OUR APPROACH

In this section, we explain the entire algorithm of our approach. Algorithm 1 shows the pseudo-codes. Our approach first preprocesses uncertain graphs and obtains decomposed uncertain graphs (line 3). For each decomposed graph, it then constructs an S^{2}BDD to compute the approximate network reliability of the decomposed graphs (lines 4–5). The product of the network reliability of each decomposed graph is the original network reliability (line 6).

Algorithm 2 shows the pseudo-codes for the construction of an S^{2}BDD. We process edges in a predefined order, and compute the set of frontiers (lines 6–8). For each node at layer l, we compute the nodes at layer $l + 1$ according to the states of the edges

Table 2: Dataset

Name	Abbr.	Type	#vertices	#edges	Avg. Deg	Avg. Prob
Zachary-karate-club	Karate	Social	34	78	4.59	0.527
American-Revolution	Am-Rv	Affiliation	141	160	2.27	0.528
DBLP before 2000	DBLP1	Coauthorship	25,871	108,459	8.38	0.222
DBLP after 2000	DBLP2	Coauthorship	48,938	136,034	5.56	0.203
Tokyo	Tokyo	Road network	26,370	32,298	2.45	0.391
New York City	NYC	Road network	180,188	208,441	2.31	0.294
Hit-direct	Hit-d	Protein	18,256	248,770	27.25	0.470

(lines 11–12). The set function (line 12) sets attributes on the new node to n and checks whether the terminals are connected or disconnected based on Lemmas 1 and 2. If the new node are 0-sink and 1-sink, we add p_n to p_d and p_c, respectively (line 13–14). Otherwise, we compute hash values for n, and if the hash of n is not null, we add the probability p_n to the node in the hash (lines 16–17). If the hash is null with respect to n, it inserts n into the set $\mathbb{N}_{next}$ of nodes at layer $l + 1$ and into the hash after computing their priorities (lines 19–21). If the number of nodes in $\mathbb{N}_n$ exceeds the maximum size w, we delete n and pick possible graphs as samples from n (lines 22–25). After sampling an enough number of possible graphs, we sample form the nodes in the S^{2}BDD (lines 26–29).

Algorithm 3 shows the pseudo-codes for the extension technique. The extension technique first reconstructs the uncertain graph (line 2). Then, it computes the minimum Steiner tree for the reconstructed graph and prunes the edges and vertices that are not included in the Steiner tree from the original uncertain graph (lines 3–4). To decompose the graph, we compute the product of the probabilities of bridges p_b (line 5). Then, we delete bridges from the uncertain graph, and the disconnected subgraphs are inserted into the set of decomposed uncertain graphs (lines 6–7). For each decomposed graph, it transforms vertices and edges that satisfy the transformation rules (lines 8–20).

7 EXPERIMENT

We evaluate our approach in terms of efficiency, accuracy, and memory usage.

7.1 Dataset

We summarize the datasets in Table 2. The first two datasets; Zachary-karate-club and American-revolution are small datasets for evaluating accuracy, which are extracted from KONECT[3]. We randomly assign probabilities based on the uniform distribution [9]. The other five datasets; DBLP before 2000, DBLP after 2000, Tokyo, New York City, and Hit-direct, are large datasets. Edge existence probabilities for each large dataset are assigned based on the attributes of the edges in each dataset. DBLP before 2000 and DBLP after 2000 are graphs extracted from DBLP[4], where vertices and edges are authors and co-author, respectively. We compute the edge existence probabilities by $\frac{\log(\alpha+1)}{\log(\alpha_M+2)}$, where α and α_M denote the number of co-authors and the maximum in each dataset, respectively [6]. The Tokyo and New York City datasets are road networks extracted from OpenStreetMap[5]. We compute the edge existence probabilities in the same manner as with the DBLP datasets, although we use road lengths instead of the number of co-authors. Note that both the Tokyo and New York City datasets are not planar graphs. Hit-direct is a protein-protein interaction network extracted from the Human Genome Center[6]. We use the interaction scores $\in (0, 1]$ of interactions as the edge existence probabilities.

7.2 Setting and Implementation

For each dataset, we generate 20 searches (except when we evaluate the accuracy, for which see Section 7.6). The terminals are selected randomly from vertices. We vary the number of terminals k, the number of samples s, and the maximum size of the S^{2}BDD w.

Because the existence probabilities of possible graphs can be very small, we use the Boost.Multiprecision library, with precision of 10,000 decimal points, for the large datasets. We compute the 2-edge-connected components using code provided by the authors [7]. We compare our approach with two existing approaches; the sampling-based and BDD-based approaches. The BDD-based approach uses the state-of-the art library, TdZDD. All algorithms are implemented in C++, and run on a server with an Intel Xenon E7-8860v4 at 2.20GHz with 256GB RAM.

7.3 Efficiency

We compare the efficiency of our approach with that of sampling-based and BDD-based approaches. Figure 3 shows the response time for each large dataset when the numbers of terminals k is set to 5, 10, and 20. DNF indicates that we cannot compute the network reliability due to the lack of memory space. We use Monte Carlo estimator for our approach and the sampling-based approach (denoted by Pro(MC) and Sampling(MC), respectively) and set s to 10,000. For our approach, we set w to 10,000. We also evaluate our approach without the extension technique denoted by Pro(MC)w/o ext. We here omit the results of Horvitz-Thompson estimator because they are almost equivalent to those of Monte Carlo estimator.

The results show that our approach is more efficient than both of the sampling-based and the BDD-based approaches for all k. The BDD-based approach cannot compute the network reliability because it runs out of memory. Our approach achieves higher efficiency than the sampling-based approach because it reduces the number of samples. Furthermore, we can see that the extension technique improves the efficiency. In particular, our approach works well on the Tokyo and NYC datasets. This is because the S^{2}BDD works well for planar-like graphs (even when they are not strictly planar graphs). In the Hit-direct dataset, the lower and upper bounds do not effectively become tight because the number of degrees is large. Nevertheless, our approach is more efficient than the sampling-based approach.

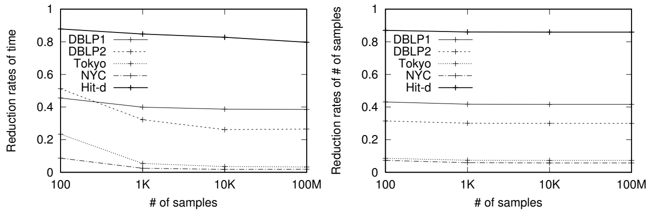
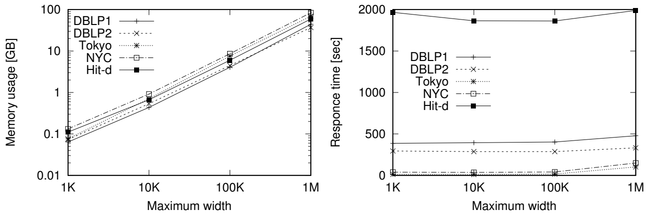
Figure 3: Overview of efficiency



(a) Response time **(b) # of samples**

Figure 4: Efficiency with varying the number of samples



(a) Memory usage **(b) Response time**

Figure 5: Efficiency with varying the maximum width

7.4 Effect of Number of Samples

We evaluate the effect of the given number of samples. Figure 4 shows (a) the rate of response time of our approach over that of the sampling-based approach and (b) the rate of updated samples s' over s, varying the number of samples. This figure shows that our approach becomes more efficient as the given number of samples increases. This is because the reduction of the number of samples is more effective when the given number of samples is large. Therefore, our approach more effectively works when we need a high accurate network reliability.

7.5 Effect of Maximum Width

We evaluate the effect of the given maximum width of S^{2}BDD. The maximum width w affects the memory usage and efficiency. Figure 5 shows (a) the memory usage and (b) the response time. From Figure 5(a), we can see that the memory usage increases as the maximum width increases. The memory usage depends on the maximum width but not depends on the size of graphs. Our approach can be used for large-scale graphs in terms of memory usage. From Figure 5(b), we can see that the response time does not largely depend on the maximum width. When the maximum width is large, our approach can reduce the number of samples but takes a large computation cost for constructing S^{2}BDD. Our approach is robust enough to the maximum width in terms of efficiency. Consequently, our approach effectively decreases the response time even for large-scale graphs.

7.6 Accuracy

We evaluate the accuracy of our approach compared with the sampling-based approaches. For both approaches, we use Horvits-Thompson estimator (denoted by Pro(HT) and Sampling(HT)) as well as Monte Carlo estimator. Since the network reliability problem is #P-complete, we cannot compute the exact answer for large datasets in terms of both response time and memory usage. We use the Karate and Am-Rv datasets which can be computed the exact network reliability. We evaluate the variance and the error rate to determine the accuracy of the approximation as follows: $variance = \frac{\Sigma_{i=1}^{q_1}\Sigma_{j=1}^{q_2}(R_i - \hat{R}_{i,j})^2}{q_1 \cdot q_2}$ and $error\ rate = \frac{\Sigma_{i=1}^{q_1}\Sigma_{j=1}^{q_2}|R_i - \hat{R}_{i,j}|}{q_1 \cdot q_2 \cdot R_i}$, where R_i and $\hat{R}_{i,j}$ denote the i-th exact network reliability and the j-th approximate network reliability for the i-th search, respectively. We generate 100 searches and compute the network reliability 100 times for each search (i.e., both q_1 and q_2 are 100).

Tables 3 and 4 show the accuracy on the Karate and Am-Rv datasets, respectively. Table 3 shows that our approach outperforms the sampling-based approaches in terms of both of the variance and error rate. Comparing the variance between the estimators, the Monte Carlo estimator is slightly better than the Horvits-Thompson sampling. This is because we sample possible graphs with replacement, and thus the Horvits-Thompson estimator is less effective. Table 4 shows that our approach always computes the exact network reliability on the Am-Rv dataset— its error rate is zero. Both of the existing sampling-based approaches have high error rates when $k = 20$ although their variances are small. Because the network reliability is very small, the sampling-based approaches rarely sample the possible graphs in which terminals are connected. Thus, the approximate network reliability is often zero, and the error rates are close to one. From these results, we conclude that our approach can achieve less variance and error rate with fewer samples than the other approaches and compute the exact answer for small-scale graphs.

7.7 Effect of Extension Technique

Finally, we evaluate the performance of the extension technique. The effect of the extension technique is detailed in Table 5 which shows the process time and the ratio of the maximum number of edges in decomposed graphs over the number of edges in the original uncertain graph. The results show that the extension technique requires a very small time compared with computing the network reliability. Thus, it effectively reduces the total response time. Since it reduces the size of uncertain graphs, it mitigates the computation cost for the S^{2}BDD. The extension technique is effective for improving the efficiency of our approach.

Table 3: Accuracy on Karate dataset

k	Method	Variance	Error rate
5	Pro(MC)	0.025	0.036
	Pro(HT)	0.025	0.036
	Sampling(MC)	0.025	0.037
	Sampling(HT)	0.029	0.042
10	Pro(MC)	0.013	0.058
	Pro(HT)	0.014	0.059
	Sampling(MC)	0.013	0.058
	Sampling(HT)	0.015	0.062
20	Pro(MC)	$0.76 \cdot 10^{-3}$	0.054
	Pro(HT)	$0.85 \cdot 10^{-3}$	0.057
	Sampling(MC)	$0.78 \cdot 10^{-3}$	0.056
	Sampling(HT)	$0.86 \cdot 10^{-3}$	0.057

Table 4: Accuracy on Am-Rv dataset

k	Method	Variance	Error rate
5	Pro(MC)	0	0
	Pro(HT)	0	0
	Sampling(MC)	$0.43 \cdot 10^{-4}$	0.061
	Sampling(HT)	$0.31 \cdot 10^{-4}$	0.059
10	Pro(MC)	0	0
	Pro(HT)	0	0
	Sampling(MC)	$0.099 \cdot 10^{-5}$	0.38
	Sampling(HT)	$0.12 \cdot 10^{-5}$	0.37
20	Pro(MC)	0	0
	Pro(HT)	0	0
	Sampling(MC)	$0.10 \cdot 10^{-3}$	1.00
	Sampling(HT)	$0.10 \cdot 10^{-3}$	1.00

Table 5: Effect of extension technique

Dataset	Process time [sec]	Reduced graph size
Karate	$0.0277 \cdot 10^{-3}$	0.757
Am-Rv	$0.310 \cdot 10^{-3}$	0.120
DBLP1	0.060	0.946
DBLP2	1.61	0.797
Tokyo	0.015	0.425
NYC	0.370	0.279
Hit-d	0.184	0.982

8 CONCLUSION

In this paper, we proposed an efficient sampling-based approach for computing the approximate network reliability. Our approach reduces the number of samples by using lower and upper bounds of the network reliability based on the stratified sampling. We developed scalable and sampling BDD, called S^{2}BDD, which efficiently computes the bounds. The S^{2}BDD preferentially searches for the possible graphs that highly improve the bounds. We further developed the extension technique of our approach to reduce the size of graphs. Experiments demonstrated that our approach is up to 51.2 times faster than the sampling-based approach with a higher accuracy.

ABSTRACT

The RDF data model has emerged as the most prominent way to interlink and exchange data on the Web due to its simplicity in the form of subject predicate object statements, but this simplicity comes with the cost of having to execute a large number of joins in order to get the desirable query results. Numerous approaches exist that aim to treat this problem, mainly focusing on disk based storage. In this work we consider a main memory setting and present a physical design and query method aiming to exploit spatial locality for efficient in-memory processing. Our design is also amenable to straightforward parallelization, something crucial for main memory database systems. Specifically, we present a join implementation that allows to achieve any desired degree of parallelism on arbitrary join queries and RDF graphs stored in memory using compact vertical partitioning. We use an adaptive join processing approach, such that we take advantage of complete or even partial ordering of RDF data, which is compactly stored in order to increase spatial locality and keep memory consumption low, coupled with an ID-to-Position vector index used when ordering does not allow for efficient scanning of the input relation. We have implemented an in-memory prototype that experimentally shows the efficiency and scalability of our proposal, taking advantage of continuously growing sizes of main memory and multi-core environments of modern hardware. Specifically, we show that for a machine with 128 GB of main memory and 16 cores, which is a reasonable amount for an average modern server, our prototype can store and query RDF graphs with up to two billion triples, and it outperforms centralized and distributed state of the art approaches.

1 INTRODUCTION

The *Resource Description Framework* (RDF) is a data model recommended by the W3C for semantic data integration, sharing and linking across different organizations and applications on the Web. RDF provides flexible modeling of data coming from heterogeneous domains in the form of triples forming subject-predicate-object statements, facilitating the construction of Knowledge Graphs. Every component of such a triple is a resource uniquely identified by an IRI or a data value in the form of a literal. The latter can only be present in the object position. A set of such statements can be considered an RDF graph, where subjects and objects are nodes and there exists an arc labeled with the property name, connecting corresponding subject and object for each statement. Several organizations publish data in the RDF model, leading to interlinking information from different sources and automatic processing using software agents. As a result, as of 2018 the *Linked Open Data* (LOD) cloud [34] contains more than 1000 datasets and 60 billion triple statements, with DBpedia [8], a dataset that contains semantic information extracted from Wikipedia, taking up a central position with 3 billion triples and around 50 million links to other datasets.

The SPARQL query language is the W3C recommendation for querying RDF graphs. The basic building block of SPARQL queries are triple patterns. A triple pattern is similar to an RDF statement, with the exception that each component (subject, predicate or object) can be either a resource or a variable. The evaluation of a single triple pattern over an RDF graph consists of finding matches of the pattern on the graph such that variables are substituted by RDF resources. A *Basic Graph Pattern* (BGP) is a set of triple patterns. During evaluation of a BGP all triple patterns are matched to an RDF statement and common variables between triple patterns are substituted by the same resource. If we consider RDF storage on a single relational triples table, a BGP with n triple patterns corresponds to $n - 1$ self joins of the triples table.

Since the adoption of the RDF data model numerous systems and research prototypes have been developed aiming at efficient SPARQL query evaluation, focusing mainly on the evaluation of BGPs which proved to be extremely demanding. Centralized systems explored different physical storage options and query execution techniques. Main storage schemas include a single triples table, denormalized property tables, vertical partitioning, graph-based storage and storage based on bit arrays. Details and references to such systems are presented in the next section. As scalability became an issue with the continuously increasing size of several datasets, distributed approaches came into play, assisted by cloud technologies such as the MapReduce framework, its implementation Apache Hadoop and several Big Data processing systems built on top of it. Most of these systems use optimizations in order to minimize the execution cycles, which correspond to Hadoop jobs and involve data transfer between the workers. This is due to the synchronous nature of the MapReduce paradigm. As a result, depending on data partitioning and replication one can achieve evaluation completely in parallel for some queries, but for queries that require communication the overhead is important due to the synchronization step.

A number of in-memory distributed systems were later proposed such that their communication is based on custom asynchronous methods, mostly on the Message Passing Interface (MPI) standard. Trinity.RDF [42] is based on graph exploration and it was the first system to follow this design. TriAD [14] and the extension of the centralized main memory RDF store RDFox with a dynamic data exchange operator [26] also use an asynchronous execution model (In what follows we will refer to the system described in [26] as the dynamic exchange operator approach), but unlike Trinity.RDF they use relational-style joins, increasing the level of parallelism for large intermediate results over the graph-based approach. In order to do so, both of these systems use expensive graph partitioning before data loading. AdPart [3] tries to overcome this problem by using simple subject-based hash partitioning and then adaptively, based on the query load, replicates specific data fragments to the workers. As a result of the initial subject-based partitioning, expensive broadcast of intermediate result occurs in case of joins on objects.

Our query processing approach is inspired by the asynchronous execution model of main-memory distributed RDF stores, mainly of TriAD and the dynamic exchange operator approach. Both these approaches use expensive preprocessing in the form of graph partitioning in order to minimize communication between servers during query execution. Also, extra effort is needed in order to track the server that contains each resource. Most importantly, even in a centralized parallel environment these systems would require some form of inter-process or inter-thread communication and as a result some form of synchronization. For example, in case of rehashing, each worker of TriAD has to wait in order to receive and rehash all intermediate results from all other workers. Same kind of overheads occur in the dynamic exchange operator where each worker must hold a queue for each query atom, where incoming messages are put. This may lead to blocking execution until some other worker process results for a subsequent query atom. Also, in the dynamic exchange operator approach detecting termination is not trivial and requires a round of message exchanging. Our method ensures parallel execution without any form of communication or synchronization between the workers (in our case threads) while at the same time avoiding expensive preprocessing like graph partitioning. Furthermore, we adaptively decide to scan the corresponding partitions when it is preferable, instead of always using index-based nested loops as done by the dynamic exchange operator approach.

Regarding the physical data storage, our approach is inspired by *column-store* systems such as MonetDB [16] and C-Store [37], as we first use vertical partitioning [1] to create a separate table for each property, and then keep subjects and objects for each property in separate arrays so that each tuple can be reconstructed by relating entities at the same positions in these arrays, reminiscent of the virtual IDs of column stores. This way we achieve increased spatial locality during processing. Also, we allocate a single array position for each distinct subject or object as a simple form of column specific compression (reminiscent of the POS and PSO indexes used by Hexastore [39]) and we keep two replicas of each two-column table in different sort orders. The main contributions presented in this work are:

- A join processing approach with low memory consumption, able to efficiently parallelize evaluation of arbitrary multi-join BGPs without any communication.
- Physical design method which compactly stores RDF data in memory, in order to increase spatial locality during join processing. For example, for scale 10240 of the LUBM dataset with about 1.4 billion triples, excluding dictionary, the storage requirements are only 22 GB (50GB if we include the dictionary).
- A cache-friendly method which adaptively, during execution, decides to switch from binary search to scan in order to take advantage of existing (even partial) sorting of RDF triples, that further improves our join implementation. An auxiliary bit vector index can be used to avoid binary search and improve efficiency.
- An implementation and experimental evaluation for datasets up to 2 billion triples which shows that our proposal outperforms existing state of the art centralized systems. Also, based on published results for other systems, it is shown that for tested datasets, like LUBM 10240, our implementation running on a single 16-core server outperforms (mostly for complex queries) or performs close to the fastest state of the art asynchronous distributed in-memory systems deployed on a cluster of machines.

We proceed by first presenting related work. Then in Section 3 we present details of the physical data storage and in Section 4 we present details of the adaptive join method that allows for incorporating parallelism into processing. We present implementation details and experimental evaluation in Section 5 and we finally conclude and discuss future work.

2 RELATED WORK

RDF storage using relational technology has been a subject of research since the proposal of the RDF data model. BGP evaluation using a single triples table that contains the whole RDF graph involves expensive self joins over this large table. As a solution, some systems like Jena [40] proposed the usage of "flattened" property tables, which contain a larger number of columns, in an effort to simulate a relational schema and avoid joins as much as possible. Nevertheless, this design has some drawbacks, like for example a lot of NULL values for wide tables, the need for UNION during a single BGP processing and difficulty to handle multi-values attributes. [5] aims at efficient evaluation using an object-relational DBMS including a two-column representation for properties. Vertical partitioning[1] uses this representation in order to treat the drawbacks of the property tables. In this approach a separate two-column table is created for every property of the RDF graph. In this case, the number of joins is not reduced in comparison to the single triples table, but each join is between smaller tables and also tables not relevant to the query do not need to be accessed at all. Column stores are ideal candidates for RDF processing using vertical partitioning, as they provide compact storage and compression over each column.

Hexastore enhances the vertical partitioning by replicating the data through six different indexes, corresponding to all possible permutations of subject, predicate and object [39]. RDF-3X [23] also uses extensive indexing such that an index is created not only for all possible permutations but also for aggregated values, resulting in 15 indexes stored as clustered B+ trees. This schema along with several optimizations, such as skipping large parts of irrelevant data during merge joins using a form of *sideways information passing*, made RDF-3X one of the most efficient disk-based RDF stores, despite conceptually using the single triples-table approach. Our design follows the vertical partitioning approach, but as in Hexastore, we keep two different replicas for each property in different sort orders (corresponding to POS and PSO indexes) and we also compactly store only distinct subjects and objects. Also, our adaptive join optimization (Section 4.1) can be considered a way of skipping irrelevant data as in RDF-3X.

Regarding SPARQL query processing using cloud technologies, an initial approach using the MapReduce framework is presented in [30, 31]. In this work, the authors describe the query evaluation of Basic Graph Patterns of SPARQL using an iterative algorithm, such that every join in the query requires a separate MapReduce job. The RDF data is stored in plain files in the distributed file system. A similar iterative approach is also used in [20], but here the authors note that more than one triple patterns that share a variable can be joined together in the same MapReduce job. They use a greedy selection algorithm that chooses in every step the variable that appears in more triple patterns and they employ reduce-side joins to get the results. In [11] predicate-based hash partitioning is employed. The query is decomposed to subqueries using the same partitioning and in every node a local Sesame RDF store is used to evaluate each subquery. Instead of hash partitioning, in [15] the authors use a graph partitioning algorithm to assign triples to nodes and also they employ data replication for triples that are on the boundaries of each partition, in order to maximize the number of subqueries that can be executed without communication between the nodes. They stress the usefulness of a heuristic that finds the minimal number of subqueries because this corresponds to a minimal number of Hadoop jobs, and they split each query to a number of such subqueries using a brute-force method, which is suitable only for queries with few triple patterns.

A number of approaches store the RDF data into an existing system that has its own declarative language and then they transform the SPARQL queries into that language. For example, [32] uses Pig Latin[24] and performs some well known optimizations to the SPARQL query, like the early execution of filters and some selectivity estimations based on variable counting. During the translation to Pig Latin, [32] just uses multi joins when consecutive joins on the same variable are found, as this is an option that Pig Latin offers. RAPID+, a system which is also based on Pig Latin, is presented in [29]. Here the authors propose an intermediate algebra which is called Nested TripleGroup Algebra, in order to facilitate the grouping of join operators during the translation of the query to the execution plan in Pig Latin. The result is that each star join involving two or more triple patterns can be executed in one Map-Reduce job, using vertical partitioning.

H_2RDF+ [25] uses HBase[1] to store the RDF data. It takes advantage of the HBase key ordering for each table and it uses six tables, each one corresponding to an RDF triple permutation. In this way there is replication of the data, so that the system can perform fast merge joins when all triples are part of the initial RDF data. When some data is result of an intermediate step, the system first performs a sorting on this intermediate data. Another key feature of the system is that during the query planning it examines the option that the query will be executed in a centralized system. The rationale behind this is that if the query is simple, its evaluation in a centralized system can be preferable, because one can avoid the overhead of the MapReduce jobs and network communication. The system uses a greedy planner to decide about the order of the joins, based on a cost model and some index statistics that it has. In a similar manner, the system named Rya[27] uses Accumulo[2], to store indexes for permutations of subject, predicate and object in the row ID field of each corresponding table, but it only uses three indexes instead of all the possible ones. Rya supports range queries and regular expressions, multi-threaded join execution and also provides some limited inferencing capabilities. S2RDF [33] uses the in-memory system Spark to store the RDF data using vertical partitioning combined with semi-join materialization and then translates the SPARQL query to Spark SQL [7].

Regarding in memory join processing, a lot of research has been concentrated on cache friendly methods, such as the radix hash join [18], and also into taking advantage of hardware features such as the SIMD vectorized instructions for efficient parallel sort-merge joins [4, 17]. These works consider the setting of relational data with arbitrary number of columns, where a single join has to be performed on previously non indexed columns and sorting or hashing is a serious overhead that has to be performed in parallel. Instead, our work is tailored for RDF graphs, as it exploits initial ordering of both subject and object RDF columns and partial ordering of subsequent joins for pipelining multiway joins, such that it completely avoids hashing or sorting during query execution. Exploiting partial ordering of values in a column has been used by main memory systems in the form of zone-maps [28, 35] where additional statistics about each such zone have to be maintained in order to skip scanning certain areas. Adaptivity during run-time regarding the decision of scanning a base relation or use a secondary index has been studied in [9, 10] for disk-based systems.

Regarding centralized parallel in memory RDF processing, to the best of our knowledge there is no work concentrating on query processing. RDFox [21] and Inferray [38] are both systems that aim at parallel in memory computation and materialization of RDF inferences. This can be thought of as a preprocessing step prior to querying. Although RDFox offers query evaluation, it seems that is not the focal point of the system and for such queries there is no support for intra-query parallelism, that is each query is evaluated in a single thread. In [12] several variations of the disk based RDF-3X are presented, such that they allow parallel join evaluation. From the experimental results it is shown that depending on the query, there is no clear variation that has better performance, whereas for some queries the original version is better, as parallel evaluation prohibits the usage of the sideways information passing optimization in RDF-3X. Also, their approach works by parallelizing each join separately and demands communication and synchronization costs.

3 PHYSICAL DATA STORAGE

In this section we present our physical data storage and give an overview of the join method that allows incorporation of parallelism. First, following the common practice used by many systems, we use dictionary encoding, by assigning an integer value to each value encountered in the RDF data. We use common numbering for values appearing in the subject and object positions and a different numbering for values appearing in the property position, but for ease of presentation here we assume common numbering for all values. Thus, after parsing of an RDF dataset that contains N distinct values, our dictionary will contain integer IDs from 1 to N. Then, we apply vertical partitioning [1] to create a separate two-column table for each property defined in the data. We keep two replicas of each two-column table, the first sorted on subject and then on object, and the second sorted first on object and then on subject. Given that a property P is assigned to integer i from our dictionary encoding, we will refer to the first replica of two-column table for P as $prop_i$ and to the second replica as $prop_{i^-}$ and we will call the tables first sorted on subject *S-O tables* and tables first sorted in object *O-S tables*.

Consider for example the following RDF data (IRIs are omitted):

```
ProfessorA teaches Mathematics
ProfessorB teaches Chemistry
ProfessorC teaches Literature
ProfessorA teaches Physics
ProfessorA worksFor University1
ProfessorB worksFor University2
ProfessorC worksFor University2
```

[1] http://hbase.apache.org/

[2] http://accumulo.apache.org/

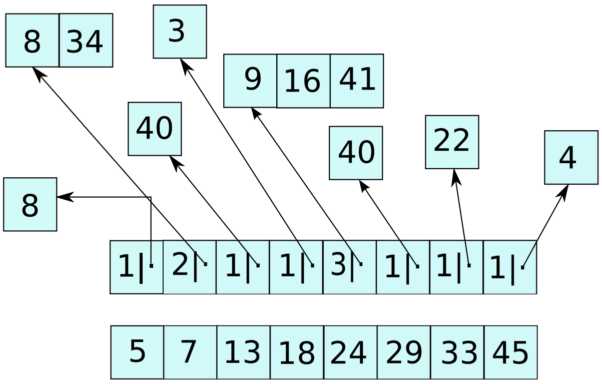

Figure 1: Example of Physical Data Storage for a Property Partition

The dictionary encoding of the data is given in Table 1. Using this encoding, the two-column tables $prop_2$ and $prop_9$ that correspond to properties $teaches$ and $worksFor$ will be created.

Table 1: Example of Dictionary Encoding

Integer	Value
1	ProfessorA
2	teaches
3	Mathematics
4	ProfessorB
5	Chemistry
6	ProfessorC
7	Literature
8	Physics
9	worksFor
10	University1
11	University2

For each table, we store a sorted integer array with the distinct subjects (for S-O tables) or distinct objects (for O-S tables). We also store a second array of same length with the first. Each position of this second array contains a pointer to a sorted integer array and an integer denoting the length of this array. This is a pointer to the objects (for S-O tables) or subjects (for O-S tables) that correspond to the subject (respectively object) located at the same position of the first array. The reason that we keep two separate arrays has simply to do with compactly storing the integers of the first array and improving spatial locality during the join processing. We also keep track of the length of the first array, using an array of length $2 * (number\ of\ properties)$ that contains this information for all properties. Getting this information involves a simple lookup at a specific position, for example, to get the number of subjects for $prop_7$, we should look at position $2 * 7$, whereas to get the number of objects for $prop_{7^-}$ we should look at position $(2 * 7) + 1$.

Figure 1 contains an example of physical storage for a property table. Given that the specific table is for property $prop_3$, then it contains the following triples: 5 $prop_3$ 8, 7 $prop_3$ 8, 7 $prop_3$ 34, 13 $prop_3$ 40, 18 $prop_3$ 3, 24 $prop_3$ 9, 24 $prop_3$ 16, 24 $prop_3$ 41, 29 $prop_3$ 40, 33 $prop_3$ 22, 45 $prop_3$ 4. Note that in order to avoid memory fragmentation, the different object arrays of this example can be allocated to a continuous memory area. In this case, instead of having different pointers for each position of the second array, we can keep a single pointer to the start of this memory area and only keep offsets in each position of the second array.

Our join method resembles an index-based nested loops join (or merge join when possible - this will be discussed later) that starts concurrently from different shards of the first table, and runs in parallel, by probing the next table to be joined for each tuple. In this way our method operates on left-deep query join trees as shown in Example 3.1.

Example 3.1. Consider a SPARQL query:

```
SELECT ?x ?y ?z
WHERE {
    ?x teaches ?z .
    ?x worksFor ?y .  }
```

Also suppose that the join order chosen by the optimizer (see Section 4.3) is the same with the order of the triples in the text of the query. This will be translated to a join $prop_2 \bowtie_{subject=subject} prop_9$. If there are two available threads, our algorithm will start concurrently scanning two different shards of $prop_2$. For each tuple encountered during this process, it will probe, using binary search, table $prop_9$. This process can be decomposed into completely independent tasks that start from different shards and operate on read-only common data, and thus it straightforward to be implemented using threads or separate processes with shared memory. It is even straightforward to be implemented on different machines using complete data replication and parallelize the query across machines without any communication.

Note that for the given query, the degree of parallelism depends on the number of different shards of the first table. For more selective queries a different strategy may be needed as shown in Example 3.2.

Example 3.2. Consider the following query, that contains an extra filter:

```
SELECT ?x ?z
WHERE {
    ?x teaches ?z.
    ?x worksFor University1 .   }
```

In this case, suppose that the optimizer chooses the inverse join order, as it is reasonable that the filter will limit the results of the second triple pattern. In this case, table $prop_9$ should be scanned first. One first observation is that instead of scanning the whole table, we can search for tuples where object is equal to 10. To do so it is better to use the replica that is first ordered by object. After we search $prop_{9^-}$ for $object = 10$, we obtain the vector of subjects that correspond to $object = 10$ (in our case it is only value 1). Then we start scanning this vector and probing table $prop_2$ using these values. In this way we do not obtain any level of parallelism for this query, as we start from a specific value of the first table. It is easy though to recover the parallelism, if we start scanning concurrently different shards of the vector that corresponds to $object = 10$. If the query contains a triple pattern with variable in the predicate position, then a union over all properties will be needed, but this is rarely encountered in real world queries[1]. In any case, if the number of distinct predicates encountered in the dataset is very large, an ID-Predicate index similar to the one use in [41] can be useful. Also note that the exact number of threads that will be used is independent of our physical data storage and can be decided on a per query basis after data loading in memory. In our current implementation (Section 5) we choose to execute each query with the same number of threads (optimally this should be equal to the number of available processing cores or greater in case hyper-threading is supported as shown in Section 5.2.3), but an extension such that very simple and selective queries could be executed with fewer resources is possible.

4 QUERY PROCESSING

The approach followed by RDF stores like RDF-3X and TriAD, is to take advantage of initial sorting of RDF triples, and perform merge joins when possible. Hash join is preferred when inputs are not sorted on the join key. On the other hand, the dynamic exchange operator approach always uses index-based nested loops aiming at low memory consumption and avoiding blocking operators. Our system uses a combination of these two approaches, by taking into consideration the following points:

- When both inputs are already sorted on the join key, merge join is preferable over hash join.
- For main memory systems, index-based nested loops (in our case in the form of binary searches over the inner table stored as an array) does not exploit data locality and also it is not amenable to efficient data prefetching due to conditional branching. Nevertheless, for very selective joins, it may still be faster than merge join.
- For RDF data processing, where the initial triples are sorted in all three subject, predicate and object columns, even if the whole input is not sorted on the join key of a subsequent join, large portions of the input can still be sorted as it is demonstrated in the following example.

Example 4.1. Consider the following SPARQL query:

```
SELECT ?x ?y
WHERE {
    ?x prop1 ?y .
    ?x prop2 ?z .
    ?z prop3 ?w .    }
```

If the selected join order is as shown in text of the query, S-O tables will be used for all properties. As shards of prop1 are scanned, for each thread of execution, *prop*2 will be probed for values sorted on ?x, but for the second join, probing *prop*3 will not in general be sorted on ?z. Nevertheless, for each distinct ?x, *prop*3 probing will still be sorted on ?z and if each subject of *prop*3 is connected to many objects, it may be more efficient to avoid binary search on *prop*3 and switch to scanning for each distinct ?x.

A single join operator has been implemented in our system, that adaptively during run-time, for each search key, decides if it will switch to binary search (a behavior similar to index-based nested loops) or keep scanning the input in the form of sequential search, continuing from the position that the cursor has been left from a previous search (a behavior similar to merge join).

4.1 Adaptive Join Processing

Given a left-deep join tree produced from the optimizer, each worker starts scanning a shard of the first relation, or a specific shard of an object/subject vector of the first S-O/O-S relation in case a filter exists, and searching the subsequent relations for each produced tuple. The search procedure is presented in Algorithm 1. The algorithm takes as input a pointer to current cursor position (*cursor_position*), which corresponds to the position of the last accessed element for the array, and decides if it will use binary or sequential search. The *cursor_position* is updated each time for both successful and unsuccessful searches inside *Sequential_Search* and *Binary_Search* functions.

Obtaining an exact cost-model in order to take the correct decision is an involved process that needs to take into consideration factors such as the exact cache hierarchy, the size and bandwidth estimation for each cache level for both sequential access (scanning) and random access, cache line size, the replacement of cache entries from operations other than the join under consideration (for example subsequent joins of the same query) and the existence in cache of relevant entries from previous operations (for example scanning of the same relation in a previous query). Obtaining such cost models for hierarchical memory systems has been studied in [19], where cost functions are defined for basic access patterns and then combinations of these functions can be used to derive the cost of complex compound access patterns. As a prerequisite, specific hardware measurements should be known, which can be obtained through a separate calibration program that estimates cache and CPU characteristics.

In our case, decision has to be made during runtime for each produced tuple and each join of the query. Instead of using an analytical cost model, we opt for a fast and lightweight method using two assumptions: a uniform distribution of integers in the first array of each table and that existing cache contents have an impact proportional to the cost of either binary search or scanning. The second assumption simply denotes that existing cache contents can improve both methods, but they will not change which the methods is more efficient in each case. For example, if binary search is preferable with completely empty cache, it will remain so independently of the cache contents and vice versa. As a result we base our decision on the difference between the last accessed element and the element that we are currently searching for. Specifically, we pass as argument to the algorithm a threshold which is computed during data loading for each table. This threshold takes into consideration an estimation about the maximum distance of the position of the last accessed element and the position of the element to be found in the array, in order for sequential search to be preferable. To switch from distance in the array to the actual arithmetic distance of the two numbers, we use the uniform distribution assumption, which leads to an estimation that the difference between an element and its subsequent one is $(array[size - 1] - array[0])/size$. Note that in Algorithm 1, if $Distance > Threshold$ then we could perform binary search using $CursorPosition$ instead of 0 as starting position, and if $Distance < -Threshold$ we could use $CursorPosition$ as the end position instead of $size$. In theory this reduces the steps needed from binary search, but in practice it is not efficient, as always performing binary search on the whole array leads to the array positions visited during the first steps to frequently occur in cache.

Regarding the determination of the threshold, a calibration process shown in Algorithm 2 is used. This process takes place after data loading, prior to query execution, and tries to determine a distance (called $WindowSize$) such that when searching for a value $ToFind$ in the $Array$ and the position of $ToFind$ is at distance $WindowSize$ from the position of the last accessed element ($CursorPosition$), then $BinarySearch$ and $SequentialSearch$ perform roughly the same. Specifically, the ratio of the larger to the smaller execution times of these two methods should be smaller than a value close to 1.0 which is specified in the input of the algorithm ($Threshold$). For each calibration step each process is called $NoOfSearches$ times, each time searching for a value estimated to be at distance equal to $CurrentWindowSize$ from the previous one. If the ratio is larger than the $Threshold$, calibration continues such that the window size is multiplied by this ratio (in case time spent on binary search is larger) or divided (otherwise). This calibration process is different from a calibration needed when using an analytical cost model, in the sense that we directly make an estimation for a value related to processing, instead of estimating values about several hardware characteristics. Once the calibration process terminates, we precompute the estimated value distance (corresponding to the position distance that we obtained) for each property, such that during query execution we only need to perform one integer subtraction, one absolute value computation and one comparison for each tuple (lines 2-3 of Algorithm 1.

Algorithm 1: Adaptively switching between binary and sequential search

```
1 Search ($Array, Value, CursorPosition, Threshold, Size$);
    Input  : $Array$: an array of integers (subjects of an S-O table
             or objects of an O-S table), $Value$: integer value to
             find, $CursorPosition$:pointer to current cursor
             position, $Threshold$: integer, $Size$: size of array
    Output : nonnegative integer corresponding to the position of
             $Value$ in $Array$ or a negative integer if $Value$ is not
             present in the $Array$
    Uses   : $Binary\_Search(Array, Value, CursorPosition, Size)$, $Sequential\_Search(Array, Value, CursorPosition, Size)$
2 $Distance := Array[CursorPosition] - Value$;
3 if $|Distance| <= Threshold$ then
4     return $Sequential\_Search(Array, Value, CursorPosition, Size)$;
5 else
6     return $Binary\_Search(Array, Value, CursorPosition, Size)$;
7 end
```

4.2 ID-to-Position Index

Our join method takes advantage of initial sorting and performs cache-friendly joins even when only a partial order of input triples is possible, but when ordering does not help we must resort to binary search. In this section we describe the structure of an ID-to-Position index that is used to avoid binary search and directly locate the position of a given integer on the property array. A separate such ID-to-Position index must be built for each S-O or O-S table, but its usage is auxiliary, in the sense that our system can operate without all or some of these indexes. Given an RDF dataset with N distinct values and a corresponding dictionary with IDs from 1 to N, in order to directly locate the position of a given value in a table, we need to store an integer array of length N, such that the value at index p denotes the exact position at the table where it is located the resource whose ID value according to the dictionary is p, or a special value to denote absence of the specific resource from the table.

For example, given the property shown in Figure 1 and supposing that the maximum ID contained in the dictionary is 45, we would need an array of integers with length 45, such that at position 5 of the array we would have the value 0, at position 7 the value 1, at position 13 the value 2 and so on for positions $18, 24, 29, 33$ and 45, and all other position of the array would have a value denoting absence. If we use M-byte integers, then for each table the memory requirement would be $M * N$ bytes. In order to save space, we use a different layout on out ID-to-Position index, such that we only use an integer to denote the position of the property table at specific intervals, and for all other positions we use a bit value to simply denote presence or absence of value from the property table. Finding the exact position for a value requires reading the previous integer and then counting bits set to 1 up to the position of the ID-to-Position Index corresponding to the value. For example, if we choose the interval to be equal to 8, then our index will store the integer -1 at start, followed by bit values $0, 0, 0, 0, 1, 0, 1, 0$, then integer value 1 and bit values $0, 0, 0, 0, 1, 0, 0, 0$, then integer value 2 and bit values $0, 1, 0, 0, 0, 0, 0, 1$, then integer value 4 and bit values $0, 0, 0, 0, 1, 0, 0, 0$, then integer value 5 and bit values $1, 0, 0, 0, 0, 0, 0, 0$ and finally integer value 6 and bit values $0, 0, 0, 0, 1$. If we want to find the position of value 29 at the property we can

Algorithm 2: Calibration Process

```
Calibrate ($Array, NoOfSearches, StartingWindowSize, Threshold$);
  Input  : $Array$: an array of integers (subjects of an S-O table
           or objects of an O-S table), $NoOfSearches$: number
           of times to run sequential and binary search in each
           calibration step, $StartingWindowSize$: initial
           window size used in first step of calibration,
           $Threshold$: A threshold ratio to stop calibration
  Output : integer corresponding to the window size such that
           if two values in array are longer apart then binary
           search is preferable
$NextWindowSize = StartingWindowSize$;
$AvgGap = (Array[Size - 1] - Array[0])/Size$;
do
    $WindowSize = NextWindowSize$;
    $TotalGap = AvgGap * WindowSize$;
    $PreviousSearchPosition = 0$;
    $StartTime = getTimeNow()$;
    $ToFind = Array[0]$;
    for $K \leftarrow 0$ to $NoOfSearches$ do

```

directly check bit at position $((29 \div 8) + 1) * M * 8 + 29$. If bit is not set, then value is not present in property table. If bit is set we read integer value that starts at bit position $(29 \div 8) * M * 8 + (29 \div 8) * 8$ at the array and we add to this the number of bits that are set after this number for $29 \ mod \ 8$ positions. With this layout, given an interval A we only need $N/8 + ((N/A) * M)$ bytes. Also, given that the integer and the number of bits followed up to the next integer fit into a single cache line (with proper alignment of the index in the memory), we only need one memory access and some computation that can be done efficiently as a popcount operation in order to determine the position.

As an example, using the dataset LUBM 10240 described in Section 5, which contains about 1.4 billion triples, 17 distinct properties and about 336 million distinct resources, using 4-byte integers and choosing the interval to be 480 we only need 44.8 MB for each property, leading to a total memory usage of about 1.5 GB if we choose to create all possible indexes for $S - O$ and $O - S$ tables, in contrast to a memory requirement of 45.7 GB if we had used the simple layout.

Regarding modification of the join processing in case the ID-to-Position index is used, the only change that needs to be addressed is a different threshold resulted from calibration process. Specifically, since we anticipate that using the index will have better behavior in comparison with binary search, we need to estimate two different thresholds with regards as to when sequential search is preferable, with the threshold when ID-to-Position index is used being smaller than the threshold when binary search is used.

4.3 Join Ordering and Cost Estimation

As in RDF-3X and TriAD, we employ a bottom-up dynamic programming optimizer. As the level of parallelism during execution is determined by the number of threads, we assume that the benefit of each possible join order from parallelism will be a fixed proportion of its centralized cost, that is the execution cost if we consider that each property is consisting of a single shard. As a result of this assumption, we disregard parallelism during optimization. During cost estimation, we assume that a specific choice will be followed for all tuples of a join, either binary search or scanning. The latter will only take place when the join inputs are already fully sorted and it is estimated to be cheaper than binary search. Adaptivity during execution is expected to give a cost equal or lower to this estimation. For each property of a specific join order we choose to use the replica that leads to more selective results.

As selectivity estimation is not the focal point of this work, currently, in order to estimate the sizes of intermediate results we use equi-depth histograms. As it is known that often estimates based on such histograms may not be accurate especially in the case of RDF data [23], we precompute some cardinalities between pairs of properties during data loading and use these as a corrective step. We plan to implement more elaborate techniques for cardinality estimation in the future, like for example estimations based on characteristic sets [22] or RDF data summaries [36].

5 EXPERIMENTS

In-memory data storage and query processing for our prototype have been implemented in C as an extension of a SQLite, which is used as disk-based storage. Disk-based tables are created and saved during data import from RDF files. On application start-up the in-memory data structures are created reading from the tables. The dictionary can either be loaded in memory or kept in disk where for IRI-to-ID transformation (during query optimization) a clustered B+ tree on IRI is used and for ID-to-IRI transformation (during IRI construction of answer tuples) a clustered B+ tree on id. Our system is called through a wrapper written in Java, where also query parsing and optimization is implemented. We use the name *PARJ* for our implementation, which stands for Parallel Adaptive RDF Joins.

All experiments were conducted on a 16-core server with Intel E5-4603 processors at 2.20 GHz and 128 GB RAM running Debian 8. We used the popular Lehigh University Benchmark (LUBM) [13] and Waterloo SPARQL Diversity Test Suite (WatDiv) [6] benchmarks. All material required to reproduce the experiments is available online [3].

5.1 Setup

We use two sets of experiments: in the first one we test the efficiency of our approach in the single-thread setting. In this setup we use as competitors the in-memory RDF store RDFox (SVN version: 2776) and also RDF-3X [23] (version 0.3.8) for comparison with a state of the art disk-based system. The second setup is about multi-threaded execution. In the second setup we use as competitor the TriAD system which in [14] it is shown to outperform all competitors in the centralized parallel setting. We have used the optimized build for TriAD, as it is suggested in the installation manual.

Due to a hard-coded limit in the TriAD source code, we could not execute queries using more than 20 workers[4]. Note that in PARJ, each worker corresponds exactly to one thread, so given that hyper-threading is enabled, we found that the optimal performance was achieved when we used two threads for each processing core, resulting in 32 workers/threads in our testing machine. More details regarding the behavior of PARJ for different number of threads are given in Section 5.2.3. For TriAD it was not clear which number of workers should be the optimal, as this could be query depended. This is also the reason that we do not use TriAD in the single-thread setting. To have a better image and find the optimal setup, we executed TriAD with different number of workers, and we also modified the hard-coded limit and tried with up to 32 workers. For most queries, TriAD performance is degrading for more than 20 workers. From our testing we found that the overall best performance was achieved for 16 workers and this is the setup we used for TriAD in our experiments. Also, we present results for both TriAD settings: with summary mode enabled and disabled. For summary mode, we used the same number of partitions used in [14]: 200K for LUBM 10240 and 70K for WatDiv 1000.

Regarding result handling, as our intention is to concentrate in join processing, all systems were tested in the so called ”silent“ mode, that is we do not include the time for dictionary lookups and result tuple construction. In multi threaded execution this also means that we do not measure the time to aggregate the results together. Each query was executed 10 times and the average execution time is shown. We have deployed RDF-3X using an in-memory filesystem and as a result there is no need to report cold and warm cache times.

5.2 Results

We present results for scale 10240 of the LUBM benchmark in Table 2 (about 1.4 billion triples) and scale 1000 of the WatDiv benchmark (about 110 million triples). For WatDiv we used both

[3] https://github.com/dbilid/experiments

[4] This was verified with the TriAD implementors

basic test workload (Table 3) and incremental linear and mixed linear extensions of basic workload (Table 4). For WatDiv we generated all the queries proposed in the workloads. For LUBM we used the seven queries commonly used to test systems that do not perform reasoning tasks, which can be found in [42], and are labeled LUBM1-LUBM7, and we also used three extra queries from [26] (LUBM8-LUBM10). A timeout of 30 minutes was used for all queries.

Regarding single thread execution, we first observe that RDFox is comparable to PARJ for some queries, but for other queries, especially for queries from the WatDiv incremental and mixed linear extensions, is highly inefficient. This confirms that this system is not optimized for query answering, but instead, it aims at efficient parallel materialization of RDF implications. Regarding RDF-3X, we can see that it performs more than one order of magnitude slower from PARJ for most queries. The reason is that despite the fact that it is deployed in an in-memory filesystem, its processing is oriented towards optimizing disk access, as it is not aware that it operates in memory. For example, it uses B+ trees to minimize the number of disk pages needed, it skips records with its sideways-information passing optimization only when it reads a new disk-page into memory, it uses compression on a per page basis and also its cost estimation is based on disk access. Nevertheless, there are some queries, for example queries in the ML-2 set or LUBM8, where RDF-3X outperforms the single-threaded PARJ execution. These are queries with large intermediate results, but only few final answers, where the record skipping using sideways information passing in RDF-3X results in substantial gains.

Regarding multi-thread execution we can see that for most queries the summary mode of TriAD is inferior to the simple mode, sometimes by a large margin. For example, for query LUBM 3 in Table 2 the execution time increases from 2 seconds to more than 15 seconds. For the specific query we saw that execution over the summary graph takes up most of the execution time. In any case, the results show that for parallel execution on a centralized environment the pruning from the graph summaries does not contribute to an important improvement which can justify the overhead of graph partitioning.

A comparison of PARJ with the best TriAD mode shows that we outperform TriAD by more than an order of magnitude for the average execution time of the LUBM 10240 queries: from 838 milliseconds for PARJ to 13263 for TriAD (Table 2). For basic WatDiv testing (Table 3), though TriAD performs slightly better for simple queries, PARJ performs better overall with a total average execution time of 11.27 ms (geomean: 7.76) whereas TriAD has a total average execution time of 13.95 (geomean: 6.8). For the more complex queries of WatDiv extended workloads (Table 4) PARJ clearly outperforms TriAD. For some queries the difference is more than two orders of magnitude. As an example, for query ML1-7 the time increases from 7 ms to 2154. The specific query contains a series of subject-object joins, which leads TriAD to perform blocking data transfers between workers and rehashing over large intermediate results, though the final result is relatively small.

Regarding the difference between the silent mode and the full result handling, we have executed all queries with full result handling (except from printing) in PARJ. That is we include answer tuple construction, dictionary lookups and sending all results to the coordinating thread. We do not include these results, as we saw that for most queries, usually with results up to a few thousand tuples, the difference is not important, but for queries with many million results the difference can be significant. This can be seen especially for query 2 from the LUBM benchmark (about 10M results) where execution time in multi threaded execution increases from 151 milliseconds in silent mode to 610 milliseconds in full result handling. The same holds for queries C3 (about 4.3M results) and IL-3-5 to IL-3-10 from WatDiv which have more than 50M results. Query IL-3-8 has by far the largest number of results (about 1.6 billion tuples with 9 columns). This is the reason that TriAD runs out of memory for the specific query, since even in silent mode, each worker keeps in memory all the results instead of using an iterator to send the results to the master (or discard the results in silent mode) as they are produced, as it is the approach used by PARJ. Execution times for the full result handling mode of PARJ are included in the online material to reproduce experiments.

5.2.1 Effect of Runtime Join Optimization. In order to examine the effect of our adaptive join method, we have executed the queries of both datasets using four different strategies as shown in Table 5. For WatDiv benchmark we only report the average and geometric mean of all execution times. In the first (Binary) column we report the execution times when we always use binary search. In the second column (AdBinary) we use our adaptive join method in order to switch from binary to sequential search. In third column (Index) we always use the ID-to-Position index, whereas in the last column (AdIndex) we use the adaptive join method in order to switch from ID-to-position index to sequential search. One can observe that the impact of the adaptive join method is more important when binary search is employed (comparison of first and second column), whereas when the ID-to-Position index is used (comparison between third and fourth column) its contribution to better performance is smaller. This is in line with the result of our calibration method, where when binary search is used, the result threshold is about 200 positions, whereas when ID-to-Position index is used the threshold is about 20 positions. Also, it seems that the impact is more important for LUBM queries, where in case of binary search it leads to a decrease of 23% in average execution time. The reason for that is that the average execution time for WatDiv queries is heavily affected by the IL-3 queries, where the impact of the adaptive method is not important, as sequential search can rarely be used in these queries. This is also the reason for the great reduction in average execution time of WatDiv queries when the ID-to-Position index is used, as the aforementioned queries are greatly profit from the index.

* RDFox returns an empty result-set for query S5, whereas the correct answer is not empty.

** TriAD returns only distinct answers for query C3, even though modifier DISTINCT is not present in the SPARQL query. The number of results returned is only 8162 instead of 4335801.

5.2.2 Effect of ID-to-Position Index. We now proceed to describe the evaluation of our ID-to-Position Index compared to standard binary search using the LUBM 10240 dataset in the single-thread setting. Table 6 shows the number of binary searches and the number of sequential searches which were performed using the decision of our adaptive join method, using a threshold of about 200 computed with our calibration algorithm. The fact that sequential searches heavily outnumber binary searches provides a strong indication that ordering is present in the RDF dataset. In order to compare our index with binary search, we kept the threshold the same as computed in the case of binary search, and executed the queries by performing our index based lookup instead of binary search, measuring the exact number of total execution cycles used in the index lookup or binary search procedure each time, as well as the cache misses for each cache level. If we exclude queries no 1 and 3-6, as they nearly perform only sequential searches, we can see that our ID-to-Position index results in more than 30% decrease in total execution cycles and similar or larger decrease in the number of cache misses for all levels of cache hierarchy.

5.2.3 Scalability. In this section we experimentally show the scalability of PARJ with regard to a varying number of threads and varying dataset size. As far as the first issue is concerned, we can already observe from Section 5.2 and specifically from Tables 2, 3 and 4, that running PARJ in multi threaded mode with 32 threads performs on average about 15 times better than the single thread version, but for the simple queries, when execution time is less than few tens milliseconds, multi-threaded execution does not seem to provide important gains. There are two reasons for that. The first one is the overhead of spawning multiple threads and

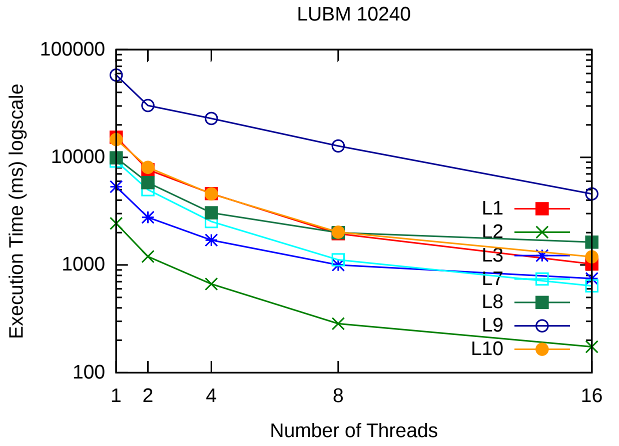

Figure 2: LUBM 10240 execution times in ms for different number of threads

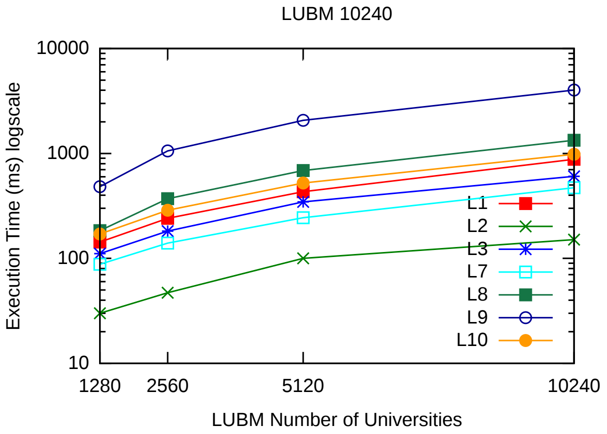

Figure 3: LUBM 32 threads execution times in ms for different dataset sizes

the second is that query parsing and optimization take up a large fragment of the total execution time, which cannot be avoided in multi-threaded execution. The best example of this is query S1 from WatDiv benchmark which is a star join query with 9 triple patterns and more than 40 milliseconds of the reported time of 49 milliseconds is spent on producing the join order in the optimizer.

In order to better examine the behavior of PARJ for a varying number of threads we have executed the queries from LUBM benchmark for scale 10240 with 1, 2, 4, 8 and 16 threads as shown in Figure 2. We exclude from this presentation simple and very selective queries L4, L5 and L6 that do not appear to improve from parallelism, since already in the single-threaded execution their execution time is only a few milliseconds, much of which is due to query parsing and optimization. On the other hand, complex queries L1, L3, and L7-L10, and also the simple but not selective query L2 show large and nearly linear improvement. The reason that we do not show results beyond 16 threads in Figure 2 has to do with the capabilities of our testing machine, which has exactly 16 processing cores. As stated before, best results were obtained with 32 threads as hyper-threading was enabled, but improvement from 16 to 32 threads cannot be evaluated and interpreted reliably for the specific scalability experiment, as here we aim to examine the behavior of PARJ for a varying number of threads given that the underlying hardware can provide full processing resources to each thread.

We have also examined the scalability of our system for a varying dataset size. Findings in Figure 3 show a similar situation for a varying number of universities in the execution with 32 threads, confirming the excellent scalability of PARJ.

5.2.4 Comparison With Distributed RDF Stores. A comparison of a parallel centralized system with distributed systems is not straightforward, as many factors come into play in order to have a result that will be as fair and complete as possible. In this section we attempt some first comparison of PARJ with existing RDF stores based on a recently published survey [2] and we plan to further investigate this issue experimentally in the future. The aforementioned survey presents an experimental comparison of 12 distributed systems designed for shared-nothing clusters, chosen as the most competitive and innovative from a variety of approaches and characteristics. The experiments were performed on a cluster with 12 servers, each with 148GB of memory and 24 cores, using, among others, the LUBM 10240 (only queries LUBM1-LUBM7) and WatDiv 1000 (only basic workload) benchmarks. For both these benchmarks the single server results of PARJ (in the full result handling mode) are comparable with the faster of the reported systems which is the non-adaptive version of AdPart (the adaptive version is not included in the results of [2]). Specifically, the average and geometric mean of execution times for first seven queries of LUBM 10240 are 918 and 75 milliseconds respectively (compared with 419 and 103 for PARJ in full result handling mode) whereas the geometric means for the 4 query categories of the basic workload of WatDiv 1000 are 9, 7, 160 and 111 milliseconds (compared with 9, 10, 12 and 48 for PARJ in full result handling mode).

6 CONCLUSIONS AND FUTURE WORK

We have presented a centralized in-memory system for parallelizing join processing on RDF graphs. We have shown that our design has excellent scaling capabilities and performance. For future work, we first plan to perform a more thorough experimental comparison with distributed RDF stores. As we mentioned, it is straightforward to extend PARJ to a "cluster" version through full replication, such that during query execution each worker start processing from different initial shard. We plan to implement and compare this version with the current state of the art distributed systems. We also want to further evaluate PARJ on a high-end server with larger available memory, in order to load and process larger RDF graphs. Based on the scaling capabilities presented during the experiments, we anticipate that our approach will be able to efficiently handle such datasets.

Furthermore, we plan to investigate the efficient incorporation of query answering with respect to class and property hierarchies into our join approach. RDF Schema (RDFS) as well as more expressive ontological languages like OWL-2 QL define ontological constraints on top of RDF graphs, such that SPARQL query answering must be extended by taking into consideration the corresponding semantics in order to provide the user with the complete answers. Deep and wide class and property hierarchies pose a serious performance issue for all systems that perform query answering with respect to such *entailment regimes*. Materializing all implied assertions, as it is the case in RDFS reasoning with forward chaining, with respect to these hierarchies may lead to data size many times larger than the original, something that may not be viable especially for an in-memory system. On the other hand, using RDFS reasoning with backward chaining may lead to complicated queries. We plan to extend our join method to handle such queries, by "unioning" tables during the pipelined join execution in order to provide complete answering with respect to hierarchies, without the need to materialize the implications.

ACKNOWLEDGMENTS

We would like to thank Stratos Idreos for his comments on an early version of this work and the anonymous reviewers for their input and corrections. The present work was co-funded the European Union's Horizon 2020 research and innovation programme under grant agreement No 825258 and by the European Union (ERDF) and Greek national funds through the Operational Program "Competitiveness, Entrepreneurship and Innovation", under the call "RESEARCH-CREATE-INNOVATE" (project code:T1EDK01000).

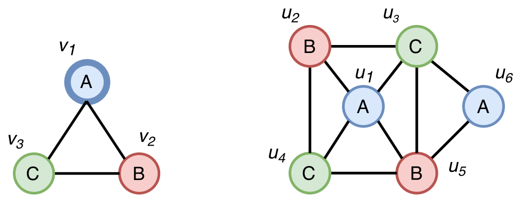
ABSTRACT

Given query graph Q with pivot node v, Pivoted Subgraph Isomorphism (*PSI*) finds all distinct nodes in an input graph G that correspond to v in all matches of Q in G. PSI is a core operation in many applications such as frequent subgraph mining, protein functionality prediction and in-network node similarity. Existing applications implement PSI as an instance of the general subgraph isomorphism algorithm, which is expensive and under-optimized. As a result, these applications perform poorly and do not scale to large graphs. In this paper, we propose SmartPSI; a system to efficiently evaluate PSI queries. We develop two algorithms, called optimistic and pessimistic, each tailored for different instances of the problem. Based on machine learning, SmartPSI builds on-the-fly a classifier to decide which of the two algorithms is appropriate for evaluating each graph node. SmartPSI also implements a machine learning-based optimizer to generate low-cost execution plans. Our experimental evaluation with large-scale real graphs shows that SmartPSI outperforms existing approaches by up to two orders of magnitude and is able to process significantly larger graphs. Moreover, SmartPSI is shown to achieve up to 6 times performance improvement when it replaces standard subgraph isomorphism in the state-of-the-art distributed frequent subgraph mining system.

1 INTRODUCTION

Graphs are widely used to model information in a variety of real world applications such as social networks [31, 32], chemical compounds [20] and protein-protein interactions [25]. Finding all valid bindings of a particular query node is an important step in various application domains such as frequent subgraph mining [4, 37], protein functionality prediction [12], neighborhood pattern mining [15], query recommendation [16] and in-network node similarity [39]. This step is called Pivoted Subgraph Isomorphism (*PSI*); for query Q with pivot node v, PSI finds the set of distinct matches of v in an input graph G. For example, PSI query S $(\underline{v_1}, v_2, v_3)$ in Figure 1 has two matches of the pivot node v_1 in G: u_1 and u_6.

Existing applications [4, 13, 15, 16, 25] depend on subgraph isomorphism [9, 17, 30] to evaluate PSI-like queries. They use subgraph isomorphism to find all matches of the query and then project distinct nodes that correspond to the pivot node. In the example of Figure 1, subgraph isomorphism generates 5 intermediate results: $(\underline{u_1}, u_2, u_3)$, $(\underline{u_1}, u_2, u_4)$, $(\underline{u_1}, u_5, u_4)$, $(\underline{u_1}, u_5, u_3)$ and $(\underline{u_6}, u_5, u_3)$), in order to project u_1 and u_6 as results for the PSI query. We show in Table 1 the number of PSI results compared to the number of intermediate isomorphic subgraphs for various real graphs and query sizes (see Section 5 for details). Observe that the number of isomorphic subgraphs grows exponentially with the query size even for small and sparse datasets like Yeast, whereas the actual PSI results are significantly fewer. Consequently, the performance of applications that depend on subgraph isomorphism degrades rapidly with complex queries and larger graphs.



(a) PSI query S

(b) Input graph G

Figure 1: (a) A PSI query with v_1 as pivot, (b) input graph. The bindings of v_1 are u_1 and u_6

A possible approach to reduce the exponential number of matches in subgraph ismorphism-based solutions is to stop the search once a match of the pivot node is found for each candidate graph node. We demonstrate the effect of this optimization by proposing TurboIso$^+$ (Section 5.2) as a modified version of TurboIso [17] which is a highly optimized subgraph isomorphism solution. We show in Table 2 that TurboIso$^+$ is significantly faster than TurboIso for all query sizes. However, it remains computationally expensive since it cannot avoid the overhead of the sophisticated data structures used to compile all occurrences of the given query. As such, using subgraph isomorphism to solve PSI queries is unnecessarily expensive. Moreover, to the best of our knowledge, there is no existing research that has been devoted to efficiently answer PSI queries.

In this paper, we formalize the pivoted subgraph isomorphism problem and introduce the *optimistic* and *pessimistic* approaches for evaluating PSI queries efficiently. The optimistic approach is highly optimized to confirm that a graph node matches the pivot node in the query. It uses a greedy depth-first guided search to minimize the number of graph explorations required to prove that a particular node is indeed a matching node. If no match exists, it would have unnecessarily wasted resources to discover non-matching nodes. The pessimistic approach, on the other hand, is highly optimized to verify that a graph node does not match the given query. It is based on a random, non-guided, search that prunes adjacent nodes early depending on their neighbourhood.

Table 1: Number of subgraph query matches using PSI vs. standard subgraph isomorphism

Dataset	Query	Query Size						
		4	**5**	**6**	**7**	**8**	**9**	**10**
Yeast	PSI	7×10^4	6×10^4	5×10^4	5×10^4	4×10^4	3×10^4	3×10^4
	Subgraph Iso.	1.3×10^7	1.2×10^8	1.1×10^9	7.4×10^9	5.8×10^{10}	6.0×10^{11}	2.8×10^{12}
Cora	PSI	2.1×10^5	1.9×10^5	1.4×10^5	1.2×10^5	1.1×10^5	0.9×10^5	0.8×10^5
	Subgraph Iso.	1.6×10^8	1.2×10^{10}	1.1×10^{12}	8.4×10^{13}	1.5×10^{15}	8.9×10^{16}	NA
Human	PSI	1.4×10^5	1.3×10^5	1.2×10^5	1.1×10^5	1.1×10^5	1.0×10^5	1.1×10^5
	Subgraph Iso.	2.6×10^{10}	7.6×10^{12}	NA	NA	NA	NA	NA

Early pruning helps the pessimistic algorithm to avoid unnecessary graph traversals. It detects non-matching nodes significantly faster than the optimistic approach, however, it has a higher cost when used for matching nodes.

To maximize the gain from these two methods, the optimistic method has to be used to validate nodes that match the query while the pessimistic method should be used to confirm other non-matching nodes. Unfortunately, we do not know which graph node matches the given PSI query prior to query evaluation, while it is counter-intuitive to use the proposed methods randomly on the input graph. To solve this problem, we propose SmartPSI, a solution that relies on machine learning to predict which method is best to evaluate each graph node. In SmartPSI, a classification model is trained to predict the type of each graph node (i.e., whether a node does or does not match the given query). Based on the prediction result, the appropriate method is picked accordingly; the optimistic method is used for matching graph nodes (predicted valid nodes) and the pessimistic is used for non-matching nodes (predicted invalid nodes). Notice that SmartPSI is an exact solution since the correctness of the result is guaranteed even when using the opposite evaluation, this is due to the fact that both algorithms traverse the whole search space in the worst-case scenario. SmartPSI is also coupled with a novel query optimizer, that recommends an efficient search order plan for evaluating each graph node. The last row of table 2 gives a hint on how the combined ideas implemented in SmartPSI, which are solely designed for PSI queries, perform compared to the more general solutions of subgraph isomorphism.

In summary, our contributions are:

- We introduce two methods for evaluating PSI queries, each method is optimized for a particular type of the input graph nodes.
- We propose a solution based on machine learning that, for each graph node, predicts the node type, picks the corresponding optimized evaluation method, and selects an efficient plan for query evaluation.
- We also propose a preemptive query processor that employs a detection and recovery technique at run-time to reduce the impact of incorrect predictions.
- We experimentally compare the performance of SmartPSI against the state-of-the-art subgraph isomorphism techniques. We show that SmartPSI is orders of magnitude faster and it scales to much larger queries and input graphs. Furthermore, we empirically show that our optimizations significantly improve the performance of a cutting edge frequent subgraph mining system.

The rest of the paper is organized as follows: Section 2 formalizes the problem and presents various PSI applications. Section 3 introduces two novel PSI evaluation methods. Section 4 presents a two-threaded baseline solution and describes machine learning based optimizations that overcome the limitations of the baseline. Section 5 presents the experimental evaluation. Section 6 surveys the related work while Section 7 concludes.

Table 2: Performance of PSI solutions on Human dataset (details in Section 5). SmartPSI is our proposed approach.

Query size	4	5	6	7
TurboIso	5.4 hrs	>24 hrs	>24 hrs	>24 hrs
TurboIso$^+$	14 min	30 min	45 min	2.4 hrs
SmartPSI	27 sec	47 sec	2 min	4.3 min

2 PIVOTED SUBGRAPH ISOMORPHISM

2.1 Definition

A labeled graph $G = (V_G, E_G, L_G)$ consists of a set of nodes V_G, a set of edges E_G and a labeling function L_G that assigns labels to nodes and edges. A graph $S = (V_S, E_S, L_S)$ is a *subgraph* of a graph G iff $V_S \subseteq V_G$, $E_S \subseteq E_G$ and $L_S(v) = L_G(v)$ for all $v \in V_S \cup E_S$. Subgraph isomorphism is the task of finding all occurrences of S inside G. It is a computationally expensive problem, known to be NP-Complete [14]; it needs to validate a huge number of intermediate and final results. PSI, which is also NP-Complete [15], relaxes subgraph isomorphism by focusing on finding all node matches of a particular query node (v_p), which is called a *pivot* node, inside the input graph G.

Definition 2.1. A pivoted graph is a tuple $\eth$={G, v_p}, where G is a labeled graph and $v_p \in V_G$ is called the pivot node of the pivoted graph $\eth$.

The pivot node (v_p) is the node of interest, and it is usually set by the user who creates the query.

Definition 2.2. A *pivoted subgraph isomorphism* of $\eth_S$=(S, v_p) to $\eth_G$={G, u_p} where $S = (V_S, E_S, L_S)$, $G = (V_G, E_G, L_G)$, $v_p \in V_S$ and $u_p \in V_G$, is an injective function $M : V_S \longrightarrow V_G$ satisfying (*i*) $L_S(v) = L_G(M(v))$ for all nodes $v \in V_S$, (*ii*) $(M(u), M(v)) \in E_G$ and $L_S(u, v) = L_G(M(u), M(v))$ for all edges $(u, v) \in E_S$, and (*iii*) $M(v_p) = u_p$.

Rather than finding all matches in subgraph isomorphism, PSI finds at most one occurrence per graph node u_p, which significantly reduces computation and memory overheads. The input graph node u_p is called a *valid* node for query $\eth_S$ if it matches v_p in at least one occurrence of S in G, otherwise it is called an *invalid* node. PSI has an important role in several applications [4, 13, 15, 16, 25]. In the following discussion, we highlight some of these applications.

2.2 PSI Applications

Frequent Subgraph Mining (FSM). FSM is an important operation for graph analytics and knowledge discovery [4, 5, 13]. Given an input graph and a support threshold, FSM evaluates the frequencies of a large number of candidate subgraphs to determine which one is frequent. Typically, this evaluation relies on finding the distinct input graph nodes that match their corresponding candidate subgraph nodes [11]. Current solutions [4, 13] employ subgraph isomorphism to conduct this step. Instead of using the expensive subgraph isomorphism algorithms, PSI can be employed to efficiently evaluate the frequencies. Using PSI instead of subgraph isomorphism results in a significant improvement in the overall efficiency of FSM techniques (see Section 5.5).

Function prediction in PPI networks. In the domain of protein-protein-interaction (PPI) networks, it is common to discover new proteins with unknown functions [12]. Knowledge about their functionality is essential to analyze these networks and discover valuable insights. In order to predict these functions, a set of significant patterns are extracted from the PPI network. Each protein with unknown function is then matched against the extracted patterns. A label that is matched to the node with unknown function represents a predicted function for this node. Each significant pattern is represented by a different pivoted subgraph query, and the matching task resembles a PSI query evaluation.

Discovering Pattern Queries by Sample Answers. Knowledge bases are effective in answering questions. Nevertheless, it is challenging for a user to issue a query that follows the schema of the knowledge base. Han et al. [16] proposed a query discovery approach to assist users by recommending candidate queries. This approach is based on having a sample answer set (i.e., a set of nodes which the user thinks they match his query). The first step finds a set of queries that match the neighborhood around the given nodes. These queries represent recommended candidate queries. This step is conducted by a series of PSI operations which tries to filter out all queries that do not match any of the given answer nodes. Queries that pass the first step are then ranked and the top ones are recommended for the user.

Neighborhood Pattern Mining. Mining frequent neighborhood patterns [15] finds the set of frequent patterns that each originates from graph nodes with a particular label. Similar to FSM, candidate patterns are generated and evaluated to determine whether they are frequent. Though, the evaluation step is different. Given a specific label, each candidate pattern is evaluated by PSI to know the number of graph nodes that satisfy this pattern. Based on this process, interesting knowledge can be obtained regarding the common connectivity patterns found around each node label.

In-network Node Similarity. In many applications, it is very important to measure the similarity among graph nodes. These applications include role discovery [28], objects similarity [21] and node clustering [19]. Two nodes are similar if they have similar neighborhoods. There are several techniques for calculating nodes similarity. A recent approach [39] proposed a unified framework for measuring the similarity between two nodes. One of the proposed metrics is the maximum common pivoted subgraph that exists around the two nodes. This metric is extended into a more general similarity metric, which is used to compare the common pivoted subgraphs occurring in the neighborhoods of any two nodes. Such approach is a direct application of PSI.

3 THE OPTIMIST AND THE PESSIMIST

In this section, we propose an optimist and a pessimist evaluation mechanisms to improve PSI evaluation. The *optimistic* method is optimized to confirm that a candidate node is valid, i.e., matches the query pivot node. On the other hand, the *pessimistic* method is effective in proving that a candidate node is invalid. Since both methods require access to a neighborhood signature, we will first describe what a neighborhood signature is and how it is calculated (Sections 3.1 and 3.2). Then, we introduce each PSI method in Sections 3.3 and 3.4.

3.1 Neighborhood Signature

The *neighborhood signature* of a graph node represents how this node interacts with its neighbors. A good neighborhood signature should be concise and effective in pruning/matching of a graph node. The literature introduces several signature definitions [7, 23, 42, 43]. We propose to use a label propagation technique inspired by the work of proximity pattern mining [23]. This technique assigns a list of weights to each graph node. Each weight corresponds to a label and reflects the proximity of that label to the graph node.

Definition 3.1. Let u be a node in the graph G. The neighborhood signature of u within a distance D is the set of pairs:

$$NS_u{}^D = \{(l_1, w_1^D), (l_2, w_2^D)...(l_n, w_n^D)\}$$

where each l_i is a node label and each weight $w_i^D \in R$.

Label weights are propagated from nearby nodes such that for each label l_i, its weight w_i^D is calculated as:

$$w_i^D = \sum_{d=0}^{D} 2^{-d} \times C_u(l_i, d)$$

where D is the maximum propagation depth, and $C_u(l_i, d)$ is the number of nodes with label l_i having a shortest distance d from node u. Notice that the signature $NS_u{}^D$ is small since its size depends on the number of distinct labels that appear in the graph. It is also effective as the used weights reflect how neighbors are structured around the node. In this work, we use the same maximum propagation depth for query graphs and the input graph. Thus, we will omit the use of the superscript D where it is not needed.

Example: Consider the data graph G in Figure 1, G contains three different labels; $\{A, B, C\}$. Assuming that the maximum propagation depth is set to 2, the signature of node u_1 is calculated as follows: (*i*) first, the label of u_1, which is 'A', is given a weight = 1. Consequently, the list of weights from distance 0 is: $\{(A, 1), (B, 0), (C, 0)\}$. (*ii*) For the first level of neighbors, there exist four nodes, two nodes are labeled 'B' and the other two are labeled 'C'. Therefore, the weight of 'B' in this case is 2×0.5 and the weight of 'C' = 2×0.5. Consequently, the list of propagated weights from this level is $\{(A, 0), (B, 1), (C, 1)\}$. (*iii*) There is only one node that is two hops away from u_1; i.e. u_6, which has label 'A', and thus the weight of 'A' = $1 \times 0.25 = 0.25$. Consequently, the propagated weights from this level = $\{(A, 0.25), (B, 0), (C, 0)\}$. (*iv*) Finally, $NS_{u_1}^2$ is the sum of weights from all levels, hence, $NS_{u_1}^2 = \{(A, 1.25), (B, 1), (C, 1)\}$.

Signature Computation. Traditional approaches [23] follow an exploration-based strategy to compute node signatures. It executes a breadth-first search algorithm iteratively till the maximum propagation depth is met. This approach is very simple to implement but has an exponential computational complexity ($O(|N|.|L|.d^D)$), where |**N**| is the number of nodes in the graph, |**L**| is the number of distinct node labels, **d** is the average node degree and **D** is the maximum traversal depth.

Optimization. To improve the performance of computing neighbourhood signatures, we propose a significantly faster approach based on matrix multiplication to compute all neighborhood signatures of the input graph. In comparison to the exploration-based technique [23], the computational complexity of our proposal is $O(|N|.|L|.d.D)$. The first step is to create a matrix NS^0 : $|N| \times |L|$. Each row $NS^0(n)$ represents the neighborhood signature of a node n and is initialized as: $NS^0(n) = [b_1, b_2, ...b_L]$ where $b_l = 1$ if $l \in L(n)$ and 0 otherwise. Then for the subsequent D iterations, the corresponding row for each node n is updated as follows:

$$NS^i(n) = NS^{i-1}(n) + \frac{1}{2}Adj(n) \times NS^{i-1}$$

where $Adj(n)$ is the adjacency matrix row that corresponds to node n. Notice that the label weights obtained by the iterative matrix multiplications may differ from the ones generated by the exploration based approach. This is because the iterative matrix approach considers neighbors labels multiple times through different paths, compared to one time through the shortest path in the previous approach. However, these weights are still based on the proximity of the labels that exist around the node under consideration.

Example: Consider the PSI query in Figure 2. Assuming a maximum propagation depth of 2, we first initialize NS^0 and Adj to be:

$$NS^0 = \begin{array}{c} \\ v_0 \\ v_1 \\ v_2 \\ v_3 \\ v_4 \end{array} \begin{array}{c} \begin{array}{cccc} A & B & C & D \end{array} \\ \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \end{array}$$

$$Adj = \begin{array}{c} \\ v_0 \\ v_1 \\ v_2 \\ v_3 \\ v_4 \end{array} \begin{array}{c} \begin{array}{ccccc} v_0 & v_1 & v_2 & v_3 & v_4 \end{array} \\ \begin{pmatrix} 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 \end{pmatrix} \end{array}$$

Then, we apply two iterations of the matrix multiplication to compute the results for NS^1 and NS^2:

$$NS^1 = \begin{array}{c} \\ v_0 \\ v_1 \\ v_2 \\ v_3 \\ v_4 \end{array} \begin{array}{c} \begin{array}{cccc} A & B & C & D \end{array} \\ \begin{pmatrix} 1 & 1/2 & 0 & 0 \\ 1/2 & 3/2 & 1/2 & 0 \\ 0 & 3/2 & 1/2 & 0 \\ 0 & 1 & 1 & 1/2 \\ 0 & 0 & 1/2 & 1 \end{pmatrix} \end{array}$$

$$NS^2 = \begin{array}{c} \\ v_0 \\ \mathbf{v_1} \\ v_2 \\ v_3 \\ v_4 \end{array} \begin{array}{c} \begin{array}{cccc} A & B & C & D \end{array} \\ \begin{pmatrix} 5/4 & 5/4 & 1/4 & 0 \\ \mathbf{1} & \mathbf{3} & \mathbf{5/4} & \mathbf{1/4} \\ 1/4 & 11/4 & 5/4 & 1/4 \\ 1/4 & 13/4 & 2 & 1 \\ 0 & 1/2 & 1 & 5/4 \end{pmatrix} \end{array}$$

Notice that row v_1 in NS^2 is the neighborhood signature of the query graph pivot node in Figure 2(a).

PSI query evaluation benefits from neighborhood signatures in two ways. First, graph traversals are guided towards the relevant graph nodes in order to efficiently reach a match for a given query. Second, significant pruning is achieved during the evaluation of graph nodes that do not satisfy the query.

3.2 Neighborhood Signature Satisfaction

The neighborhood signatures of two nodes can be utilized to quickly judge if they have the same neighbourhood and hence could be a match. A signature NS_i is said to satisfy another signature NS_j if for every $(l_j, w_j) \in NS_j$, there exists $(l_i, w_i) \in NS_i$ where $l_i = l_j$ and $w_i \geq w_j$. In Figure 1(b), u_1 has a neighborhood signature $NS^2_{u_1} = \{(A, 1.25), (B, 1), (C, 1)\}$. For query S in Figure 1(a), $NS_{v_1} = \{(A, 1), (B, 0.5), (C, 0.5)\}$. NS_{u_1} satisfies NS_{v_1} since the weights of all labels in NS_{u_1} are larger than their corresponding ones in NS_{v_1}.

Proposition 3.2. *Given a graph G, a graph node u and a pivoted query $\eth$={S, v_p}, where S is a subgraph and v_p is the pivot node, if NS_u does not satisfy NS_v, then u is an invalid node given the pivoted query $\eth$.*

Proof: We will use a proof by contradiction approach. Let NS_u do not satisfy NS_v. Let's assume a graph node u be valid for the pivot node v of subgraph S. Since NS_u do not satisfy NS_v. This implies that there exists at least one pair $(l_i, w_u) \in NS_u$ and a pair $(l_j, w_v) \in NS_v$, where $l_i = l_j$ and $w_u < w_v$. For w_u to be less than w_v, the contribution to the weight w_u from neighbor nodes with label l_i should be less than of neighbors of node v with the same label. The weight contribution relies on the number of neighbors labeled l_i and their distances. Accordingly, either the number of neighbor nodes of u with label l_i is less than that for neighbors of node v with the same label, or their distances are larger than their corresponding ones in the query. The last statement contradicts with the assumption that v is a valid node of u since this requires that each neighbor of v to have a distinct corresponding match with a neighbor of u. □

3.3 The Optimist

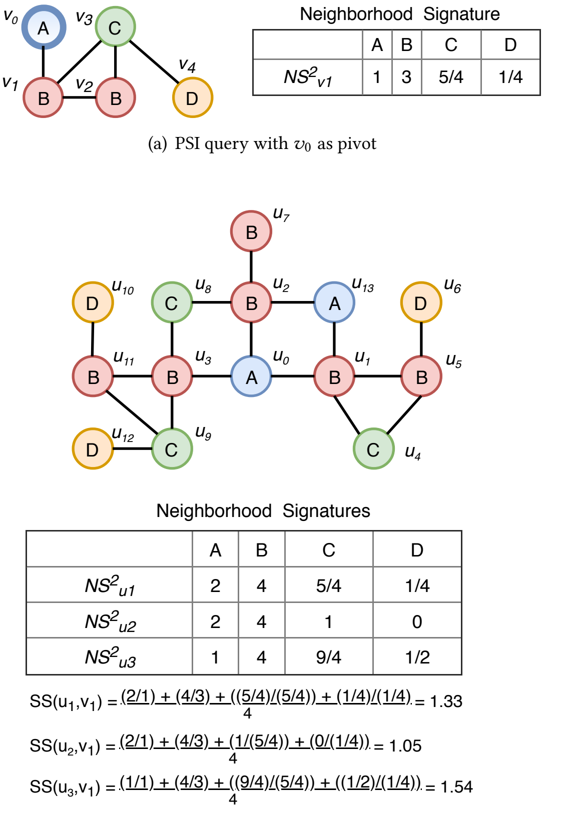
The optimistic algorithm uses a greedy depth-first guided search to quickly find a match for the given query. Its name is derived from the fact that it assumes that input candidate nodes are valid and optimizes the evaluation accordingly. The algorithm starts by generating a satisfiability score for each neighbor of the candidate node and then it sorts them based on the calculated scores descendingly. The satisfiability score measures the likelihood of a graph node being a match for its corresponding query node, it is calculated as:

$$SS(u, v) = avg_{(l,w_l) \in NS_v}(NS_u(l)/w_l)$$

For example, the satisfiability score of u_1 in G and v_1 in S from Figure 1, where $NS_{u_1} = \{(A, 1.25), (B, 1), (C, 1)\}$ and $NS_{v_1} = \{(A, 1), (B, 0.5), (C, 0.5)\}$, is calculated as follows:

$$\frac{(1.25/1) + (1/0.5) + (1/0.5)}{3} = 1.75$$

We show more examples of satisfiability scores in Figure 2. Moreover, Figure 2 shows how to use the computed neighborhood signatures of v_1, u_1, u_2 and u_3 (based on Section 3.1) to determine the satisfiability scores of node pairs (u_1, v_1), (u_2, v_1) and (u_3,



Neighborhood Signature

	A	B	C	D
NS^2_{v1}	1	3	5/4	1/4

(a) PSI query with v_0 as pivot

Neighborhood Signatures

	A	B	C	D
NS^2_{u1}	2	4	5/4	1/4
NS^2_{u2}	2	4	1	0
NS^2_{u3}	1	4	9/4	1/2

$$SS(u_1,v_1) = \frac{(2/1) + (4/3) + ((5/4)/(5/4)) + (1/4)/(1/4)}{4} = 1.33$$

$$SS(u_2,v_1) = \frac{(2/1) + (4/3) + (1/(5/4)) + (0/(1/4))}{4} = 1.05$$

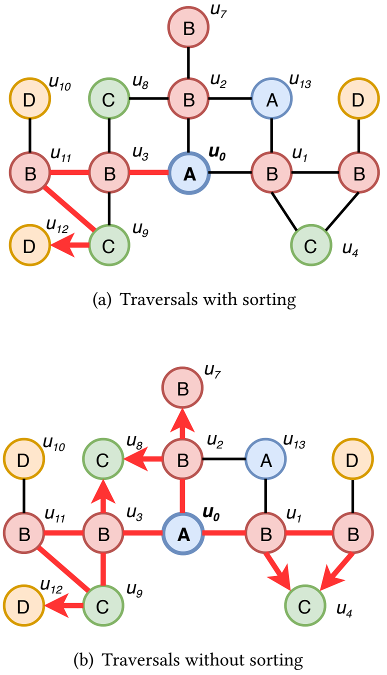
$$SS(u_3,v_1) = \frac{(1/1) + (4/3) + ((9/4)/(5/4)) + ((1/2)/(1/4))}{4} = 1.54$$

(b) Input graph G

Figure 2: (a) PSI query S, showing the neighbors signature for v_1 (b) Input graph G with satisfiability scores with regard to query node v_1

v_1). Note that a higher neighbourhood signature of label l for v_i means that v_i is connected with many nodes having label l which increases the chance for finding a match for u. As a result, the larger the satisfiability score of a graph node, the higher the chances that it satisfies a corresponding node in the PSI query. Once the satisfiability scores are calculated for all neighbors, the optimistic algorithm sorts them according to their scores and traverses those with higher scores first. The idea is to prioritize nodes with high likelihood to reach a result over other nodes with less chances, and thus the algorithm can finish faster. This step is repeated recursively by calculating the satisfiability scores of the new neighboring nodes and change paths until a match is found or all possible graph traversals are exhausted. The optimistic algorithm is useful only when used with valid nodes; i.e. nodes that match the pivot node. Otherwise, it suffers from performance degradation caused by the overhead of calculating the satisfiability scores for candidate nodes and sorting them, which is an unnecessary overhead for the case of invalid nodes.

Figure 3(a) shows an example of how the optimistic algorithm employs the satisfiability scores obtained in Figure 2(b) to reach a solution quickly. Consider evaluating the neighbors of u_0 for matching with query node v_1, the optimistic algorithm is going to traverse the graph starting from u_3, as shown in Figure 3(a), since it has the highest score ($SS(u_3) = 1.54$). As a result, the optimistic algorithm is able to find that u_0 is valid using the least number of traversals by avoiding the traversal of u_1 and u_2. A random traversal would have exhausted up to 3 different traversals from u_0, as shown in Figure 3(b), since u_1 and u_2 do not lead to an occurrence.



(a) Traversals with sorting

(b) Traversals without sorting

Figure 3: The behaviour of the optimistic algorithm starting from u_0 with (a) sorting and (b) without sorting

Algorithm 1: PSI Evaluation

```
   Input: G the input graph, S query subgraph, M Mapping, T
          Method type; Optimistic or Pessimistic
   Output: R true if a result is found, false otherwise
1  if M is full mapping then Return true
2  $v_{next}$ ←GetNextQueryNode(S)
3  C ←GetNextCandidateNodes(G, S, $v_{next}$)
4  if Super Optimistic then C ←GetLimitedCandidates(C,
   Max)
5  if T is Optimistic then C ←SortBySatisfiabilityScore(C)
6  foreach $c \in C$ do
7      if T is Pessimistic And ¬Satisfy(c, $v_{next}$) then Continue
8      $M_{new} \leftarrow M + (v_{next}, c)$
9      if ValidMapping(M) then
10         valid ←PSI(G, S, $M_{new}$, T)
11         if valid is true then Return true
12 Return false
```

Algorithm 1 shows the steps required for evaluating PSI queries. To enable the optimistic algorithm, the input flag T is set to optimistic. Note that this algorithm is recursive where it stops whenever a result is found (Line 1). The crux of the optimistic method is the sorting of graph nodes based on their satisfiability scores (Line 5). The sorting function introduces extra overhead, which might be unacceptable when evaluating nodes with high degrees. To avoid such problem and benefit from situations where a match can be quickly found, we propose a super optimistic step, where only a small portion of the neighbor nodes are checked. The difference between the "super" optimistic and the original optimistic method is in Line 4. For the super optimistic version, the number of candidates is limited by a maximum value (we use 10 in our experiments). Therefore, the overhead of sorting is significantly minimized and less intermediate graph nodes are visited. For each graph node, the optimistic approach proceeds with the super optimistic version. If a result is found, it returns that result without further processing. Otherwise, the normal optimistic method is used.

3.4 The Pessimist

In this method, we exploit aggressive pruning to quickly reach a decision. The pessimistic algorithm evaluates the label, degree and the neighborhood signature of the candidate nodes against the corresponding query node. Then, it prunes non-matching candidate nodes without carrying out further graph traversals. In comparison to a typical subgraph isomorphism evaluation, this early pruning reduces the number of intermediate results since it does not go deeper in the search plan for pruned nodes. This pruning results in a significant improvement, especially for graphs with high degree nodes. Although pruning has a notable computation price due to its excessive calculations per evaluated node, it is worth exploiting it for invalid nodes to reduce the cost of unproductive traversals. On the contrary, using this pruning for valid nodes introduces unnecessary overhead to reach the conclusion that a node is valid.

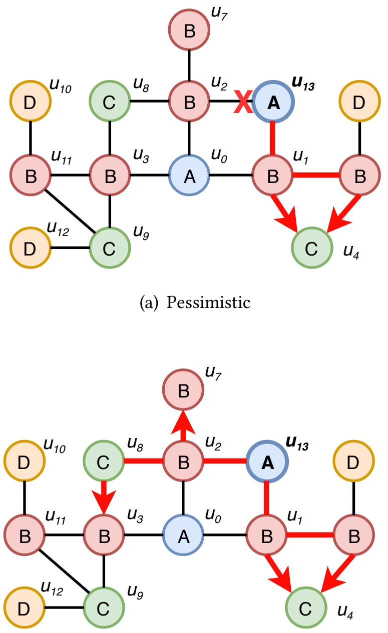
The utilization of the neighborhood signature in pruning is important since it captures wider properties of the area surrounding each graph node. Proposition 3.2 allows pruning of a node when its neighborhood signature cannot satisfy the neighborhood signature of the query node. Based on this proposition, a significant number of graph nodes are pruned but with a small number of false positive nodes (i.e., nodes that satisfy the corresponding neighborhood signature but are non-candidates because they do not match the query graph). Algorithm 1 follows the pessimistic approach by setting the flag T to Pessimistic. It is similar to the optimistic method except Line 7 which applies pruning on nodes using Proposition 3.2 and the neighborhood signature.

We show in Figure 4 the difference between the pessimistic and optimistic algorithms when evaluating an invalid node, i.e., u_{13}, against v_0 in Figure 2(a). In this example, the candidate mappings of query node v_1 are u_1 and u_2. Notice that both nodes satisfy label and direct neighbors requirements; both have label "B" and are connected to nodes labeled "B" and "C". When looking at the neighborhood signatures of both nodes, we discover that u_1 satisfies the neighborhood signature of v_1, i.e., its features have weights higher than or equal to those of the features of v_1. On the other hand, the neighborhood signature of u_2 does not satisfy that of v_1 because weights corresponding to labels "C" and "D" are both less than those for v_1. As a result, the pessimistic algorithm prunes u_2 early in the evaluation and traverse u_1 for further evaluation as shown in Figure 4(a). The optimistic algorithm, if employed, would explore both paths, u_1 and u_2, as shown in Figure 4(b).

4 THE REALIST: SMARTPSI

4.1 Two-threaded PSI Baseline

In order to benefit from the optimistic and pessimistic methods, we need to know the type of each graph node; i.e., valid or invalid, and pick the appropriate method accordingly. However, such knowledge is not available beforehand. Therefore, we propose a simple baseline, based on threading, that leverages the two algorithms for PSI evaluation. Figure 5 shows how this baseline works. For each graph node, two threads are executed concurrently. One thread runs the optimistic method while the other runs the pessimistic method. The thread that finishes its evaluation first stops the other thread and returns the result. This approach guarantees that each node is evaluated in almost the least wall-clock time of both methods (optimistic and pessimistic). However, it suffers from two issues: (*i*) under-utilization, as two threads are doing the job of a single task, and (*ii*) initiating and stopping millions of threads to evaluate the candidate graph nodes leads to a huge unnecessary cumulative overhead.



(a) Pessimistic

(b) Optimistic

Figure 4: The behaviour of (a) the pessimistic vs. (b) the optimistic algorithm starting from u_{13}

4.2 SmartPSI

This section discusses SmartPSI; our proposed PSI solution that employs machine learning techniques to avoid the limitations of the above-mentioned two-threaded baseline. We show in Figure 6 the architecture of SmartPSI which integrates the utilization of both PSI methods with two independent classification models. The first model (Model α) is a node type classifier that identifies whether a graph node is valid or invalid. Compared to the two-threaded approach, this model allows SmartPSI to benefit from the optimized PSI methods, i.e., the optimistic and the pessimistic, without sacrificing extra resources. The second classification model (Model β) is trained to predict an efficient query execution plan for each candidate node.

SmartPSI starts by loading the entire input graph in-memory, then it computes the neighborhood signatures for each graph node. When receiving a query, it extracts the candidate nodes from the input graph. A small percentage of the candidate nodes (around 10% up to a maximum value) is randomly selected to train

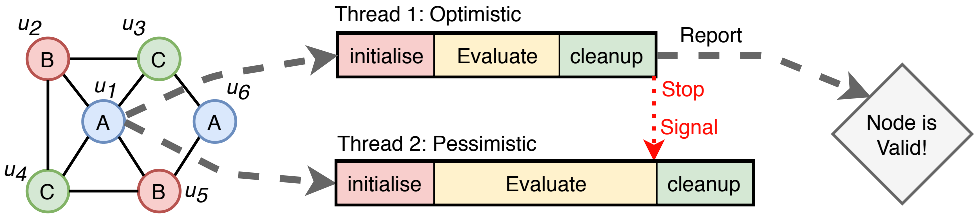


Figure 5: The two-threaded PSI solution

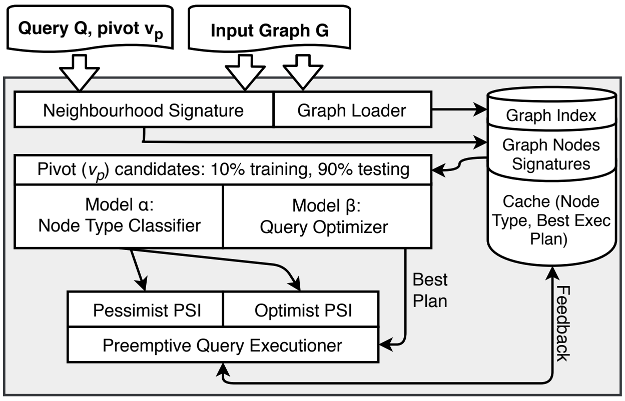

Figure 6: SmartPSI System Architecture

both models (α and β) using the Random Forest classification algorithm [10]. Our empirical evaluation shows that using this simple classifier is effective since it provides both a lightweight training time as well as a decent prediction accuracy (see Section 5.4). However, utilizing other machine learning classifiers; e.g. Neural Networks or Support Vector Machines, is orthogonal to our work. The remaining candidate nodes are passed to the trained models to predict their types and evaluation plans based on their neighborhood signatures. SmartPSI uses these predictions to evaluate each node against the query and the result of this evaluation is cached for future use. In the rest of this section, we describe in more details each one of these steps.

4.2.1 *Predicting the Node Type (Model α).*

Correctly predicting the candidate node type (as *valid* or *invalid*) helps SmartPSI to decide the node's most efficient graph matching method (optimistic or pessimistic). Valid nodes are best evaluated using the optimistic algorithm while the pessimistic algorithm is much better at evaluating invalid nodes. To select the best method for each graph node, we utilize a binary classification model to predict the node's type (class) based on its neighborhood signature, and accordingly decide which method to use for evaluation.

Training: The neighborhood signature of each graph node is used to build the feature vectors for our classifier. Each label in the neighborhood signature represents a feature and the value associated with this label in the signature is considered as the feature's weight. Each training node is evaluated using the pessimistic method and is labeled based on its confirmed type. The pessimistic method is used during model training since, on average, it is more stable and performs better than the optimistic method.

Prediction: For the remaining graph nodes, the trained model is used to predict the node type, either valid or invalid. Nodes predicted as valid are passed to the optimistic method while invalid nodes are given to the pessimistic method.

4.2.2 *Predicting an Optimal Plan (Model β).*

Selecting the order in which query nodes are evaluated is important for efficient evaluation. A bad order results in an excessive number of intermediate results and consequently poor performance. Existing techniques [17, 18, 30] employ heuristic approaches to prioritize the evaluation of query nodes that have higher selectivity. However, these approaches may not consistently provide good performance since their proposed plans are not adapted to the local features of each graph node. We describe next how SmartPSI trains a classifier to predict an efficient locality-aware query plan for each graph node based on its neighborhood signature.

Training: Model β is a *multi-class* classifier; its training phase uses the same set of graph nodes used for model α. For each query, a set of plans are generated and evaluated for each training node u_t. The plan that results in the least time is selected as the optimal plan for u_t. This plan is considered the class of u_t and is fed along with u_t feature vector to the multi-class classifier.

The training time can be very large especially for big queries with a considerably large number of possible plans. For example, a subgraph with 6 nodes can have up to 6! (or 720) plans. It is not practical and very expensive to evaluate all these plans. To mitigate this problem, we only train using a small sample of these plans to minimize the training time. Furthermore, we avoid evaluating very expensive plans by enforcing a configurable time limit when evaluating each one of the sample plans. We first set the time limit to a relatively small value. Evaluations of subsequent plans are not allowed to exceed that time limit. If no plan is able to finish within the allotted time, the time limit is gradually increased. This process repeats until at least one plan can finish within the time limit.

Prediction: For each remaining candidate node, SmartPSI uses the created model β to predict a good query execution plan based on its neighborhood signature. Then, this plan is fed to the corresponding PSI method for evaluation.

4.2.3 *Prediction Caching.*

As shown in Figure 6, correct predictions of both models are cached to improve the run-time performance of SmartPSI. The cache module stores the node signature of already evaluated nodes. Upon checking next candidate nodes, SmartPSI checks if a similar node has been evaluated before. If exists, the PSI evaluation model and execution plan decisions are looked up from the cache without consulting the classifiers. Using caching improves the efficiency of SmartPSI since the time needed to consult the prediction model and possible wrong predictions are avoided. This is because nodes having the same neighborhood signature are deemed similar since they have similar graph structures around them. Thus, they are expected to have the same optimal method and execution plan.

4.3 Preemptive Query Execution

As in any classifier, the trained model may result in incorrect predictions. In our case, there are two types of prediction errors; incorrect plan prediction and incorrect node type prediction. SmartPSI, however, employs a *detection and recovery* technique to minimize the impact of wrong predictions. As shown in Figure 6, the preemptive query processor monitors the evaluation of a node u_i and an incorrect prediction is detected if the time of this evaluation exceeds a maximum value. We calculate this value as follows:

$$MaxTime(u_i) = 2 \times AvgT(PSIMethod(u_i), Plan(u_i))$$

$PSIMethod(u_i)$ returns the used PSI method for u_i while $Plan(u_i)$ is the currently used plan. Note that $AvgT(X, Y)$ returns the average time needed for the selected PSI method X and plan Y during the training phase. To be able to recover from bad predictions, the query processor goes through three states; (*i*) it evaluates candidate nodes using predicted plan and PSI method with a time limit. If the execution timed-out, (*ii*) the processor uses the opposite PSI method and restarts the evaluation with a time limit. This step overcomes wrong predictions in the first model (Model α). If the execution timed-out again, (*iii*) the processor restarts the node evaluation, without time limits, by using the original predicted PSI method with a standard execution plan generated by selectivity-based heuristics. This step uses a best guess for the execution plan because Model β was not able to provide a credible suggestion. Since the accuracy of our classification models is high (as we show later in Section 5.4), the majority of candidate nodes should be able to finish before hitting the first timeout.

5 EVALUATION

In this section, we experimentally evaluate the performance of SmartPSI and compare it against existing competitors using several real large-scale datasets. Specifically, we show the following: (*i*) SmartPSI significantly outperforms the state-of-the-art subgraph isomorphism solutions for solving PSI queries (Section 5.2). (*ii*) Our proposed optimizations provide significant improvements including the optimized matrix-based signature generation and the proposed machine-learning approach compared to optimistic-only, pessimistic-only and the two-threaded baseline search techniques (Section 5.3). (*iii*) Our machine-learning model achieves both high accuracy and minimal run-time overhead (Section 5.4). Finally, (*iv*) we show a significant improvement in the efficiency of ScaleMine [4]; the state-of-the-art distributed frequent subgraph mining system; when subgraph isomorphism is replaced by pivoted subgraph isomorphism (Section 5.5).

5.1 Experimental setup

Datasets: We use six real graphs to evaluate the performance of SmartPSI and compare it to existing techniques. These graphs are widely used in the subgraph isomorphism and frequent subgraph mining literature [4, 9, 17]. Table 3 shows the details of each dataset. *Yeast* [8] and *Human* [26] are protein-protein interaction networks where nodes represent proteins and edges represent the interactions among them. *Cora* [1] is a citation graph where each node represents a publication with a label representing a machine learning area. In the *YouTube* [3] graph, each node represents a YouTube video and is labeled with its category, while edges connect similar videos. *Twitter* [2] models the Twitter social network where each node represents a user and edges represent follower-followee relationships. The original Twitter graph is unlabeled, we follow the same approach used in [4] to assign node labels. Finally, *Weibo* [40] is a social network crawled from Sina Weibo micro-blogging website. Each node represents a user and is labeled with the city that user lives in, while each edge represents a follower-followee relationship.

Table 3: Datasets and their characteristics

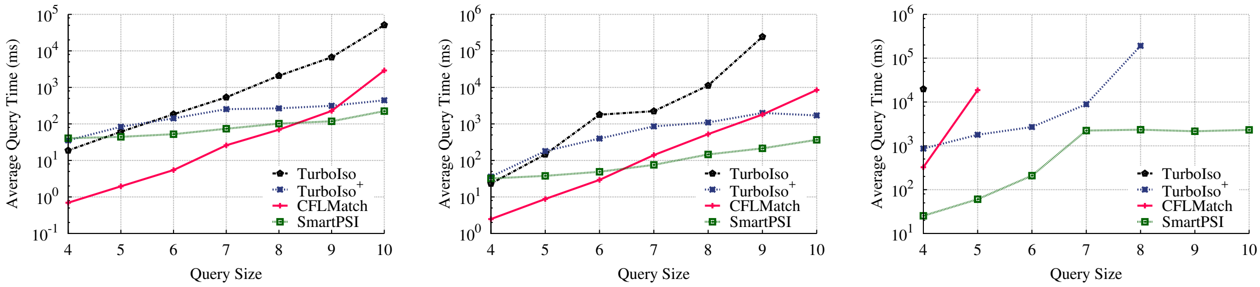
Dataset	Nodes	Edges	#node labels
Yeast [8]	3,112	12,519	71
Cora [1]	2,708	5,429	7
Human [26]	4,674	86,282	44
Youtube [3]	5,101,938	42,546,295	25
Twitter [2]	11,316,811	85,331,846	25
Weibo [40]	1,655,678	369,438,063	55

Query Graphs: From each input graph, we extract a set of random connected subgraphs as query graphs. Then, a random node is assigned as a pivot node for each query. Similar to the related work in [9, 17], a random walk with restart algorithm is used to extract 1000 query graphs for each size. Query sizes range from four to ten nodes. The resulted queries span a wide range of query complexities including paths, trees, stars and other complex shapes. Thus, they cover query loads for a wide variety of PSI applications. Unless stated otherwise, in all experiment, we use 1000 queries per query size.

Hardware Setup: SmartPSI and its competitors are deployed on a single Linux machine with 148GB RAM and two 2.1GHz AMD Opteron 6172 CPUs, each with 12 cores. We also use a distributed hardware setting for deploying ScaleMine [4] and its PSI version. In particular, we conduct ScaleMine experiments (see Section 5.5) on a Cray XC40 supercomputer which has 6,174 dual sockets compute nodes based on 16 cores Intel processors running at 2.3GHz with 128GB of RAM. We used up to 32 compute nodes with a total of 1024 cores. In all experiments, the maximum allowed time is 24 hours, any task which exceeds this limit is aborted.

5.2 Comparison with Existing Systems

SmartPSI is evaluated against three state-of-the-art subgraph isomorphism solutions: (*i*) CFL-Match [9]; the fastest reported subgraph isomorphism solution, (*ii*) TurboIso [17]; a recent subgraph ismorphism system that utilizes the query structure to combine the evaluation of similar parts of the query in a single task. and (*iii*) TurboIso$^+$; a modified version of TurboIso. Since TurboIso is a subgraph isomorphism algorithm, it finds all matches of a given query regardless of the pivot node. To optimize the performance for PSI queries, we configured TurboIso$^+$ to start evaluating the given queries using candidate matches of the pivot nodes and stop the evaluation once a pivot node match is found. Since the source code of CFL-Match is not publicly available, we could not follow a similar approach to provide a modified version of CFL-Match that is optimized for PSI queries. We also tried to



(a) Yeast Dataset (b) Cora Dataset (c) Human Dataset

Figure 7: Query Performance of SmartPSI vs. state-of-the-art Subgraph Isomorphism Systems

compare against TurboIso-Boost [30]; however, similar to what mentioned in [9], we encountered several run-time problems and we could not resolve them even after communicating with the authors. Thus, we had to omit its results. Notice that SmartPSI and all its competitors are single-machine in-memory systems. Moreover, for each input graph, we use a maximum of 1000 nodes to train the classification models in SmartPSI.

This experiment shows how available solutions (i.e., subgraph isomorphism techniques) perform when solving pivoted subgraph isomorphism queries in comparison to SmartPSI. In order to evaluate PSI queries, these algorithms use subgraph isomorphism to find all matches, then generates the list of distinct graph nodes that correspond to the pivot query node. Figure 7 shows the results on Yeast, Cora and Human datasets. The x-axis shows the query size (in number of nodes) and the y-axis shows the processing time. For Yeast (Figure 7(a)), subgraph isomorphism is a comparably easy task since this dataset is relatively small. As a result, existing techniques outperform SmartPSI on queries of size four. As the query size increases, subgraph isomorphism techniques become slower than SmartPSI. The optimizations proposed by CFLMatch allows it to outperform other systems up to queries of size 8, however, SmartPSI starts gaining momentum and becomes the fastest for larger queries. Notice that TurboIso$^+$ is significantly faster than TurboIso due to its optimization step, however, it is still slower than SmartPSI on larger queries.

For Cora dataset (Figure 7(b)), SmartPSI significantly outperforms other systems with up to two orders of magnitude. CFLMatch's optimizations worked well for small queries; it is the fastest for queries of size 4, 5 and 6. As the query size grows, similar to the Yeast dataset, CFLMatch generates huge amounts of intermediate query matches and becomes worse than SmartPSI. For queries with size 10, TurboIso fails to finish query evaluation within 24 hours. Finally for Human dataset (Figure 7(c)), both TurboIso and CFLMatch fail to evaluate most of the queries as this dataset is significantly larger and denser. TurboIso$^+$ could only complete its evaluation for queries of size up to 8. Compared to all systems, SmartPSI is able to evaluate all queries on the Human dataset with performance improvements of up to two orders of magnitude. This experiment highlights the unsuitability of the state-of-the-art subgraph isomorphism solutions to solve PSI queries even for small graphs. It also shows SmartPSI's significant improvements over the existing solutions.

5.3 SmartPSI Optimizations

Neighborhood Signature Overhead: Figure 8 compares between the matrix-based and exploration-based methods in terms of the total time for populating the neighborhood signatures (see Section 3.1). As shown in Figure 8, the processing time of both methods increases as the input graph gets larger. Exploration-based method, however, suffers from being computationally expensive especially for large datasets. For Twitter, exploration-based could not finish generating the nodes' neighborhood signatures within 24 hours. On the other hand, the matrix-based method reduces the overhead of exploration-based method significantly. It requires around 400 seconds, which is more than two orders of magnitude faster than the exploration-based method. This significant improvement is a direct result of the difference in complexities between the two methods.

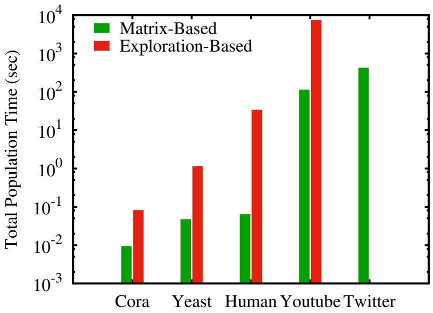


Figure 8: Exploration vs. Matrix Based Approach for Populating Neighborhood Signatures of various datasets.

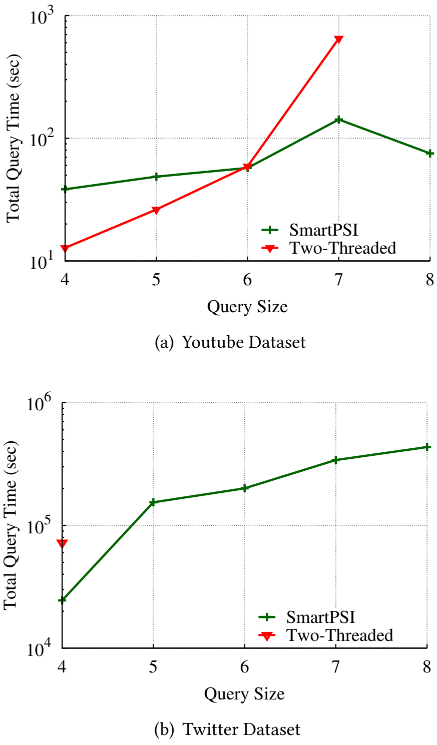
SmartPSI vs. the two-threaded baseline: Figure 9 shows the run-time overhead of evaluating 100 queries on SmartPSI compared to the two-threaded solution using YouTube and Twitter datasets. The X-axis shows the query size in terms of number of nodes, while the Y-axis shows the total time to evaluate the corresponding queries. Only 100 queries are used since evaluating 1000 queries takes too much time for the two threaded approach. Since the two-threaded baseline utilizes two parallel threads, for a fair comparison, only in this experiment we run a modified version of SmartPSI that uses two concurrent threads to evaluate two different graph nodes in parallel. Using YouTube datatset, Figure 9(a) shows that the two-threaded baseline outperforms SmartPSI for small queries because it does not possess the overhead of training and prediction. Nevertheless, the two-threaded solution becomes slower than SmartPSI as queries grow in size till it exceeds the time limit on queries larger than 7 nodes. This is also true for Twitter dataset in Figure 9(b), where the two-threaded baseline can only evaluate queries of size 4. SmartPSI



(a) Youtube Dataset

(b) Twitter Dataset

Figure 9: SmartPSI (2 threads) vs. two-threaded Baseline

has an upper hand since the two-threaded baseline underutilizes the available resources by using two threads to finish a task that can be conducted by one thread. Moreover, the heuristic-based query execution plans, which are used in the two-threaded solution, are far less competent than the optimized plans of SmartPSI.

SmartPSI vs. optimistic and pessimistic: Figure 10 compares SmartPSI against *Pessimistic*-only and *Optimistic*-only using 10 queries for each query size on the Twitter dataset. In particular, the Pessimistic solution uses the pessimistic PSI method regardless of the type of the graph node. Likewise, Optimistic solution always use the optimistic PSI method. Moreover, the *Pessimistic* and *Optimistic* solutions use a heuristic-based query evaluation plan. SmartPSI significantly outperforms the optimistic and pessimistic methods. Furthermore, the two competitors fail to evaluate queries of size eight. The node type prediction in SmartPSI allows it to avoid exploring the full search space (compared to *Pessimistic*) and to reduce the overhead of calculating scores and sorting graph nodes accordingly (compared to *Optimistic*). Moreover, SmartPSI is able to predict the best evaluation plan for the candidate nodes, which is not achievable for the other two solutions.

5.4 Prediction Accuracy and Training Overhead

Machine Learning Models: We tested several machine learning models to build SmartPSI's classifier including Random Forest (RF), Support Vector Machines (SVM) and Neural Networks (NN). In our experiments, we found that the RF classifier provides the best accuracy. For example, it always achieves more than 95% accuracy on Human dataset compared to SVM (90%) and NN (92%). At the same time, RF is two times faster in building the model and getting predictions. We also observed similar performance results for the other datasets. Therefore, we use RF as it provides consistently good performance in terms of accuracy and training time.

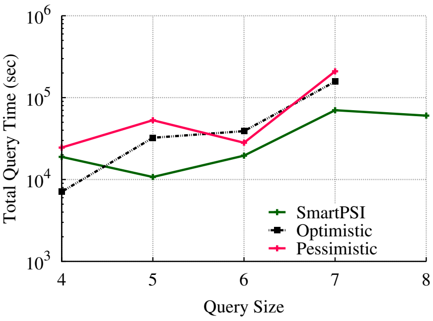


Figure 10: SmartPSI vs. Optimistic and Pessimistic on Twitter Dataset

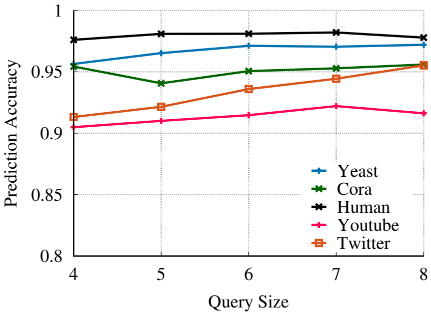

Figure 11: Prediction Accuracy

Model accuracy: We conducted a set of experiments to measure the prediction accuracy of the node type prediction model using Yeast, Human, Cora, YouTube and Twitter datasets. Accuracy is calculated by comparing the result of the model's prediction to the ground truth result obtained by node evaluation using subgraph isomorphism, i.e., the number of correctly predicted node types divided by the total number of examined nodes. Figure 11 shows that the prediction accuracy of the proposed classification model is always higher than 90% for the used datasets. Furthermore, it also shows that prediction accuracy is effective and stable where the variation in predictions quality among the different datasets is small regardless of the query size.

Training overhead: Table 4 shows the overhead of models training/prediction compared to the total query evaluation time. This overhead includes model building, node type prediction and suggesting a good execution plan. In this experiment, we ran 100 queries per query size for each dataset. For small datasets and queries, the training overhead is relatively large compared to the total time. For example in Human dataset, the prediction overhead exceeds the PSI evaluation time for small queries. The reason is that query evaluation on small graphs is usually comparably fast. For larger query sizes in Human dataset, PSI evaluation becomes more expensive which reduces the relative overhead of the classification model. For larger datasets; e.g., YouTube and Twitter, the training time is very insignificant compared to PSI evaluation time. This shows that high accuracy of our classification model comes at a low computation cost, especially on large graphs.

Table 4: The overhead of model training and prediction to the total time of SmartPSI

Dataset	4	5	6	7	8
Human	75.41%	57.94%	50.85%	34.88%	33.05%
YouTube	1.13%	1.19%	1.20%	1.79%	2.83%
Twitter	1.98%	5.33%	20.15%	2.35%	5.19%

5.5 PSI Application: Frequent Subgraph Mining

This experiment highlights the advantage of using SmartPSI to boost the efficiency of an example PSI-dependent application; Frequent Subgraph Mining (FSM). For this experiment, we use ScaleMine[1] [4]; the state-of-the-art distributed FSM system. Note that ScaleMine uses subgraph isomorphism for finding occurrences for each candidate subgraph. We implemented ScaleMine+SmartPSI, a variation of ScaleMine that employs SmartPSI's techniques instead of the traditional subgraph isomorphism for computing the frequency of each candidate subgraph. Figures 12(a) and 12(b) show the performance of ScaleMine compared to the optimized version, ScaleMine+SmartPSI, using Twitter and Weibo datasets on frequency thresholds of 155K and 460K, respectively. The X-axis shows the total number of compute nodes while the Y-axis shows the overall time required to finish the mining task. For the Weibo dataset, the maximum size of allowed frequent subgraphs is set to six edges. In this experiment, ScaleMine+SmartPSI outperforms ScaleMine significantly for both datasets. For Twitter, ScaleMine+SmartPSI is up to 5X faster than ScaleMine. As for Weibo, ScaleMine+SmartPSI is up to 6X faster. By replacing the traditional subgraph isomorphism, ScaleMine+SmartPSI generates significantly less intermediate results and quickly reaches the final answer.

6 RELATED WORK

6.1 Subgraph Isomorphism

Subgraph isomorphism is the bottleneck of many graph operations since it is an NP-complete problem. Therefore, many research efforts attempted to reduce its overhead in practice. The first practical algorithm that addresses this problem follows a backtracking approach [35]. Since then, several performance enhancements were proposed, ranging from CSP-based techniques [29], search order optimization [18], indexing [38] and parallelization [33]. As reported in [26], GraphQL [18] is considered one of the best subgraph isomorphism techniques, though its performance is not stable over the different datasets. GraphQL prunes the search space by using local and global graph information. Moreover, it utilizes a search order optimization technique based on a global cost model.

TurboIso [17] is a recent approach that outperforms previous techniques by grouping similar parts of the query and process them at once. Moreover, TurboIso adapts its search order plan according to each input graph node. BoostIso [30] is a plugin that enhances the efficiency of other approaches. It is able to avoid duplicate computations by exploiting the relationship among the input graph nodes. CFLMatch [9] is the current state-of-the-art technique for subgraph isomorphism. It decomposes the query graph into a core and multiple trees. Such decomposition allows better search order optimization. Moreover, CFLMatch avoids redundant evaluations of tree leaf nodes by representing the mappings of these nodes in a compressed way. Although these techniques lead to relatively significant improvements in the domain of subgraph isomorphism, the algorithm itself is impractical especially for large graphs. The main reason behind this limitation of subgraph isomorphism is the excessive number of results it generates.

The closest approach to our work is Ψ-framework [22]. It utilizes both isomorphic query re-writings and existing alternative algorithms in parallel to improve the performance of subgraph isomorphism. Ψ-framework is similar to our two-threaded prototype (Section 4.1) where it requires more processing power to achieve a reasonable performance. Unlike SmartPSI, Ψ-framework is unable to decide on which approach is better to use during runtime.

6.2 Neighborhood Signature

A graph node can be represented by a signature that reflects the neighborhood structures around it. This neighborhood signature can be represented as a feature vector and used in many important applications such as abnormal nodes detection [6] and predicting missing links [27].

Neighborhood signatures are also used for indexing and pruning. GADDI [41] is a subgraph matching solution that builds an index based on graph structures that exist between any pair of vertices. Based on this index,a two way pruning technique is used to efficiently prune candidate matches. GADDI suffers from the excessive cost required for creating its index. NOVA [43] and DSI [24] maintain the paths to and from surrounding nodes. These paths are used to filter out unqualified graph nodes. Both Nova and DSI rely on maintaining a huge number of paths. As such, both technique comprise excessive overhead, especially

[1] https://github.com/ehab-abdelhamid/ScaleMine

when processing large-scale dense graphs. (NNT) [36] is a more effective index that relies on finding the trees around each graph node. NNT requires the use of tree matching algorithms which makes pruning and matching more complex.

The above approaches are expensive, especially for large-scale dense graphs. Other simpler indexes were proposed such as SMS [42] which maintains the list of labels and node degrees that appear in the neighborhood. Although this indexing technique is simple, it significantly outperforms NOVA and GADDI. Tale [34] is a system that finds approximate matches of query subgraphs in an input graph. It relies on an index, called NH-Index, which maintains information about the direct neighbors of each graph node. NH-Index maintains information such as node label, node degree, neighbor nodes and how they are connected. Both SMS and Tale focus on the direct neighbors. Thus, their pruning and descriptive power is limited. More recently, k-hop label [7] extends its indexing by considering all neighbor nodes within K-hops. Such representation extends beyond direct neighbors, but it lacks effective representation of the surrounding structure. Finally, label propagation [23] captures the neighborhood structure around each graph node using a list of labels along with their corresponding weights. Weights represent how labels are placed and connected around the node under consideration. Thus, more informative structural information is captured.

7 CONCLUSION

In this paper, we propose SmartPSI; an efficient machine-learning based system for evaluating Pivoted Subgraph Isomorphism (PSI) queries. It is based on two effective PSI algorithms; each is optimized for a certain graph node type. SmartPSI is also coupled with a machine-learning model to predict the graph node type and call the appropriate PSI algorithm accordingly. It also uses a machine-learning based query optimizer to select execution plans that reduce the total query run-time by minimizing intermediate query results. Our experiments show that SmartPSI is efficient and able to scale PSI evaluation where it is up to two orders of magnitude faster compared to existing subgraph isomorphism techniques. Furthermore, when applied to Frequent Subgraph Mining (FSM), PSI improves the performance of the state-of-the-art distributed FSM system by up to a factor of 6X.

ABSTRACT

Entity Resolution (ER) aims to identify different descriptions in various Knowledge Bases (KBs) that refer to the same entity. ER is challenged by the *Variety*, *Volume* and *Veracity* of entity descriptions published in the Web of Data. To address them, we propose the MinoanER framework that simultaneously fulfills *full automation*, support of *highly heterogeneous* entities, and *massive parallelization* of the ER process. MinoanER leverages a token-based similarity of entities to define a new metric that derives the similarity of neighboring entities from the most important relations, as they are indicated only by statistics. A *composite blocking method* is employed to capture different sources of matching evidence from the content, neighbors, or names of entities. The search space of candidate pairs for comparison is compactly abstracted by a novel *disjunctive blocking graph* and processed by a non-iterative, massively parallel matching algorithm that consists of four generic, schema-agnostic matching rules that are quite robust with respect to their internal configuration. We demonstrate that the effectiveness of MinoanER is comparable to existing ER tools over real KBs exhibiting *low Variety*, but it outperforms them significantly when matching KBs with *high Variety*.

1 INTRODUCTION

Even when data integrated from multiple sources refer to the same real-world entities (e.g., persons, places), they usually exhibit several quality issues such as *incompleteness* (i.e., partial data), *redundancy* (i.e., overlapping data), *inconsistency* (i.e., conflicting data) or simply *incorrectness* (i.e., data errors). A typical task for improving various data quality aspects is *Entity Resolution* (ER). In the Web of Data, ER aims to facilitate interlinking of data that describe the same real-world entity, when unique entity identifiers are not shared across different Knowledge Bases (KBs) describing them [8]. To resolve entity descriptions we need (a) *to compute effectively the similarity of entities*, and (b) *to pair-wise compare entity descriptions*. Both problems are challenged by the three Vs of the Web of Data, namely Variety, Volume and Veracity [10]. Not only does the *number of entity descriptions* published by each KB never cease to increase, but also the *number of KBs* even for a single domain, has grown to thousands (e.g., there is a x100 growth of the LOD cloud size since its first edition[1]). Even in the same domain, KBs are *extremely heterogeneous* both regarding how they semantically structure their data, as well as how diverse properties are used to describe even substantially similar entities (e.g., only 109 out of ~2,600 LOD vocabularies are shared by more than one KB). Finally, KBs are of *widely differing quality*, with significant differences in the coverage, accuracy and timeliness of data provided [9]. Even in the same domain, various inconsistencies and errors in entity descriptions may arise, due to the limitations of the automatic extraction tools [34], or of the crowd-sourced contributions.

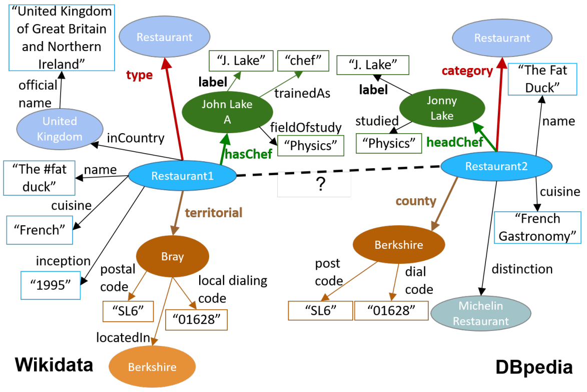

Figure 1: Parts of entity graphs, representing the Wikidata (left) and DBpedia (right) KBs.

The Web of Data essentially calls for novel ER solutions that relax a number of assumptions underlying state-of-the-art methods. The most important one is related to the notion of similarity that better characterizes *entity descriptions* in the Web of Data - we define an entity description to be a URI-identifiable set of attribute-value pairs, where values can be literals, or the URIs of other descriptions, this way forming an *entity graph*. Clearly, Variety results in extreme *schema heterogeneity*, with an unprecedented number of attribute names that cannot be unified under a global schema [15]. This situation renders all schema-based similarity measures that compare specific attribute values inapplicable [15]. We thus argue that similarity evidence of entities within and across KBs can be obtained by looking at the bag of strings contained in descriptions, regardless of the corresponding attributes. As this **value-based similarity** of entity pairs may still be weak, due to a highly heterogeneous description content, we need to consider additional sources of matching evidence; for instance, the **similarity of neighboring entities**, which are interlinked via various semantic relations.

Figure 1 presents parts of the Wikidata and DBpedia KBs, showing the entity graph that captures connections inside them. For example, Restaurant2 and Jonny Lake are neighbor entities in this graph, connected via a "headChef" relation. If we compare John Lake A to Jonny Lake based on their values only, it is easy

*Work conducted during the Ph.D research of the author at ICS-FORTH.

Series ISSN: 2367-2005

10.5441/002/edbt.2019.33

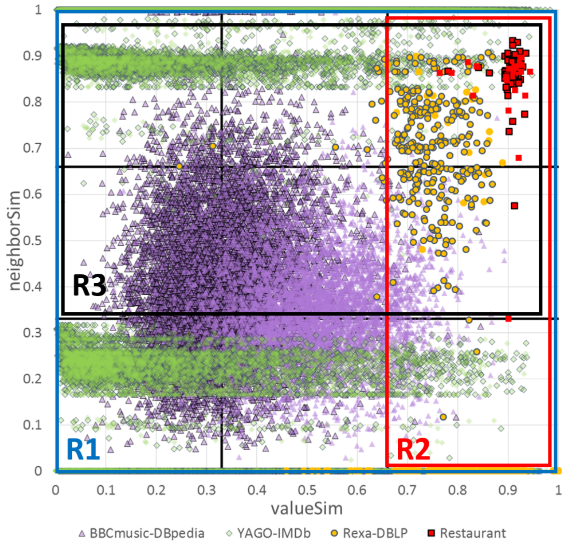

Figure 2: Value and neighbor similarity distribution of matches in 4 datasets (see Table 1 for more details).

to infer that those descriptions are matching; they are *strongly similar*. However, we cannot be that sure about Restaurant1 and Restaurant2, if we only look at their values. Those descriptions are *nearly similar* and we have to look further at the similarity of their neighbors (e.g, John Lake A and Jonny Lake) to verify that they match.

Figure 2 depicts both sources of similarity evidence (*valueSim*, *neighborSim*) for entities known to match (i.e., ground truth) in four benchmark datasets that are frequently used in the literature (details in Table 1). Every dot corresponds to a matching pair of entities, and its shape denotes its origin KBs. The horizontal axis reports the normalized value similarity (weighted Jaccard coefficient [21]) based on the tokens (i.e., single words in attribute values) shared by a pair of descriptions, while the vertical one reports the maximum value similarity of their neighbors. The value similarity of matching entities significantly varies across different KBs. For **strongly similar entities**, e.g., with a value similarity > 0.5, existing duplicate detection techniques work well. However, a large part of the matching pairs of entities is covered by **nearly similar entities**, e.g., with a value similarity < 0.5. To resolve them, we need to additionally exploit evidence regarding the similarity of neighboring entities.

This also requires revisiting the blocking (aka indexing) techniques used to reduce the number of candidate pairs [7]. To avoid restricting candidate matches (i.e., descriptions placed on the same block) to strongly similar entities, we need to assess both *value* and *neighbor* similarity of candidate matches. In essence, rather than a unique indexing function, we need to consider a *composite blocking* that provides matching evidence from different sources, such as the content, the neighbors or even the names (e.g., `rdfs:label`) of entities. Creating massively parallelizable techniques for processing the search space of candidate pairs formed by such composite blocking is an open research challenge.

Overall, the main requirements for Web-scale ER are: *(i)* identify both strongly and nearly similar matches, *(ii)* do not rely on a given schema, *(iii)* do not rely on domain experts for aligning relations and matching rules, *(iv)* develop non-iterative solutions to avoid late convergence, and *(v)* scale to massive volumes of data. None of the existing ER frameworks proposed for the Web of Data (e.g., LINDA [4], SiGMa [21] and RiMOM [31]) simultaneously fulfills all these requirements. In this work, we present the MinoanER framework for a Web-scale ER[2]. More precisely, we make the following contributions:

• We leverage a token-based similarity of entity descriptions, introduced in [27], to define a new metric for the similarity of a set of neighboring entity pairs that are linked via important relations to the entities of a candidate pair. Rather than requiring an *a priori* knowledge of the entity types or of their correspondences, we rely on *simple statistics over two KBs to recognize the most important entity relations* involved in their neighborhood, as well as, *the most distinctive attributes that could serve as names of entities* beyond the `rdfs:label`, which is not always available in descriptions.

• We exploit several indexing functions to place entity descriptions in the same block either because they share a common token in their values, or they share a common name. Then, we introduce a novel abstraction of multiple sources of matching evidence regarding a pair of entities (from the content, neighbors, or the names of their descriptions) under the form of a *disjunctive blocking graph*. We present an efficient algorithm for weighting and then pruning the edges with low weights, which are unlikely to correspond to matches. As opposed to existing disjunctive blocking schemes [3, 18], *our disjunctive blocking is schema-agnostic and requires no (semi-)supervised learning*.

• We propose a *non-iterative matching process* that is implemented in Spark [36]. Unlike the data-driven convergence of existing systems (e.g., LINDA [4], SiGMa [21], RiMOM [31]), the matching process of MinoanER involves a specific number of predefined generic, schema-agnostic matching rules (R1-R4) that traverse the blocking graph. First, we identify matches based on their name (R1). This is a very effective method that can be applied to all descriptions, regardless of their values or neighbor similarity. Unlike the schema-based blocking keys of relational descriptions usually provided by domain experts, *MinoanER automatically specifies distinctive names of entities from data statistics*. Then, the value similarity is exploited to find matches with many common and infrequent tokens, i.e., strongly similar matches (R2). When value similarity is not high, nearly similar matches are identified based on both value and neighbors' similarity using a *threshold-free rank aggregation function* (R3), as opposed to existing works that combine different matching evidence into an aggregated score. Finally, *reciprocal evidence* of matching is exploited as a verification of the returned results: only entities that are mutually ranked in the top positions of their unified ranking lists are considered matches (R4). Figure 2 abstractly illustrates the type of matching pairs that are covered by each matching rule.

• We experimentally compare the effectiveness of MinoanER against state-of-the-art methods using established benchmark data that involve real KBs. The main conclusion drawn from our experiments is that MinoanER achieves at least equivalent performance over KBs exhibiting a *low Variety* (e.g., those originating from a common data source like Wikipedia) even though the latter make more assumptions about the input KBs (e.g., alignment of relations); yet, MinoanER significantly outperforms state-of-the-art ER tools when matching KBs with high Variety. The source code and datasets used in our experimental study are publicly available[3].

The rest of the paper is structured as follows: we introduce our value and neighbor similarities in Section 2, and we delve into the

[2] A preliminary, abridged version of this paper appeared in [13].

[3] http://csd.uoc.gr/~vefthym/minoanER

blocking schemes and the blocking graph that lie at the core of our approach in Section 3. Section 4 describes the matching rules of our approach along with their implementation in Spark, while Section 5 overviews the main differences with the state-of-the-art ER methods. We present our thorough experimental analysis in Section 6 and we conclude the paper in Section 7.

2 BASIC DEFINITIONS

Given a KB $\mathcal{E}$, an entity description with a URI identifier i, denoted by $e_i \in \mathcal{E}$, is a set of attribute-value pairs about a real-world entity. When the identifier of an entity description e_j appears in the values of another entity description e_i, the corresponding attribute is called a *relation* and the corresponding value (e_j) a *neighbor* of e_i. More formally, the relations of e_i are defined as $relations(e_i) = \{p|(p,j) \in e_i \wedge e_j \in \mathcal{E}\}$, while its neighbors as $neighbors(e_i) = \{e_j|(p,j) \in e_i \wedge e_j \in \mathcal{E}\}$. For example, for the Wikidata KB in the left side of Figure 1 we have: $relations(Restaurant1) = \{$hasChef, territorial, inCountry$\}$, and $neighbors(Restaurant1) = \{$John Lake A, Bray, United Kingdom$\}$.

In the following, we exclusively consider clean-clean ER, i.e., the sub-problem of ER that seeks matches among two duplicate-free (clean) KBs. Thus, we simplify the presentation of our approach, but the proposed techniques can be easily generalized to more than two clean KBs or a single dirty KB, i.e., a KB that contains duplicates.

2.1 Entity similarity based on values

Traditionally, similarity between entities is computed based on their values. In our work, we apply a similarity measure based on the number and the frequency of common words between two values[4].

Definition 2.1. Given two KBs, $\mathcal{E}_1$ and $\mathcal{E}_2$, the **value similarity** of two entity descriptions $e_i \in \mathcal{E}_1, e_j \in \mathcal{E}_2$ is defined as: $valueSim(e_i,e_j)= \sum_{t \in tokens(e_i) \cap tokens(e_j)} \frac{1}{log_2(EF_{\mathcal{E}_1}(t) \cdot EF_{\mathcal{E}_2}(t)+1)}$, where $EF_{\mathcal{E}}(t) = |\{e_l|e_l \in \mathcal{E} \wedge t \in tokens(e_l)\}|$ stands for "Entity Frequency", which is the number of entity descriptions in $\mathcal{E}$ having token t in their values.

This value similarity shares the same intuition as TF-IDF in information retrieval. If two entities share many, infrequent tokens, then they have high value similarity. On the contrary, very frequent words (resembling stopwords in information retrieval) are not considered an important matching evidence, when they are shared by two descriptions, and therefore, they only contribute insignificantly to the $valueSim$ score. The number of common words is accounted by the number of terms that are considered in the sum and the frequency of those words is given by the inverse Entity Frequency (EF), similar to the inverse Document Frequency (DF) in information retrieval.

Proposition 1. $valueSim$ is a *similarity metric*, since it satisfies the following properties [5]:

- $valueSim(e_i,e_i) \geq 0$,
- $valueSim(e_i,e_j) = valueSim(e_j,e_i)$,
- $valueSim(e_i,e_i) \geq valueSim(e_i,e_j)$,
- $valueSim(e_i,e_i) = valueSim(e_j,e_j) = valueSim(e_i,e_j) \Leftrightarrow e_i{=}e_j$,
- $valueSim(e_i,e_j) + valueSim(e_j,e_z) \leq valueSim(e_i,e_z) + valueSim(e_j,e_j)$.

PROOF. Please refer to the extended version of this paper[5]. □

Note that $valueSim$ has the following properties: *(i)* it is not a normalized metric, since it can take any value in $[0,+\infty)$, with 0 denoting the existence of no common tokens in the values of the compared descriptions. *(ii)* The maximum contribution of a single common token between two descriptions is 1, in case this common token does not appear in the values of any other entity description, i.e., when $EF_{\mathcal{E}_1}(t) \cdot EF_{\mathcal{E}_2}(t) = 1$. *(iii)* It is a *schema-agnostic similarity metric*, as it disregards any schematic information[6].

2.2 Entity similarity based on neighbors

In addition to value similarity, we exploit the relations between descriptions to find the matching entities of the compared KBs. This can be done by aggregating the value similarity of all pairs of descriptions that are neighbors of the target descriptions.

Given the potentially high number of neighbors that a description might have, we propose considering only the most valuable neighbors for computing the neighbor similarity between two target descriptions. These are neighbors that are connected with the target descriptions via important relations, i.e., relations that exhibit high *support* and *discriminability*. Intuitively, high support for a particular relation p indicates that p appears in many entity descriptions, while high discriminability for p indicates that it has many distinct values. More formally:

Definition 2.2. The **support of a relation** $p \in \mathcal{P}$ in a KB $\mathcal{E}$ is defined as: $support(p) = \frac{|instances(p)|}{|\mathcal{E}|^2}$, where $instances(p) = \{(i,j)|e_i,e_j \in \mathcal{E} \wedge (p,j) \in e_i\}$.

Definition 2.3. The **discriminability of a relation** $p \in \mathcal{P}$ in a KB $\mathcal{E}$ is defined as: $discriminability(p) = \frac{|objects(p)|}{|instances(p)|}$, where $objects(p) = \{j|(i,j) \in instances(p)\}$.

Overall, we combine support and discriminability via their harmonic mean in order to locate the most important relations.

Definition 2.4. The **importance of a relation** $p \in \mathcal{P}$ in a KB $\mathcal{E}$ is defined as: $importance(p) = 2 \cdot \frac{support(p) \cdot discriminability(p)}{support(p)+discriminability(p)}$.

On this basis, we identify the most valuable relations and neighbors for every single entity description (i.e., *locally*). We use $topNrelations(e_i)$ to denote the N relations in $relations(e_i)$ with the maximum importance scores. Then, the **best neighbors** for e_i are defined as: $topNneighbors(e_i) = \{ne_i|(p,ne_i) \in e_i \wedge p \in topNrelations(e_i)\}$.

Intuitively, strong matching evidence (high value similarity) for the important neighbors leads to strong matching evidence for the target pair of descriptions. Hence, we formally define neighbor similarity as follows:

Definition 2.5. Given two KBs, $\mathcal{E}_1$ and $\mathcal{E}_2$, the **neighbor similarity** of two entity descriptions $e_i \in \mathcal{E}_1, e_j \in \mathcal{E}_2$ is:

$$neighborNSim(e_i,e_j)= \sum_{\substack{ne_i \in topNneighbors(e_i)\\ ne_j \in topNneighbors(e_j)}} valueSim(ne_i,ne_j).$$

Proposition 2. $neighborNSim$ is a similarity metric.

[4] We handle numbers and dates in the same way as strings, assuming string-dominated entities.

[5] http://csd.uoc.gr/~vefthym/DissertationEfthymiou.pdf

[6] Note that our value similarity metric is crafted for the token-level noise in literal values, rather than the character-level one. Yet, our overall approach is tolerant to character-level noise, as verified by our extensive experimental analysis with real datasets that include it. The reason is that it is highly unlikely for matching entities to have character-level noise in all their common tokens.

Proof. Given that *neighborNSim* is the sum of similarity metrics (*valueSim*), it is a similarity metric, too [5]. □

Neither *valueSim* nor *neighborNSim* are normalized, since the number of terms that contribute in the sums is an important matching evidence that can be mitigated if the values were normalized.

Example 2.6. Continuing our example in Figure 1, assume that the best two relations for $Restaurant1$ and $Restaurant2$ are:
$top2relations(Restaurant1)$ = {hasChef, territorial} and
$top2relations(Restaurant2)$ = {headChef, county}. Then,
$top2neighbors(Restaurant1)$ = {John Lake A, Bray} and
$top2neighbors(Restaurant2)$ = {Jonny Lake, Berkshire}, and
$neighbor2Sim(Restaurant1, Restaurant2)$ =
$valueSim(Bray, JonnyLake)$+$valueSim(John\ Lake\ A, Berkshire)$
+$valueSim(Bray, Berkshire)$+$valueSim(John\ Lake\ A, Jonny\ Lake)$.
Note that since we don't have a relation mapping, we also consider the comparisons (Bray, JonnyLake) and (John Lake A, Berkshire).

Entity Names. From every KB, we also derive the *global* top-k attributes of highest importance, whose *literal* values act as **names** for any description e_i that contains them. Their support is simply defined as: $support(p) = |subjects(p)|/|\mathcal{E}|$, where $subjects(p) = \{i|(i, j) \in instances(p)\}$ [32]. Based on these statistics, function $name(e_i)$ returns the names of e_i, and $\mathcal{N}_x$ denotes all names in a KB $\mathcal{E}_x$. In combination with $topNneighbors(e_i)$, this function covers both local and global property importance, exploiting both the rare and frequent attributes that are distinctive enough to designate matching entities.

3 BLOCKING

To enhance performance, *blocking* is typically used as a preprocessing step for ER in order to reduce the number of unnecessary comparisons, i.e., comparisons between descriptions that do not match. After blocking, each description can be compared only to others placed within the same block. The desiderata of blocking are [6]: (i) to place matching descriptions in common blocks (*effectiveness*), and (ii) to minimize the number of suggested comparisons (*time efficiency*). However, efficiency dictates skipping many comparisons, possibly yielding many missed matches, which in turn implies low effectiveness. Thus, the main objective of blocking is to achieve a good trade-off between minimizing the number of suggested comparisons and minimizing the number of missed matches [7].

In general, blocking methods are defined over key values that can be used to decide whether or not an entity description could be placed in a block using an *indexing function* [7]. The 'uniqueness' of key values determines the number of entity descriptions placed in the same block, i.e., which are considered as *candidate matches*. More formally, the building blocks of a blocking method can be defined as [3]:

- An *indexing function* $h_{key} : \mathcal{E} \rightarrow 2^B$ is a unary function that, when applied to an entity description using a specific blocking key, it returns as a value the subset of the set of all blocks B, under which the description will be indexed.
- A *co-occurrence function* $o_{key} : \mathcal{E} \times \mathcal{E} \rightarrow \{true, false\}$ is a binary function that, when applied to a pair of entity descriptions, it returns 'true' if the intersection of the sets of blocks produced by the indexing function on its arguments, is non-empty, and 'false' otherwise; $o_{key}(e_k, e_l) = true$ iff $h_{key}(e_k) \cap h_{key}(e_l) \neq \emptyset$.

In this context, each pair of descriptions whose co-occurrence function returns 'true' shares at least one common block, and the distinct union of the block elements is the input entity collection (i.e., all the descriptions from a set of input KBs). Formally:

Definition 3.1. Given an entity collection $\mathcal{E}$, **atomic blocking** is defined by an indexing function h_{key} for which the generated blocks, B^{key}=$\{b_1^{key}, \ldots, b_m^{key}\}$, satisfy the following conditions:

(i) $\forall e_k, e_l \in b_i^{key} : b_i^{key} \in B^{key}, o_{key}(e_k, e_l) = true$,
(ii) $\forall (e_k, e_l) : o_{key}(e_k, e_l)$=$true, \exists b_i^{key} \in B^{key}, e_k, e_l \in b_i^{key}$,
(iii) $\bigcup_{b_i^{key} \in B^{key}} b_i^{key} = \mathcal{E}$.

Given that a single key is not enough for indexing loosely structured and highly heterogeneous entity descriptions, we need to consider several keys that the indexing function will exploit to build different sets of blocks. Such a composite blocking method is characterized by a disjunctive co-occurrence function over the atomic blocks, and it is formally defined as:

Definition 3.2. Given an entity collection $\mathcal{E}$, **disjunctive blocking** is defined by a set of indexing functions H, for which the generated blocks $B = \bigcup_{h_{key} \in H} B^{key}$ satisfy the following conditions:

(i) $\forall e_k, e_l \in b : b \in B, o_H(e_k, e_l) = true$,
(ii) $\forall (e_k, e_l) : o_H(e_k, e_l) = true, \exists b \in B, e_k, e_l \in b$,
where $o_H(e_k, e_l) = \bigvee_{h_{key} \in H} o_{key}(e_k, e_l)$.

Atomic blocking can be seen as a special case of composite blocking, consisting of a singleton set, i.e., $H = \{h_{key}\}$.

3.1 Composite Blocking Scheme

To achieve a good trade-off between effectiveness and efficiency, our *composite blocking scheme* assesses the name and value similarity of the candidate matches in combination with similarity evidence provided by their neighbors on important relations. We consider the blocks constructed for all entities $e_i \in \mathcal{E}$ using the indexing function $h_i(\cdot)$ both over entity names ($\forall n_j \in names(e_i) : h_N(n_j)$) and tokens ($\forall t_j \in tokens(e_i) : h_T(t_j)$). The composite blocking scheme O of MinoanER is defined by the following disjunctive co-occurrence condition of any two entities $e_i, e_j \in \mathcal{E}$:
$O(e_i, e_j) = o_N(e_i, e_j) \vee o_T(e_i, e_j) \vee$
$(\bigvee_{(e_i', e_j') \in topNneighbors(e_i) \times topNneighbors(e_j)} o_T(e_i', e_j'))$, where o_N, o_T is the co-occurrence function applied on names and tokens, respectively. Intuitively, two entities are placed in a common block, and are then considered candidate matches, if at least one of the following three cases holds: (i) they have the same name, which is not used by any other entity, in which case the common block contains only those two entities, or (ii) they have at least one common word in any of their values, in which case the size of the common block is given by the product of the Entity Frequency (EF) of the common term in the two input collections, or (iii) their top neighbors share a common word in any of their values. Note that token blocking (i.e., h_T) allows for deriving $valueSim$ from the size of blocks shared by two descriptions. As a result, no additional blocks are needed to assess neighbor similarity of candidate entities: token blocking is sufficient also for estimating $neighborNsim$ according to Definition 2.5.

3.2 Disjunctive Blocking Graph

The disjunctive blocking graph G is an abstraction of the disjunctive co-occurrence condition of candidate matches in blocks. Nodes represent candidates from our input entity descriptions, while edges represent pairs of candidates for which at least one

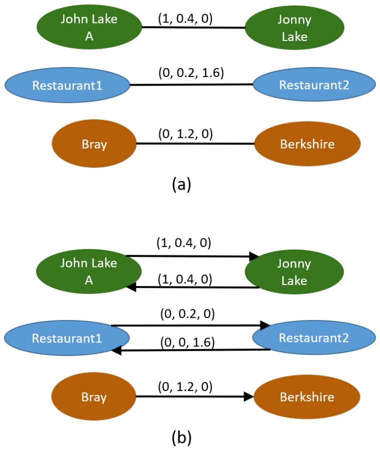

Figure 3: (a) Parts of the disjunctive blocking graph corresponding to Figure 1, and (b) the corresponding blocking graph after pruning.

of the co-occurrence conditions is 'true'. Each edge is actually labeled with three weights that quantify similarity evidence on names, tokens and neighbors of candidate matches. Specifically, the disjunctive blocking graph of MinoanER is a graph $G = (V, E, \lambda)$, with λ assigning to each edge a label (α, β, γ), where α is '1' if $o_N(e_i, e_j)$ is true and the name block in which e_i, e_j co-occur is of size 2, and '0' otherwise, $\beta = valueSim(e_i, e_j)$, and $\gamma = neighborNSim(e_i, e_j)$. More formally:

Definition 3.3. Given a block collection $B = \bigcup_{h_{key} \in H} B^{key}$, produced by a set of indexing functions H, the **disjunctive blocking graph** for an entity collection $\mathcal{E}$, is a graph $G = (V, E, \lambda)$, where each node $v_i \in V$ represents a distinct description $e_i \in \mathcal{E}$, and each edge $<v_i, v_j> \in E$ represents a pair $e_i, e_j \in \mathcal{E}$ for which $O(e_i, e_j) = `true'$; $O(e_i, e_j)$ is a disjunction of the atomic co-occurrence functions o^k defined along with H, and $\lambda : E \longrightarrow R^n$ is a labeling function assigning a tuple $[w^1, \ldots, w^n]$ to each edge, where w^k is a weight associated with each co-occurrence function o^k of H.

Definition 3.3 covers the cases of an entity collection $\mathcal{E}$ being composed of one, two, or more KBs. When matching k KBs, assuming that all of them are clean, the disjunctive blocking graph is k-partite, with each of the k KBs corresponding to a different independent set of nodes, i.e., there are only edges between descriptions from different KBs. The only information needed to match multiple KBs is to which KB every description belongs, so as to add it to the corresponding independent set. Similarly, the disjunctive blocking graph covers dirty ER, as well.

Example 3.4. Consider the graph of Figure 3(a), which is part of the disjunctive blocking graph generated from Figure 1. John Lake A and Jonny Lake have a common name ("J. Lake"), and there is no other entity having this name, so there is an edge connecting them with $\alpha = 1$. Bray and Berkshire have common, quite infrequent tokens in their values, so their similarity (β in the edge connecting them) is quite high ($\beta = 1.2$). Since Bray is a top neighbor of Restaurant1 in Figure 1, and Berkshire is a top neighbor of Restaurant2, there is also an edge with a non-zero γ connecting Restaurant1 with Restaurant2. The γ score of this edge (1.6) is the sum of the β scores of the edges connecting Bray with Berkshire (1.2), and John Lake A with Jonny Lake (0.4).

3.3 Graph Weighting and Pruning Algorithms

Each edge in the blocking graph represents a suggested comparison between two descriptions. To reduce the number of comparisons suggested by the disjunctive blocking graph, we keep for each node the K edges with the highest β and the K edges with the highest γ weights, while *pruning* edges with trivial weights (i.e., (α, β, γ)=(0,0,0)), since they connect descriptions unlikely to match. Given that nodes v_i and v_j may have different top K edges based on β or γ, we consider each undirected edge in G as two directed ones, with the same initial weights, and perform pruning on them.

Example 3.5. Figure 3(b) shows the pruned version of the graph in Figure 3(a). Note that *the blocking graph is only a conceptual model, which we do not materialize; we retrieve any necessary information from computationally cheap inverted indices.*

The process of weighting and pruning the edges of the disjunctive blocking graph is described in Algorithm 1. Initially, the graph contains no edges. We start adding edges by checking the name blocks B_N (Lines 5-9). For each name block b that contains exactly two entities, one from each KB, we create an edge with α=1 linking those entities (note that in Algorithm 1, b^k, $k \in \{1, 2\}$, denotes the sub-block of b that contains the entities from $\mathcal{E}_k$, i.e., $b^k \subseteq \mathcal{E}_k$). Then, we compute the β weights (Lines 10-14) by running a variation of Meta-blocking [27], adapted to our value similarity metric (Definition 2.1). Next, we keep for each entity, its connected nodes from the K edges with the highest β (Lines 15-18). Line 20 calls the procedure for computing the top in-neighbors of each entity, which operates as follows: first, it identifies each entity's *topNneigbors* (Lines 36-43) and then, it gets their reverse; for every entity e_i, we get the entities $topInNeighbors[i]$ that have e_i as one of their $topNneighbors$ (Lines 44-47). This allows for estimating the γ weights according to Definition 2.5. To avoid re-computing the value similarities that are necessary for the γ computations, we exploit the already computed βs. For each pair of entities $e_i \in \mathcal{E}_1$, $e_j \in \mathcal{E}_2$ that are connected with an edge with $\beta > 0$, we assign to each pair of their $inNeighbors$, (in_i, in_j), a partial γ equal to this β (Lines 20-27). After iterating over all such entity pairs e_i, e_j, we get their total neighbor similarity, i.e., $\gamma[i, j] = neighborNsim(e_i, e_j)$. Finally, we keep for each entity, its K neighbors with the highest γ (Lines 28-33).

The time complexity of Algorithm 1 is dominated by the processing of value evidence, which iterates twice over all comparisons in the token blocks B_T. In the worst-case, this results in one computation for every pair of entities, i.e., $O(|\mathcal{E}_1| \cdot |\mathcal{E}_2|)$. In practice, though, we bound the number of computations by removing excessively large blocks that correspond to highly frequent tokens (e.g., stop-words). Following [27], this is carried out by Block Purging [26], which ensures that the resulting blocks involve two orders of magnitude fewer comparisons than the brute-force approach, without any significant impact on recall. This complexity is higher than that of name and neighbor evidence, which are both linearly dependent on the number of input entities. The former involves a single iteration over the name blocks B_N, which amount to $|\mathcal{N}_1 \cap \mathcal{N}_2|$, as there is one block for every name shared by $\mathcal{E}_1$ and $\mathcal{E}_2$. For neighbor evidence, Algorithm 1 checks all pairs of N neighbors between every entity e_i and its K most value-similar descriptions, performing $K \cdot N^2 \cdot (|\mathcal{E}_1| + |\mathcal{E}_2|)$ operations; the cost of estimating the top in-neighbors for each entity is lower, dominated by the ordering of all relations in $\mathcal{E}_1$ and $\mathcal{E}_2$ (i.e., $|R_{max}| \cdot log|R_{max}|$), where $|R_{max}|$ stands for the maximum number of relations in one of the KBs.

Algorithm 1: Disjunctive Blocking Graph Construction.

```
Input: $\mathcal{E}_1$, $\mathcal{E}_2$, the blocks from name and token blocking, $B_N$ and $B_T$
Output: A disjunctive blocking graph $G$.
procedure getCompositeBlockingGraph($\mathcal{E}_1$, $\mathcal{E}_2$, $B_N$, $B_T$)
    $V \leftarrow \mathcal{E}_1 \cup \mathcal{E}_2$;
    $E \leftarrow \emptyset$;
    $W \leftarrow \emptyset$ ;                                  // init. to $(0, 0, 0)$
    // Name Evidence
    for $b \in B_N$ do
        if $|b^1| \cdot |b^2| = 1$ then        // only 1 comparison in $b$
            $e_i \leftarrow b^1.get(0)$, $e_j \leftarrow b^2.get(0)$ ;    // entities in b
            $E \leftarrow E \cup \{< v_i, v_j >\}$;
            $W \leftarrow W.set(\alpha, < v_i, v_j >, 1)$;
    // Value Evidence
    for $e_i \in \mathcal{E}_1$ do
        $\beta[] \leftarrow \emptyset$ ;        // value weights wrt all $e_j \in \mathcal{E}_2$
        for $b \in B_T \wedge b \cap e_i \neq \emptyset$ do
            for $e_j \in b^2$ do                        // $e_j \in \mathcal{E}_2$
                $\beta[j] \leftarrow \beta[j] + 1/log_2(|b^1| \cdot |b^2| + 1)$ ;     // valueSim
        $ValueCandidates \leftarrow getTopCandidates(\beta[], K)$;
        for $e_j \in ValueCandidates$ do
            $E \leftarrow E \cup \{< v_i, v_j >\}$;
            $W \leftarrow W.set(\beta, < v_i, v_j >, \beta[j])$;
    for $e_i \in \mathcal{E}_2$ do ...;            // ...do the same for $\mathcal{E}_2$
    // Neighbor Evidence
    $inNeighbors[] \leftarrow getTopInNeighbors(\mathcal{E}_1, \mathcal{E}_2)$;
    $\gamma[][] \leftarrow \emptyset$ ;     // neighbor weights wrt all $e_i, e_j \in V$
    for $e_i \in \mathcal{E}_1$ do
        for $e_j \in \mathcal{E}_2$, s.t. $W.get(\beta, < v_i, v_j >) > 0$ do
            for $in_j \in inNeighbors[j]$ do
                for $in_i \in inNeighbors[i]$ do        // neighborNSim
                    $\gamma[i][j] \leftarrow \gamma[i][j] + W.get(\beta, < n_i, n_j >)$;
    for $e_i \in \mathcal{E}_2$ do ...;            // ...do the same for $\mathcal{E}_2$
    for $e_i \in \mathcal{E}_1$ do
        $NeighborCandidates \leftarrow getTopCandidates(\gamma[i][], K)$;
        for $e_j \in NeighborCandidates$ do
            $E \leftarrow E \cup \{< v_i, v_j >\}$;
            $W.set(\gamma, < v_i, v_j >, \gamma[i][j])$;
    for $e_i \in \mathcal{E}_2$ do ...;            // ...do the same for $\mathcal{E}_2$
    return $G = (V, E, W)$;
procedure getTopInNeighbors($\mathcal{E}_1$, $\mathcal{E}_2$)
    $topNeighbors[] \leftarrow \emptyset$ ;      // one list for each entity
    $globalOrder \leftarrow$ sort $\mathcal{E}_1$'s relations by importance;
    for $e \in \mathcal{E}_1$ do
        $localOrder(e) \leftarrow relations(e).sortBy(globalOrder)$;
        $topNrelations \leftarrow localOrder(e).topN$;
        for $(p, o) \in e$, where $p \in topNrelations$ do
            $topNeighbors[e].add(o)$;
    for $e_i \in \mathcal{E}_2$ do ...;            // ...do the same for $\mathcal{E}_2$
    $topInNeighbors[] \leftarrow \emptyset$;      // the reverse of topNeighbors
    for $e \in \mathcal{E}_1 \cup \mathcal{E}_2$ do
        for $ne \in topNeighbors[e]$ do
            $topInNeighbors[ne].add(e)$;
    return $topInNeighbors$;
```

4 NON-ITERATIVE MATCHING PROCESS

Our matching method receives as input the disjunctive blocking graph G and performs four steps – unlike most existing works, which involve a data-driven iterative process. In every step, a matching rule is applied with the goal of extracting new matches from the edges of G by analyzing their weights. The functionality of our algorithm is outlined in Algorithm 2. Next, we describe its rules in the order they are applied:

Algorithm 2: Non-iterative Matching.

```
   Input: $\mathcal{E}_1$, $\mathcal{E}_2$, The pruned, directed disjunctive blocking graph $G$.
   Output: A set of matches $M$.
1  $M \leftarrow \emptyset$;                            // The set of matches
   // Name Matching Value (R1)
2  for $< v_i, v_j > \in G.E$ do
3      if $G.W.get(\alpha, < v_i, v_j >) = 1$ then
4          $M \leftarrow M \cup (e_i, e_j)$;
   // Value Matching Value (R2)
5  for $v_i \in G.V$ do
6      if $e_i \in \mathcal{E}_1 \setminus M$ then        // check the smallest KB for
        efficiency
7          $v_j \leftarrow argmax_{v_k \in G.V} G.W.get(\beta, < v_i, v_k >)$ ;    // top
            candidate
8          if $G.W.get(\beta, < v_i, v_j >) \geq 1$ then
9              $M \leftarrow M \cup (e_i, e_j)$;
   // Rank Aggregation Matching Value (R3)
10 for $v_i \in G.V$ do
11     if $e_i \in \mathcal{E}_1 \cup \mathcal{E}_2 \setminus M$ then
12         $agg[] \leftarrow \emptyset$;       // Aggregate scores, init. zeros
13         $valCands \leftarrow G.valCand(e_i)$ ; // nodes linked to $e_i$
            in decr. $\beta$
14         $rank \leftarrow |valCands|$;
15         for $e_j \in valCands$ do
16             $agg[e_i].update(e_j, \theta \cdot rank/|valCands|)$;
17             $rank \leftarrow rank - 1$;
18         $ngbCands \leftarrow G.ngbCand(e_i)$ ; // nodes linked to $e_i$
            in decr. $\gamma$
19         $rank \leftarrow |ngbCands|$;
20         for $e_j \in ngbCands$ do
21             $agg[e_i].update(e_j, (1 - \theta) \cdot rank/|ngbCands|)$;
22             $rank \leftarrow rank - 1$;
23     $M \leftarrow M \cup (e_i, getTopCandidate(agg[e_i]))$;
   // Reciprocity Matching Value (R4)
24 for $(e_i, e_j) \in M$ do
25     if $< v_i, v_j > \notin G.E \vee < v_j, v_i > \notin G.E$ then
26         $M \leftarrow M \setminus (e_i, e_j)$;
27 return $M$;
```

Name Matching Rule (R1). The matching evidence of R1 comes from the entity names. It assumes that *two candidate entities match, if they, and only they, have the same name n.* Thus, R1 traverses G and for every edge $<v_i, v_j>$ with $\alpha = 1$, it updates the set of matches M with the corresponding descriptions (Lines 2-4 in Alg. 2). All candidates matched by R1 are not examined by the remaining rules.

Value Matching Rule (R2). It presumes that *two entities match, if they, and only they, share a common token t, or, if they share many infrequent tokens.* Based on Definition 2.1, R2 identifies pairs of descriptions with high value similarity (Lines 5-9). To this end, it goes through every node v_i of G and checks whether the corresponding description stems from the smaller in size KB, for efficiency reasons (fewer checks), but has not been matched yet. In this case, it locates the adjacent node v_j with the maximum β weight (Line 7). If $\beta \geq 1$, R2 considers the pair (e_i, e_j) to be a match. Matches identified by R2 will not be considered in the sequel.

Rank Aggregation Matching Rule (R3). This rule identifies further matches for candidates whose value similarity is low ($\beta < 1$), yet their neighbor similarity (γ) could be relatively high. In this respect, the order of candidates rather than their absolute similarity values are used. Its functionality appears in Lines 10-23 of Algorithm 2. In essence, R3 traverses all nodes of G that correspond to a description that has not been matched yet. For every such node v_i, it retrieves two lists: the first one contains adjacent edges with a non-zero β weight, sorted in descending order (Line 13), while

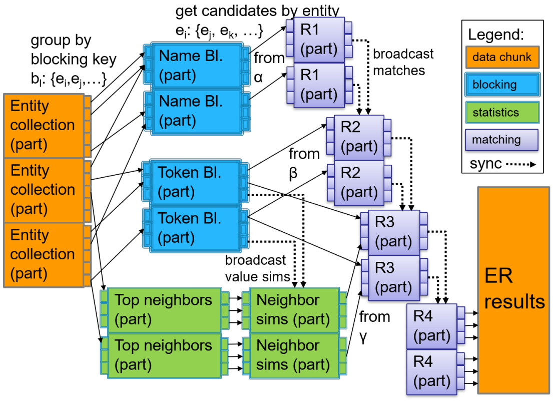

Figure 4: The architecture of MinoanER in Spark.

the second one includes the adjacent edges sorted in decreasing non-zero γ weights (Line 18). Then, R3 aggregates the two lists by considering the normalized ranks of their elements: assuming the size of a list is K, the first candidate gets the score K/K, the second one $(K-1)/K$, while the last one $1/K$. Overall, each adjacent node of v_i takes a score equal to the weighted summation of its normalized ranks in the two lists, as determined through the trade-off parameter $\theta \in (0,1)$ (Lines 16 & 21): the scores of the β list are weighted with θ and those of the γ list with 1-θ. At the end, v_i is matched with its top-1 candidate match v_j, i.e., the one with the highest aggregate score (Line 23). Intuitively, R3 *matches e_i with e_j, when, based on all available evidence, there is no better candidate for e_i than e_j.*

Reciprocity Matching Rule (R4). It aims to clean the matches identified by R1, R2 and R3 by exploiting the reciprocal edges of G. Given that the originally undirected graph G becomes directed after pruning (as it retains the best edges per node), a pair of nodes v_i and v_j are reciprocally connected when there are two edges between them, i.e., an edge from v_i to v_j and an edge from v_j to v_i. Hence, R4 aims to improve the precision of our algorithm based on the rationale that two entities are unlikely to match, when one of them does not even consider the other to be a candidate for matching. Intuitively, *two entity descriptions match, only if both of them "agree" that they are likely to match.* R4 essentially iterates over all matches detected by the above rules and discards those missing any of the two directed edges (Lines 24-26), acting more like a filter for the matches suggested by the previous rules.

Given a pruned disjunctive blocking graph, every rule can be formalized as a function that receives a pair of entities and returns true (T) if the entities match according to the rule's rationale, or false (F) otherwise, i.e., $Rn : \mathcal{E}_1 \times \mathcal{E}_2 \longrightarrow \{T, F\}$. In this context, we formally define the MinoanER matching process as follows:

Definition 4.1. The **non-iterative matching** of two KBs $\mathcal{E}_1$, $\mathcal{E}_2$, denoted by the Boolean matrix $M(\mathcal{E}_1, \mathcal{E}_2)$, is defined as a filtering problem of the pruned disjunctive blocking graph G: $M(e_i, e_j) = (\text{R1}(e_i, e_j) \vee \text{R2}(e_i, e_j) \vee \text{R3}(e_i, e_j)) \wedge \text{R4}(e_i, e_j)$.

The time complexity of Algorithm 2 is dominated by the size of the pruned blocking graph G it receives as input, since R1, R2 and R3 essentially go through all directed edges in G (in practice, though, R1 reduces the edges considered by R2 and R3, and so does R2 for R3). In the worst case, G contains $2K$ directed edges for every description in $\mathcal{E}_1 \cup \mathcal{E}_2$, i.e., $|V|_{max} = 2 \cdot K \cdot (|\mathcal{E}_1| + |\mathcal{E}_2|)$. Thus, the overall complexity is linear with respect to the number of input descriptions, i.e., $O(|\mathcal{E}_1| + |\mathcal{E}_2|)$, yielding high scalability.

4.1 Implementation in Spark

Figure 4 shows the architecture of MinoanER implementation in Spark. Each process is executed in parallel for different chunks of input, in different Spark workers. Each dashed edge represents a synchronization point, at which the process has to wait for results produced by different data chunks (and different Spark workers).

In more detail, Algorithm 1 is adapted to Spark by applying name blocking simultaneously with token blocking and the extraction of top neighbors per entity. Name blocking and token blocking produce the sets of blocks B_N and B_T, respectively, which are part of the algorithm's input. The processing of those blocks in order to estimate the α and β weights (Lines 5-9 for B_N and Lines 10-18 for B_T) takes place during the construction of the blocks. The extraction of top neighbors per entity (Line 20) runs in parallel to these two processes and its output, along with the β weights, is given to the last part of the graph construction, which computes the γ weights for all entity pairs with neighbors co-occuring in at least one block (Lines 21-33).

To minimize the overall run-time, Algorithm 2 is adapted to Spark as follows: R1 (Lines 2-4) is executed in parallel with name blocking and the matches it discovers are broadcasted to be excluded from subsequent rules. R2 (Lines 5-9) runs after both R1 and token blocking have finished, while R3 (Lines 10-23) runs after both R2 and the computation of neighbor similarities have been completed, skipping the already identified (and broadcasted) matches. R4 (Lines 24-26) runs in the end, providing the final, filtered set of matches. Note that during the execution of every rule, each Spark worker contains only the partial information of the disjunctive blocking graph that is necessary to find the match of a specific node (i.e., the corresponding lists of candidates based on names, values, or neighbors).

5 RELATED WORK

To the best of our knowledge, there is currently no other Web-scale ER framework that is fully automated, non-iterative, schema-agnostic and massively parallel, at the same time. For example, WInte.r [22] is a framework that performs multi-type ER, also incorporating the steps of blocking, schema-level mapping and data fusion. However, it is implemented in a sequential fashion and its solution relies on a specific level of structuredness, i.e., on a schema followed by the instances to be matched. Dedoop [20] is a highly scalable ER framework that comprises the steps of blocking and supervised matching. However, it is the user that is responsible for selecting one of the available blocking and learning methods and for fine-tuning their internal parameters. This approach is also targeting datasets with a predefined schema. Dedupe [16] is a scalable open-source Python library (and a commercial tool built on this library) for ER; however, it is not fully automated, as it performs active learning, relying on human experts to decide for a first few difficult matching decisions. Finally, we consider progressive ER (e.g., [1]) orthogonal to our approach, as it aims to retrieve as many matches as possible as early as possible.

In this context, we compare MinoanER independently to state-of-the-art matching and blocking approaches for Web data.

Entity Matching. Two types of similarity measures are commonly used for entity matching [21, 31]. (i) *Value-based similarities* (e.g., Jaccard, Dice) usually assess the similarity of two descriptions based on the values of specific attributes. Our value similarity is a variation of ARCS, a Meta-blocking weighting scheme [12], which disregards any schema information and considers each entity description as a bag of words. Compared to

ARCS, though, we focus more on the *number than the frequency of common tokens between two descriptions*. (ii) *Relational similarity* measures additionally consider neighbor similarity by exploiting the value similarity of (some of) the entities' neighbors.

Based on the nature of the matching decision, ER can be characterized as *pairwise* or *collective*. The former relies exclusively on the value similarity of descriptions to decide if they match (e.g., [20]), while the latter iteratively updates the matching decision for entities by dynamically assessing the similarity of their neighbors (e.g., [2]). Typically, the starting point for this similarity propagation is a set of seed matches identified by a value-based blocking.

For example, SiGMa [21] starts with seed matches having identical entity names. Then, it propagates the matching decisions on the 'compatible' neighbors, which are linked with pre-aligned relations. For every new matched pair, the similarities of the neighbors are recomputed and their position in the priority queue is updated. LINDA [4] differs by considering as compatible neighbors those connected with relations having similar names (i.e., small edit distance). However, this requirement rarely holds in the extreme schema heterogeneity of Web data. RiMOM-IM [23, 31] is a similar approach, introducing the following heuristic: if two matched descriptions e_1, e_1' are connected via aligned relations r and r' and all their entity neighbors via r and r', except e_2 and e_2', have been matched, then e_2 and e_2' are also considered matches.

All these methods employ Unique Mapping Clustering for detecting matches: they place all pairs into a priority queue, in decreasing similarity. At each iteration, the top pair is considered a match, if none of its entities has been already matched. The process ends when the top pair has a similarity lower than t.

MinoanER employs Unique Mapping Clustering, too. Yet, it differs from SiGMa, LINDA and RiMOM-IM in five ways: (i) the matching process iterates over the disjunctive blocking graph, instead of the initial KBs. (ii) MinoanER employs statistics to automatically discover distinctive entity names and important relations. (iii) MinoanER exploits different sources of matching evidence (values, names and neighbors) to statically identify candidate matches already from the step of blocking. (iv) MinoanER does not aggregate different similarities in one similarity score; instead, it uses a disjunction of the different evidence it considers. (v) MinoanER is a static collective ER approach, in which all sources of similarity are assessed only once per candidate pair. By considering a composite blocking not only on the value but also on the neighbors similarity, we discover in a non-iterative way most of the matches returned by the data-driven convergence of existing systems, or even more (see Section 6).

PARIS [33] uses a probabilistic model to identify matches, based on previous matches and the functional nature of entity relations. A relation is considered *functional* if, for a source entity, there is only one destination entity. If $r(x, y)$ is a function in one KB and $r(x, y')$ a function in another KB, then y and y' are considered matches. The functionality of a relation and the alignment of relations along with previous matching decisions determine the decisions in subsequent iterations. *Unlike MinoanER, PARIS cannot deal with structural heterogeneity, while it targets both ontology and instance matching*.

Finally, [30] parallelizes the collective ER approach of [2], relying on a black-box matching and exploits a set of heuristic rules for structured entities. It essentially runs multiple instances of the matching algorithm in subsets of the input entities (similar to blocks), also keeping information for all the entity neighbors, needed for similarity propagation. Since some rules may require the results of multiple blocks, an iterative message-passing framework is employed. *Rather than a block-level synchronization, the MinoanER parallel computations in Spark require synchronization only across the 4 generic matching rules* (see Figure 4).

Regarding the matching rules, the ones employed by MinoanER based on values and names are similar to rules that have already been employed in the literature individually (e.g., in [21, 23, 31]). In this work, we use a combination of those rules for the first time, also introducing a novel rank aggregation rule to incorporate value and neighbor matching evidence. Finally, the idea of reciprocity has been applied to enhance the results of Meta-blocking [28], but was never used in matching.

Blocking. Blocking techniques for relational databases [6] rely on blocking keys defined at the schema-level. For example, the *Sorted Neighborhood* approach orders entity descriptions according to a sorting criterion and performs blocking based on it; it is expected that matching descriptions will be neighbors after the sorting, so neighbor descriptions constitute candidate matches [17]. Initially, entity descriptions are lexicographically ordered based on their blocking keys. Then, a window, resembling a block, of fixed length slides over the ordered descriptions, each time comparing only the contents of the window. An adaptive variation of the sorted neighborhood method is to dynamically decide on the size of the window [35]. In this case, adjacent blocking keys in the sorted descriptions that are significantly different from each other, are used as boundary pairs, marking the positions where one window ends and the next one starts. Hence, this variation creates non-overlapping blocks. In a similar line of work, the sorted blocks method [11] allows setting the size of the window, as well as the degree of desired overlap.

Another recent schema-based blocking method uses Maximal Frequent Itemsets (MFI) as blocking keys [19] – an itemset can be a set of tokens. Abstractly, each MFI of a specific attribute in the schema of a description defines a block, and descriptions containing the tokens of an MFI for this attribute are placed in a common block. Using frequent itemsets to construct blocks may significantly reduce the number of candidates for matching pairs. However, since many matching descriptions share few, or even no common tokens, further requiring that those tokens are parts of frequent itemsets is too restrictive. The same applies to the requirement for a-priori schema knowledge and alignment, thus resulting in many missed matches in the Web of Data.

Although blocking has been extensively studied for tabular data, the proposed approaches cannot be used for the Web of Data, since their blocking keys rely on the existence of a global schema. However, the use of schema-based blocking keys is inapplicable to the Web of Data, due to its extreme schema heterogeneity [15]: entity descriptions do not follow a fixed schema, as even a single description typically uses attributes defined in multiple LOD vocabularies. In this context, schema-agnostic blocking methods are needed instead. Yet, the schema-agnostic functionality of most blocking methods requires extensive fine-tuning to achieve high effectiveness [29]. The only exception is token blocking, which is completely parameter-free [26]. Another advantage of token blocking is that it allows for computing value similarity from its blocks, as they contain entities with *identical* blocking keys – unlike other methods like Dedoop [20] and Sorted Neighborhood [17], whose blocks contain entities with *similar* keys.

SiGMa [21] considers descriptions with at least two common tokens as candidate matches, which is more precise than our token blocking, but misses more matches. The missed matches will be considered in subsequent iterations, if their neighbor similarity is

strong, whereas *MinoanER identifies such matches from the step of blocking*. RiMOM-IM [31] computes the tokens' TF-IDF weights, takes the top-5 tokens of each entity, and constructs a block for each one, along with the attribute this value appears. *Compared to the full automation of MinoanER, this method requires attribute alignment.* [25] iteratively splits large blocks into smaller ones by adding attributes to the blocking key. This leads to a prohibitive technique for voluminous KBs of high Variety.

Disjunctive blocking schemes have been proposed for KBs of high [18] and low [3] levels of schema heterogeneity. Both methods, though, are of limited applicability, as they require labelled instances for their supervised learning. *In contrast, MinoanER copes with the Volume and Variety of the Web of Data, through an unsupervised, schema-agnostic, disjunctive blocking*.

Finally, LSH blocking techniques (e.g., [24]) hash descriptions multiple times, using a family of hash functions, so that similar descriptions are more likely to be placed into the same bucket than dissimilar ones. This requires tuning a similarity threshold between entity pairs, above which they are considered candidate matches. *This tuning is non-trivial, especially for descriptions from different domains, while its effectiveness is limited for nearly similar entities* (see Figure 2).

6 EXPERIMENTAL EVALUATION

In this section, we thoroughly compare MinoanER to state-of-the-art tools and a heavily fine-tuned baseline method.

Experimental Setup. All experiments were performed on top of Apache Spark v2.1.0 and Java 8, on a cluster of 4 Ubuntu 16.04.2 LTS servers. Each server has 236GB RAM and 36 Intel(R) Xeon(R) E5-2630 v4 @2.20GHz CPU cores.

Datasets. We use four established benchmark datasets with entities from real KBs. Their technical characteristics appear in Table 1. All KBs contain relations between the described entities.

Restaurant[7] contains descriptions of restaurants and their addresses from two different KBs. It is the smallest dataset in terms of the number of entities, triples, entity types[8], as well as the one using the smallest number of vocabularies. We use it for two reasons: *(i)* it is a popular benchmark, created by the Ontology Alignment Evaluation Initiative, and *(ii)* it offers a good example of a dataset with very high value and neighbor similarity between matches (Figure 2), involving the easiest pair of KBs to resolve.

Rexa-DBLP[9] contains descriptions of publications and their authors. The ground truth contains matches between both publications and authors. This dataset contains strongly similar matches in terms of values and neighbors (Figure 2). Although it is relatively easy to resolve, Table 1 shows that it exhibits the greatest difference with respect to the size of the KBs to be matched (DBLP is 2 orders of magnitude bigger than Rexa in terms of descriptions, and 3 orders of magnitude in terms of triples).

BBCmusic-DBpedia [14] contains descriptions of musicians, bands and their birthplaces, from BBCmusic and the BTC2012 version of DBpedia[10]. In our experiments, we consider only entities appearing in the ground truth, as well as their immediate in- and out-neighbors. The most challenging characteristic of this dataset is the high heterogeneity between its two KBs in terms of both schema and values: DBpedia contains ~11,000 different attributes, ~60,000 entity types, 953 relations, the highest number of different vocabularies (6), while using on average 4 times more tokens than BBCmusic to describe an entity. The latter feature means that all normalized, set-based similarity measures like Jaccard fail to identify such matches, since a big difference in the token set sizes yields low similarity values (see Figure 2). A thorough investigation has shown that in the median case, an entity description in this dataset contains only 2 words in its values that are used by both KBs [14].

YAGO-IMDb [33] contains descriptions of movie-related entities (e.g., actors, directors, movies) from YAGO[11] and IMDb[12]. Figure 2 shows that a large number of matches in this dataset has low value similarity, while a significant number has high neighbor similarity. Moreover, this is the biggest dataset in terms of entities and triples, challenging the scalability of ER tools, while it is the most balanced pair of KBs with respect to their relative size.

Baselines. In our experiments, we compare MinoanER against four state-of-the-art methods: SiGMa, PARIS, LINDA and RiMOM. PARIS is openly available, so we ran its original implementation. For the remaining tools, we report their performance from the original publications[13]. We also consider BSL, a custom baseline method that receives as input the disjunctive blocking graph *G*, before pruning, and compares every pair of descriptions connected by an edge in *G*. The resulting similarities are then processed by Unique Mapping Clustering. Unlike MinoanER, though, BSL disregards all evidence from entity neighbors, relying exclusively on value similarity. Yet, it optimizes its performance through a series of well-established string matching methods that undergo extensive fine-tuning on the basis of the ground-truth.

In more detail, we consider numerous configurations for the four parameters of BSL in order to maximize its F1: *(i)* The schema-agnostic representation of the values in every entity. BSL uses token *n*-grams for this purpose, with $n \in \{1, 2, 3\}$, thus representing every resource by the token uni-/bi-/tri-grams that appear

in its values. *(ii)* The weighting scheme that assesses the importance of every token. We consider TF and TF-IDF weights. *(iii)* The similarity measure, for which we consider the following well-established similarities: Cosine, Jaccard, Generalized Jaccard and SiGMa (which applies exclusively to TF-IDF weights [21]). All measures are normalized to $[0, 1]$. *(iv)* The similarity threshold that prunes the entity pairs processed by Unique Mapping Clustering. We use all thresholds in $[0, 1)$ with a step of 0.05. In total, we consider 420 different configurations, reporting the highest F1.

6.1 Effectiveness Evaluation

Blocks Performance. First, we examine the performance of the blocks used by MinoanER (and BSL). Their statistics appear in Table 2. We observe that the number of comparisons in token blocks ($||B_T||$) is at least 1 order of magnitude larger than those of name blocks ($||B_N||$), even if the latter may involve more blocks ($|B_N|>|B_T|$ over YAGO-IMDb). In fact, $||B_N||$ seems to depend linearly on the number of input descriptions, whereas $||B_T||$ seems to depend quadratically on that number. Nevertheless, the overall comparisons in $B_T \cup B_N$ are at least 2 orders of magnitude lower than the Cartesian product $|E_1| \cdot |E_2|$, even though recall is consistently higher than 99%. On the flip side, both precision and F-Measure (F1) remain rather low.

Parameter Configuration. Next, we investigate the robustness of our method with respect to its internal configuration. To this end, we perform a *sensitivity analysis*, using the following meaningful values for the four parameters of MinoanER: $k \in \{1, 2, 3, 4, 5\}$ (the number of most distinct predicates per KB whose values serve as names), $K \in \{5, 10, 15, 2, 25\}$ (the number of candidate matches per entity from values and neighbors), $N \in \{1, 2, 3, 4, 5\}$ (the number of the most important relations per entity), and $\theta \in \{0.3, 0.4, 0.5, 0.6, 0.7, 0.8\}$ (the trade-off between value- vs neighbor-based candidates). Preliminary experiments demonstrated that the configuration $(k, K, N, \theta) = (2, 15, 3, 0.6)$ yields a performance very close to the average one. Therefore, we use these parameter values as the default ones in our sensitivity analysis.

In more detail, we sequentially vary the values of one parameter, keeping the others fixed to their default value, so as to examine its effect on the overall F1 of MinoanER. The results appear in the diagrams of Figure 5. We observe that MinoanER is quite robust in most cases, as small changes in a parameter value typically lead to an insignificant change in F1. This should be attributed to the composite functionality of MinoanER and its four matching rules,in particular: even if one rule is misconfigured, the other rules make up for the lost matches. There are only two exceptions:

(i) There is a large increase in F1 over BBCmusic-DBpedia when k increases from 1 to 2. The former value selects completely different predicates as names for the two KBs, due to the schema heterogeneity of DBpedia, thus eliminating the contribution of the name matching rule to F1. This is ameliorated for k=2.

(ii) F1 is significantly lower over BBCmusic-DBpedia and YAGO-IMDb for $\theta < 0.5$. This should be expected, since Figure 2 demonstrates that both datasets are dominated by nearly-similar matches, with the value similarity providing insufficient evidence for detecting them. Hence, θ should promote neighbor-similarity at least to the same level as the value-similarity (i.e., $\theta \geq 0.5$).

Table 3: Evaluation of MinoanER in comparison to the state-of-the-art methods and the heavily fine-tuned baseline, BSL.

		Restau-rant	Rexa-DBLP	BBCmusic-DBpedia	YAGO-IMDb
SiGMa [21]	Prec.	99	**97**	-	**98**
	Recall	94	90	-	85
	F1	97	94	-	91
LINDA [4]	Prec.	**100**	-	-	-
	Recall	63	-	-	-
	F1	77	-	-	-
RiMOM [23]	Prec.	86	80	-	-
	Recall	77	72	-	-
	F1	81	76	-	-
PARIS [33]	Prec.	95	93.95	19.40	94
	Recall	88	89	0.29	90
	F1	91	91.41	0.51	**92**
BSL	Prec.	**100**	96.57	85.20	11.68
	Recall	**100**	83.96	36.09	4.87
	F1	**100**	89.82	50.70	6.88
MinoanER	Prec.	**100**	**96.74**	**91.44**	91.02
	Recall	**100**	**95.34**	**88.55**	**90.57**
	F1	**100**	**96.04**	**89.97**	90.79

As a result, next, we can exclusively consider the configuration $(k, K, N, \theta) = (2, 15, 3, 0.6)$ for MinoanER. This is the suggested global configuration that works well over all datasets, but parameter tuning per individual dataset may yield better results.

Comparison with Baselines. Table 3 shows that MinoanER offers competitive performance when matching KBs with few attributes and entity types, despite requiring no domain-specific input. Specifically, it achieves 100% F1 in Restaurant, which is 3% higher than SiGMa, 9% higher than PARIS, and ~20% higher than LINDA and RiMOM. BSL also achieves perfect F1, due to the strongly similar matches (see Figure 2). In Rexa-DBLP, MinoanER also outperforms all existing ER methods. It is 2% better than SiGMa in F1, 4.6% better than PARIS, 20% better than RiMOM, and 6% better than BSL. In YAGO-IMDb, MinoanER achieves similar performance to SiGMa (91% F1), with more identified matches (91% vs 85%), but lower precision (91% vs 98%). Compared to PARIS, its F1 is 1% lower, due to 3% lower precision, despite the 1% better recall. The high structural similarity between the two KBs make this dataset a good use case for PARIS. BSL exhibits the worst performance, due to the very low value similarity of matches in this KB. Most importantly, MinoanER achieves the best performance by far over the highly heterogeneous KBs of BBCmusic-DBpedia. PARIS struggles to identify the matches, with BSL performing significantly better, but still poorly in absolute numbers. In contrast, MinoanER succeeds in identifying 89% of matches with 91% precision, achieving a 90% F1.

Comparing the performance of MinoanER to that of its input blocks, precision raises by several orders of magnitude at the cost of slightly lower recall. The lower recall is caused by missed

Table 4: Evaluation of matching rules.

		Restaurant	Rexa-DBLP	BBCmusic-DBpedia	YAGO-IMDb
R1	Precision	**100**	**97.36**	**99.85**	97.55
	Recall	68.54	87.47	66.11	66.53
	F1	81.33	92.15	79.55	79.11
R2	Precision	**100**	96.15	90.73	**98.02**
	Recall	**100**	30.56	37.01	69.14
	F1	**100**	46.38	52.66	81.08
R3	Precision	98.88	94.73	81.49	90.51
	Recall	98.88	**94.73**	**81.49**	**90.50**
	F1	98.88	**94.73**	**81.49**	**90.50**
¬R4	Precision	100	96.03	89.93	90.58
	Recall	100	96.03	89.93	90.57
	F1	100	96.03	89.93	90.58
No Neighbors	Precision	100	96.59	89.22	88.05
	Recall	100	95.26	85.36	87.42
	F1	100	95.92	87.25	87.73

matches close to the lower left corner of Figure 2, i.e., with very low value and neighbor similarities. This explains why the impact on recall is larger for BBCmusic-DBpedia and YAGO-IMDb.

Evaluation of Matching Rules. Table 4 summarizes the performance of each matching rule in Algorithm 2, when executed alone, as well as the overall contribution of neighbor similarity evidence.

• *Name Matching Rule (R1).* This rule achieves both high precision (> 97%) and a decent recall (> 66%) in all cases. Hence, given no other matching evidence, R1 alone yields good matching results, emphasizing precision, with only an insignificant number of its suggested matches being false positives. To illustrate the importance of this similarity evidence in real KBs, we have marked the matches with identical names in Figure 2 as bordered points. Thus, we observe that matches may agree on their names, regardless of their value and neighbor similarity evidence.

• *Value Matching Rule (R2).* This rule is also very precise (> 90% in all cases), but exhibits a lower recall (> 30%). Nevertheless, even this low recall is not negligible, especially when it complements the matches found from R1. In the case of strongly similar matches as in Restaurant, this rule alone can identify all the matches with perfect precision.

• *Rank Aggregation Matching Rule (R3).* The performance of this rule varies across the four datasets, as it relies on neighborhood evidence. For KBs with low value similarity (left part of Figure 2), this rule is the only solution for finding matches having no/different names. In BBCmusic-DBpedia and YAGO-IMDb, it has the highest contribution in recall and F1 of all matching rules, with the results for YAGO-IMDb being almost equivalent to those of Table 3 (YAGO-IMDb features the lowest value similarities in Figure 2). For KBs with medium value similarity (middle part of Figure 2), but not enough to find matches with R2, aggregating neighbor with value similarity is very effective. In Rexa-DBLP, R3 yields almost perfect results. Overall, R3 is the matching rule with the greatest F1 in 3 out of 4 datasets.

• *Reciprocity Matching Rule (R4).* Given that R4 is a filtering rule, i.e., it does not add new results, we measure its contribution by running the full workflow without it. Its performance in Table 4 should be compared to the results in Table 3. This comparison shows that this rule increases the precision of MinoanER, with a small, or no impact on recall. Specifically, it increases the precision of BBCmusic-DBpedia by 1.51%, while its recall is decreased by 1.38%, and in the case of YAGO-IMDb, it improves precision by 0.44% with no impact on recall. This results in an increase of 0.04% and 0.21% in F1. Overall, R4 is the weakest matching rule, yielding only a minor improvement in the results of MinoanER.

Contribution of neighbors. To evaluate the contribution of neighbor evidence in the matching results, we have repeated Algorithm 2, without the rule R3. Note that this experiment is not the same as our baseline; here, we use all the other rules, also operating on the pruned disjunctive blocking graph, while the baseline does not use our rules and operates on the unpruned graph. The results show that *neighbor evidence plays a minor or even no role in KBs with strongly similar entities*, i.e., Restaurant and Rexa-DBLP, *while having a bigger impact in KBs with nearly similar matches*, i.e., BBCmusic-DBpedia and YAGO-IMDb (see Figure 2). Specifically, compared to the results of Table 3, the use of neighbor evidence improves precision by 2.22% and recall by 3.19% in BBCmusic-DBpedia, while, in YAGO-IMDB, precision is improved by 2.97% and recall by 3.15%.

6.2 Efficiency Evaluation

To evaluate the scalability of matching in MinoanER, we present in Figure 6 the running times and speedup of matching for each dataset, as we change the number of available CPU cores in our cluster, i.e., the number of tasks that can run at the same time. In each diagram, the left vertical axis shows the running time and the right vertical axis shows the speedup, as we increase the number of available cores (from 1 to 72) shown in the horizontal axis[14]. Across all experiments, we have kept the same total number of tasks, which was defined as the number of all cores in the cluster multiplied by a parallelism factor of 3, i.e., 3 tasks are assigned to each core, when all cores are available. This was to ensure that each task would require the same amount of resources (e.g., memory), regardless of the number of available cores.

We observe that the running times decrease as more cores become available, and this decrease is steeper when using a small number of cores. For example, resolving Rexa-DBLP with 6 cores is 6 times faster than with 1 core, while it is 10 times faster with 12 cores than with 1 core (top-right of Figure 6). We observe a sub-linear speedup in all cases, which is expected when synchronization is required for different steps (see Section 4.1). Though, the bigger datasets have a speedup closer to linear than the smaller ones, because the Spark overhead is smaller with respect to the overall running time in these cases. We have also measured the percentage of time spent for the matching phase (Algorithm 2) compared to the total execution time of MinoanER. In Restaurant and Rexa-DBLP, matching takes 45% of the total time, in BBCmusic-DBpedia 30% and in YAGO-IMDb 20%. Thus, in all cases, matching takes less than half the execution time, while it takes smaller percentage of time as the tasks get bigger.

It is not possible to directly compare the efficiency of MinoanER with the competitive tools of Table 3; most of them are not publicly available, while the available ones do not support parallel execution using Spark. The running times reported in the original works are about sequential algorithms executed in machines with a different setting than ours. However, we can safely argue that our fixed-step process, as opposed to the data-iterative processes of existing works, boosts the efficiency of MinoanER at no cost in (or, in most cases, with even better) effectiveness. Indicatively, the running time of MinoanER for Rexa-DBLP was 3.5 minutes (it took PARIS 11 minutes on one of our cluster's servers - see Experimental Setup - for the same dataset), for BBCmusic-DBpedia it was 69 seconds (it took PARIS 3.5 minutes on one of

[14] We could not run MinoanER on the YAGO-IMDb dataset with only 1 core, due to limited space in a single machine, so we report its running time starting with a minimum of 4 cores. This means that the linear speedup for 72 tasks would not be 72, but 18 (72/4).

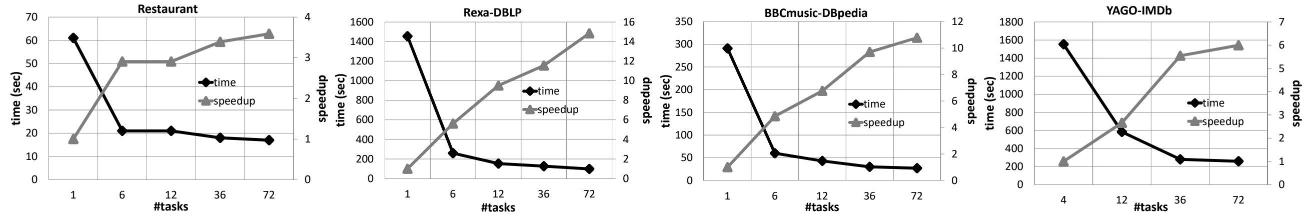

Figure 6: Scalability of matching in MinoanER w.r.t. running time (left vertical axis) and speedup (right vertical axis) as more cores are involved.

our cluster's servers), while the running time for YAGO-IMDb was 28 minutes (SiGMa reports 70 minutes, and PARIS reports 51 hours). In small datasets like Restaurant, MinoanER can be slower than other tools, as Spark has a setup overhead, which is significant for such cases (it took MinoanER 27 seconds to run this dataset, while PARIS needed 6 seconds).

7 CONCLUSIONS

In this paper, we have presented MinoanER, a fully automated, schema-agnostic and massively parallel framework for ER in the Web of Data. To resolve highly heterogeneous entities met in this context, MinoanER relies on schema-agnostic similarity metrics that consider both the content and the neighbors of entities. It exploits these metrics in a composite blocking scheme and conceptually builds a disjunctive blocking graph - a novel, comprehensive abstraction that captures all sources of similarity evidence. This graph of candidate matches is processed by a non-iterative algorithm that consists of four generic, schema-agnostic matching rules, with linear cost to the number of entity descriptions and robust performance with respect to their internal configuration.

The results show that neighbor evidence plays a minor role in KBs with strongly similar entities, such as Restaurant and Rexa-DBLP, while having a big impact in KBs with nearly similar entities, such as in BBCmusic-DBpedia and YAGO-IMDb. MinoanER achieves at least equivalent performance with state-of-the-art ER tools over KBs exhibiting low Variety, but outperforms them to a significant extent when matching KBs with high Variety. The employed matching rules (R1, R2, R3, R4) manage to cover a wide range of matches, as annotated in Figure 2, but there is still room for improvement, since the recall of blocking is better than that of matching. As an improvement, we will investigate how to create an ensemble of matching rules and how to set the parameters of pruning candidate pairs dynamically, based on the local similarity distributions of each node's candidates.

Extending Cross-Domain Knowledge Bases with Long Tail Entities using Web Table Data

{yaser,chris}@informatik.uni-mannheim.de

ABSTRACT

Cross-domain knowledge bases such as YAGO, DBpedia, or the Google Knowledge Graph are being used as background knowledge within an increasing range of applications including web search, data integration, natural language understanding, and question answering. The usefulness of a knowledge base for these applications depends on its completeness. Relational HTML tables from the Web cover a wide range of topics and describe very specific long tail entities, such as small villages, less-known football players, or obscure songs.

This systems and applications paper explores the potential of web table data for the task of completing cross-domain knowledge bases with descriptions of formerly unknown entities. We present the first system that handles all steps that are necessary for this task: schema matching, row clustering, entity creation, and new detection. The evaluation of the system using a manually labeled gold standard shows that it can construct formerly unknown instances and their descriptions from table data with an average F1 score of 0.80. In a second experiment, we apply the system to a large corpus of web tables extracted from the Common Crawl. This experiment allows us to get an overall impression of the potential of web tables for augmenting knowledge bases with long tail entities. The experiment shows that we can augment the DBpedia knowledge base with descriptions of 14 thousand new football players as well as 187 thousand new songs. The accuracy of the facts describing these instances is 0.90.

1 INTRODUCTION

Cross-domain knowledge bases like YAGO [18], DBpedia [20], Wikidata [30], or the Google Knowledge Graph are being employed for an increasing range of applications, including natural language processing, web search, and question answering.

The YAGO, DBpedia, and Wikidata knowledge bases all rely on data that has been extracted from Wikipedia and as a result cover mostly head instances that fulfill the Wikipedia notability criteria. Their coverage of less well known instances from the long tail is rather low [11]. As the usefulness of a knowledge base often increases with its completeness, adding long tail instances to an existing knowledge base is an important task.

Web tables [8], which are relational HTML tables extracted from the Web, contain large amounts of structured information, covering a wide range of topics, and describe very specific long tail instances. Web tables are thus a promising source of information for the task of augmenting cross-domain knowledge bases.

Augmenting knowledge bases with descriptions of long tail instances requires, on the one hand, identifying instances of a specific class that are not yet part of a knowledge base, and, on the other hand, compiling descriptions of the new instances according to the schema of the knowledge base. Two areas of related work are relevant for this task: Existing work on slot filling [11, 22, 23, 27, 29] focuses on adding missing facts describing existing instances to a knowledge base. The methods do not attempt to discover new instances. In contrast, existing research on set expansion [24, 31, 32] focuses on determining the names of new instances and is not concerned with compiling structured descriptions of those instances according to a schema of a knowledge base. As most set expansion methods disambiguate new instances solely based on names, they miss the potential of exploiting additional features for disambiguation.

As a result, no viable methods that are able to automatically augment a knowledge base with new instances and their descriptions exist. In this work, we close this gap by introducing and evaluating the first system that is able to generate descriptions of formerly unknown long-tail entities given a corpus of relational web tables. The system exploits the synergies between the task of identifying new instances and compiling descriptions of these instances using an iterative approach. The contributions of the paper are as follows:

- We introduce the first system that is able to generate descriptions of new instances given the set of all instances of a class from a knowledge base and a corpus of relational web tables.
- We evaluate our system using a manually built gold standard of annotated web tables and report the lessons learned from this experiment.
- We run our system over a large corpus of web tables which allows us to profile the general potential of web table data for augmenting knowledge bases with descriptions of long tail instances.

Figure 1 gives an overview of the overall process performed by our system. The process consists of four main steps which are executed in two iterations. We first apply schema matching methods to match web tables and attribute columns of those tables to classes and properties in the knowledge base. Second, a row clustering method identifies rows that describe the same entity. From these row clusters, the entity creation component creates entity descriptions according to the schema of the knowledge base. Finally, the new detection component determines whether an entity already exists in the knowledge base. We iterate over the pipeline a second time using the row clusters and entity-to-instance correspondences from the first run in order to refine the schema mapping. After the second run of the pipeline, entities identified as new are added to the knowledge base.

The paper is structured as follows: First, we describe the profile of the knowledge base, the web table corpus, and the gold standard that are used for the experiments throughout the paper. Section 3 describes and evaluates the individual steps of the overall process. Section 4 discusses the overall performance of the pipeline on the gold standard, while in Section 5 we run our

system on the large corpus of web tables in order to profile the overall potential of web tables for the task at hand. Section 6 compares our system to the related work.

2 EXPERIMENTAL SETUP

This section describes the datasets that we use to evaluate our system. We will first describe the knowledge base and the selection of classes we aim to extend. We then describe the web table corpus in which we hope to find new instances. We finally describe the gold standard that we use throughout this work.

2.1 Knowledge Base and Classes

We employ DBpedia [20] as the target knowledge base to be extended. It is extracted from Wikipedia and especially Wikipedia infoboxes. As a result, the covered instances are limited to those identified as notable by the Wikipedia community.

From DBpedia we selected three classes on which we focus throughout this work. To ensure that information covered by the classes is diverse, we selected each from a different first-level class, i.e. Agent, Work, and Place. To ensure that the classes are not too broad, we preferred classes further down in the hierarchy. As a result we chose the following three classes: GridironFootballPlayer (GF-Player), Song and Settlement. The class Song includes all instances of the class Single. Tables 1 and 2 provide an overview of the number of instances and facts, and the property densities of those classes. We only consider properties that have an initial density of at least 30 %. We use the 2014 release of DBpedia, as this release has been used in related work [22, 23, 26, 27], and its release date is also closer to the extraction of the web table corpus used in this work.

Table 1 shows that DBpedia already covers tens of thousands of instances for the profiled classes. This could indicate that most of the well-known instances are already covered, so that we are especially interested in finding instances from the long tail.

Table 2 also reveals that the density differs significantly from property to property. Only the properties of class Song have consistently high densities larger than 60 %. The football player class has many properties, but half of them have a density below 50 %. The class Settlement suffers from both, a small number of properties, and low densities for some of them.

Table 2: Number of facts and property densities for selected DBpedia properties.

2.2 Web Table Corpus

In this work, we utilize the english-language relational tables set of the Web Data Commons 2012 Web Table Corpus.[1] The set consists of 91.8 million tables. Table 3 gives an overview of the general characteristics of tables in the corpus. We can see that the majority of tables are rather short, with an average of 10.4 rows and a median of 2, whereas the average and median number of columns are 3.5 and 3. As a result, a table on average describes 10 instances with 30 values, which likely is a sufficient size and potentially useful for finding new instances and their descriptions. In [27] we have profiled the potential of the same corpus for the task of slot filling, meaning to find missing values for existing DBpedia instances.

For every table we assume that there is one attribute that contains the labels of the instances described by the rows. The remaining columns contain values, which potentially can be used to generate descriptions according to the knowledge base schema.

Song	58,594	1,315,381	443,194
Settlement	11,757	82,816	13,735

For the three evaluated classes, Table 4 shows the result of matching the table corpus to existing instances and properties in DBpedia, using a method from previous work [26, 27]. The first column shows the number of matched tables that have at least one matched attribute column. Rows of those tables were matched directly to existing instances of DBpedia. From the second and third columns we see how many values were matched to existing instances and how many values remained unmatched. While more values were matched, the number of unmatched values is still large, especially for the song class.

2.3 Gold Standard

For the purpose of this work we built a publicly available gold standard of annotated web tables. We first annotated clusters of rows that describe the same instance. Additionally, we annotated if these clusters describe new instances and for clusters that overlap with existing instances in DBpedia, we also annotated the clusters with the correspondence to the existing instance. We annotated attribute-to-property correspondences, where table columns are mapped to properties in DBpedia. Finally, we annotate facts for all cluster and property combinations for which a candidate value exist in the annotated web tables.

The gold standard contains tables with instances of varying degree of popularity, so that they describe head and long tail instances. We also prioritized tables with rows that are unlikely to have a match in DBpedia and ensured that for some labels, we select at least five rows to be able to form large enough clusters.

Table 5 provides an overview of the annotations per class. In the first three columns we see the number of table, attribute and row annotations. On average, we have 1.85 attribute annotations per table, not counting the label attribute. The two following columns show the number of annotated clusters, followed by the number of values within those clusters that match a knowledge base property. The second to last column shows the number of overall value groups, i.e. the number of cluster and property combinations for which at least one candidate value exists. For all groups we included facts, i.e. the correct value given the group's cluster and property. The last column shows for how many of the groups, the correct value is contained among the candidate values. We annotated 271 clusters, of which 39 % are new. On average, each cluster has approximately 3.42 rows, 7.69 values, 3.17 value groups and their facts, and 2.88 groups where the correct value is present in the web tables.

We use the gold standard for learning and testing. For this, we split the data into three folds and performed cross-validation. We ensured that we evenly split new clusters and homonym groups, which are groups of clusters with highly similar labels. All clusters of a homonym group were always placed in one fold.

The gold standard, along with the code and other data, is publicly available.[2] The results of this work are therefore replicable.

3 METHODOLOGY

In this section we present our system and evaluate alternative approaches for the individual components of the pipeline. As shown in Figure 1, the pipeline begins with the web tables and ends with entities being added to the knowledge base as new instances. In between, the pipeline consists of four components: schema matching, row clustering, entity creation and new detection.

We iterate over the pipeline twice. During the second run, we utilize the output of the row clustering and the new detection to generate a refined schema mapping. The attribute-to-property correspondences derived by the schema matching are important, because they allow us to extract for a row a set of values which correspond to the schema of the knowledge base. These values are utilized by the row clustering and new detection components with a positive impact on performance. More importantly, these values are required to create descriptions for new instances.

During the schema matching phase, we also match each table to a class in the knowledge base. Afterwards we run the remainder of the pipeline for each class separately.

3.1 Schema Matching

The first step in the pipeline is to create a mapping between the schemata of the individual web tables and the schema of the knowledge base. As the web tables have heterogeneous schemata, this task is non-trivial. Overall there are four steps necessary: (1) data type detection, (2) label attribute detection, (3) table-to-class matching and (4) attribute-to-property matching.

Data Type Detection

Throughout our pipeline we utilize a number of data types to type individual values, facts, attribute columns or knowledge base properties. Each type has a corresponding similarity function, and an equivalence threshold, which is used to determine if the compared values are equal. We employ overall six data types:

- **Text:** string, where two strings do not have to be exactly equal to be similar, e.g. label of an instance.
- **Nominal String:** string, where two strings are either completely equal or unequal, e.g. ISO code of a country.
- **Instance Reference:** reference to an instance, e.g. team of an athlete or musical artist of a song.
- **Date:** date with two possible granularities: year or specific day, e.g. release date of song, or birth date of a person.
- **Quantity:** numeric quantity, where numeric closeness has a semantic relevance, e.g. population of a settlement.
- **Nominal Integer:** integer, where numbers close to each other are not semantically related. This include e.g. numbers or draft rounds of athletes. Typing nominal integers in addition to nominal strings allows some components, especially the attribute-to-property matcher, to use methods tailored for this type.

We run a data-type detection algorithm [26] that assigns to each table attribute one of the following types: text, date and quantity. Detecting the other three types requires an understanding of the

[2] http://data.dws.informatik.uni-mannheim.de/expansion/LTEE/

Table 5: Overview of the gold standard.

Class	Tables	Attributes	Rows	Existing Clusters	New Clusters	Matched Values	Value Groups	Correct Value Present
GF-Player	192	572	358	81	19	1,207	475	444
Song	152	248	193	34	63	425	231	212
Settlement	188	162	376	49	25	451	152	124

actual semantics of an attribute, so that they are assigned by the attribute-to-property matcher, after an attribute has successfully been matched to a knowledge base property.

The data type detection is performed using manually defined regular expressions. We decide the data type of an attribute based on the majority data type among its values.

Label Attribute Detection

For each table we assign one column as the label attribute, which contains natural language labels for the entities described in the table rows [26]. For this we find the column with the data type text and the highest number of unique values. In case there is a tie between multiple columns, we choose the column that is furthest to the left [26].

Table-to-Class Matching

We utilize an approach that performs both row-to-instance and attribute-to-property matching to find the class of a table.

We first extract from the label attribute a label for each row, and use the label to find candidate instances from the knowledge base. A class, for which many rows of a table have a candidate instance, is chosen as a possible candidate class of that table. We assign the number of rows with a match as a score to that class.

Given these candidate classes, we then evaluate how well their properties match. We compare the values in the rows with facts of their candidate instance in the knowledge base, to find if they match a certain property of the candidate class. We block comparisons based on data type as detected above. Using the matched values we are able to perform duplicate-based attribute-to-property matching [5], where we chose the property with the highest number of matched cells as the property of the attribute, and assign the number as the score of the correspondence.

Per candidate class, we aggregate all scores to compute a ranked list of candidate classes. We choose the class with the highest score as the class of the table. This approach was proposed and evaluated by Ritze et al., where authors find that it can achieve an F1 score of 0.97 on a web table corpus [26].

Attribute-to-Property Matching

Our attribute-to-property matching approach consists of three steps. We first select candidate properties from the knowledge base schema based on data types. For text attributes, we choose all properties with types instance reference, nominal string and text, for quantity attributes we choose properties with types quantity and nominal integer and finally for date attributes, we choose properties with types date, quantity and nominal integer as candidates. After matching, the data type of the attribute is changed to the data type of the matched property and the values are accordingly normalized.

Secondly, we use various matchers, described further below, to compute matching scores. Given a candidate knowledge base property, a matcher finds a score from 0.0 to 1.0 that measures the likelihood that the attribute matches the property. Scores of multiple matchers are then aggregated based on a weighted average, where weights are learned for each class individually.

Table 6: Attribute-to-property matching performance by iteration.

Iteration	P	R	F1
First	0.929	0.608	0.735
Second	0.924	0.916	0.920
Third	0.929	0.916	0.922

We then utilize thresholds on the aggregated scores to determine if a certain candidate property matches an attribute. The thresholds are learned per property of the knowledge base schema. An attribute is matched to a property if it is both, a property that achieves a score above the property-specific threshold, and the property with the highest aggregated score.

Overall we implement five matchers, three of which exploit the knowledge base. `KB-Overlap` computes the proportion of values in the attribute that generally fit the candidate property in the knowledge base. `KB-Label` compares the label in the attribute header row to the labels of the candidate property in the knowledge base. `KB-Duplicate` computes the proportion of values in the attribute that is equal to the fact of the candidate property in the knowledge base, based on the instance correspondences generated by the new detection component.

We further implement two matchers that exploit the large web table corpus. For this, we first match attributes using the above described matchers for a preliminary mapping. We then rerun the matching using two additional matchers that exploit the preliminary mapping and the web table corpus. `WT-Label` utilizes the column headers of columns matched in the preliminary run, to derive label-to-property scores, where the score represents the likelihood that an attribute with a certain header row label corresponds to a certain candidate property of the knowledge base. `WT-Duplicate` knows through a previous row clustering run which rows in the tables describe the same instances. Using the preliminary mappings, we can find values in the corpus that are matched to same instance and property. This matcher measures and returns the proportion of values in an attribute, for which an equal value matched to same instance exists.

Table 6 shows by iteration the performance of an attribute-to-property matching method that aggregates all matchers. The duplicate-based methods are not included in the first iteration, as they require output from the other pipeline components. We evaluated the methods on the attribute annotations in the gold standard. We split the annotations first into a learning and a testing set, where the learning set contains two third of annotations.

From the table we can see that a second iteration and the utilization of the output of the row clustering and the new detection components have a large positive effect on schema matching performance. The table also shows that a third iteration has only a marginal positive effect, so that two iterations suffice.

To determine the usefulness of each individual matcher, we evaluate the weights assigned in the aggregated method of the second iteration. As we learn weights per class, the following weights are averages. The duplicate-based matchers have a combined weight of 0.43, where the `KB-Duplicate` matcher with a weight of 0.25 is more important. The label-based matchers achieve a higher combined weight of 0.46 where the `WT-Label` with a weight of 0.25 is very effective. Finally the `KB-Overlap` method is the least important method with a weight of 0.10. Additionally, the distribution of weights for the individual classes were similar to the here mentioned averages.

From the weights we can first of all see, that the attribute label is quite an effective method for schema matching. More importantly, we can conclude, that the most effective approach is one that combines various matchers and thereby exploits the highest number of individual signals for schema matching.

3.2 Row Clustering

After matching tables to classes and table attributes to properties of the knowledge base, we cluster rows that describe the same instance together. This step is especially important, as it reveals the overall number of unique instances described in the tables.

Our row clustering methods consist of a row similarity metric, which measures the likelihood that two rows describe the same instance, and a clustering algorithm, that utilizes the similarity metric to create clusters of rows.

In earlier work [25–27], we determined which rows describe the same instance by matching them to existing instances in the knowledge base. As a result, our earlier methods were unable to cluster rows of new instances, unlike in this work, where we perform clustering independently from existing instances.

Clustering Algorithm

In the context of this work, a required feature of the clustering algorithm is its ability to determine the number of clusters. In case of a perfect clustering, this number would correspond to the exact number of instances described by the rows of all tables.

Correlation clustering approaches [1, 2, 6, 10] fulfill this requirement. Clustering here is viewed as an optimization problem that aims to find the optimal partitioning of a set of vertices by maximizing a fitness function that aggregates similarities within a partition and dissimilarities between partitions.

Due to the large number of rows that need to be clustered (see Table 11), we need clustering methods that scale. As correlation clustering approaches try to find the globally optimum solution, they do not scale for the task at hand. We therefore utilize a greedy correlation clustering algorithm [15, 16], which solves the optimization problem locally for each decision made by the clusterer. The algorithm employs a row similarity function with a normalized output from −1.0 to 1.0 and sequentially tries to assign each row to the optimum cluster by summing the similarity scores of the current row with all individual rows in already created clusters in order to compute aggregated row-to-cluster scores. If there are scores larger than zero, the row is assigned to the cluster with the highest score. If no score is larger than zero, a new cluster is created, and the row is assigned to it. While every row assignment or cluster creation would maximize the fitness function locally, this does not ensure global optimization.

To achieve further scalability, we perform the row assignment in parallel instead of sequentially. While this is much faster, it can results in errors during clustering. We therefore run the Kernighan-Lin with joins (KLj) [19] clustering algorithm as a secondary step. The algorithm improves an existing preliminary clustering, in our case the output of the parallelized greedy clustering, by comparing cluster pairs and attempting to move individual rows between those clusters or merging the clusters fully. Similarly, each cluster is compared with an empty set to find whether splitting a cluster increases the fitness function locally. The operations are repeated until no further operation is able to increase the local fitness function.

As a result, we are able to quickly build a preliminary clustering with complete parallelization, while with a second step, we ensure that clustering quality is still high. Scalability is further ensured by the blocking approach described below.

Row Similarity Metrics

A row similarity metric compares two rows and returns a score that measures the likelihood that the two rows describe the same instance. Depending on the exact implementation, other input, e.g. from the knowledge base or the web table corpus, might be utilized. We implement six different similarity metrics:

- **`LABEL`:** We use the label attribute of a table to derive labels for all rows to then derive a similarity score by comparing labels using the Monge-Elkan similarity with Levenshtein as the inner similarity function.
- **`BOW`:** For each row we create a bag-of-words binary term vector that contains the terms that occur in all cells of a row. For this, cell values are cleaned, normalized and tokenized. To compare two rows, we compute the cosine similarity of their vectors.
- **`PHI`:** This approach allows us to compare two rows by comparing their tables. It derives a similarity between two tables using the PHI correlation of row labels, which we first compute using the following formula:

$$PHI(x,y) = \frac{n \times n_{xy} - n_x \times n_y}{\sqrt{n_x \times n_y \times (n - n_x) \times (n - n_y)}},$$

$$\begin{aligned} \text{where } n &= \text{total number of unique labels,} \\ n_{ab} &= \text{occurrence of labels a and b in same table,} \\ n_a &= \text{occurrence of label a in a table.} \end{aligned}$$

  For each label we therefore have a vector that measures its correlation with all other labels in the corpus. We then create such a vector for each table, by averaging the vectors of the table's row labels. With this we attempt to derive a vector that captures semantic information about all rows described in the table. When comparing two rows, we return the cosine similarity of the vectors of their tables.
- **`ATTRIBUTE`:** Using the attribute-to-property correspondences we can derive for each row values matched to the knowledge base schema. This allows us to perform value normalization and apply data-type-specific similarity functions to compare row values. If the two rows being compared have overlapping value pairs, so that both values are matched to same property, we use the data type similarity function to determine if those values are equal, assigning them a score of either 1.0 or 0.0. As there are possibly more than one overlapping value pair, the similarity returned equals to the average similarity scores of all pairs. Additionally, a confidence score is attached that

equals the number of pairs compared. This confidence score is used by the aggregation methods described below.

- **IMPLICIT_ATT:** Many tables have rows that describe instances that are similar, e.g. cities in Germany or athletes drafted in 2010. This information is not stated explicitly in any of the row cells. Using the following approach, we attempt to derive for a table implicit property-value combinations that apply to all instances described by the table. We can then use these implicit property-value combinations to compare rows with each other.
  We first use the row labels to find candidate instances for all rows, and then for each row all property-value combinations that exist for at least one candidate in the knowledge base. For each property-value combination we then derive a score for the whole table, which equals the proportion of rows that have this combination. We keep only combinations with a score above a certain threshold. The remaining combinations are the implicit attributes of a table and their score is assigned as a confidence score.
  Given two rows we compare the implicit attributes of one row with overlapping implicit attributes and column attributes of the other row and vice versa. We return the average of the similarities of all compared pairs and the sum of the implicit attribute scores as the confidence.
- **SAME_TABLE:** This metric builds on the observation that rows in a single table usually describe different entities. The metric assigns two rows of the same table a similarity of 0.0, otherwise 1.0.

Similarity Score Aggregation

We implement two approaches to aggregate the row similarity scores. We first utilize a weighted average, where the weights assigned to each metric are learned. In this case, attached confidence scores are not considered. We also learn a threshold, where scores above the threshold indicate that the rows describe the same instance. This threshold is used to normalize the similarity metric to −1.0 and 1.0. To learn the weights, we model the data in the learning set as row-pairs that either match or not, i.e. with scores of either 1.0 or 0.0. When learning weights we utilize a genetic algorithm that attempts to maximize the matching performance on the learning set.

As a second, alternative aggregation approach, we use random forest regression tree [7], where as features we include both similarity and confidence scores. We again model the data as row-pairs, where non-matching row-pairs are assigned a score of −1.0, while matching pairs a score of 1.0. To learn the random forest regression tree we utilize the WEKA library. We learn the hyperparameters of the algorithm by using the out-of-bag error with different out-of-bag rates on the learning set.

As a third aggregation approach, we combine both aggregation methods using a weighted average, where the weights are also learned as described above. In all cases we upsample to balance the number of matching and non-matching row pairs.

Blocking

To ensure the scalability of the row clustering for large web table corpora, we implement a blocking algorithm. We block comparisons by first limiting the number of clusters a row is compared to during the parallel greedy clustering, and, secondly, limiting the cluster pairs that are compared with each other during the KLj clustering.

Table 7: Average clustering performance and metric importance scores for alternative row clustering methods.

Run	PCP	AR	F1	MI
LABEL	0.71	0.83	0.76	0.33
+ BOW	0.73	0.84	0.78	0.18
+ PHI	0.74	0.84	0.78	0.05
+ ATTRIBUTE	0.75	0.85	0.80	0.21
+ IMPLICIT_ATT	0.78	0.87	0.82	0.17
+ SAME_TABLE	0.79	0.87	0.83	0.07

We utilize the row labels for the blocking mechanism. We first normalize the labels of all rows and use them to build a Lucene index. Each label in the index forms a block, which includes all rows with that exact label. For each row we use the index to retrieve a number of labels similar to the row's label, and assign their blocks to the row.

During the parallelized greedy clustering, we compare a row only to clusters with which the row shares a block. The blocks of a cluster are the union of the blocks of all rows in that cluster. Similarly, during the KLj clustering, two clusters are only compared when they share a block.

Evaluation

To evaluate the performance of the row clustering, we employ the evaluation approach proposed by Hassanzadeh et al. [17]. We use the set of clusters annotated in the gold standard, denoted as G, and the set of clusters returned by our method, denoted as C, to first compute a one-to-one mapping between the clusters in G and the clusters in C. We map a cluster in C to a cluster in G, if it contains the highest fraction of rows that are from that cluster in G. In case two clusters in C have the same proportion, we take the cluster with the highest absolute number of overlapping rows. We denote the mapping as M.

Using this mapping we compute average recall, penalized clustering precision and their F1 score. Average recall is the average of the individual recalls of the clusters in G. The recall of a cluster in G is equal to the ratio of rows in the mapped cluster from C that are also in G to the number of total rows in G. If no cluster from C was mapped to a cluster in G, the recall of that cluster is zero.

To compute the clustering precision we compute the precision of all pairs of rows that are part of the same cluster in C. A pair is determined to be correct if both rows are part of the same cluster in G. Unlike the average recall, this does not measure how well we find cluster, but how well we place rows in the same cluster.

As finding the correct number of unique instances described in the web tables is important, finding the correct number of clusters is important. We therefore penalize the clustering precision, as is also suggested by [17], if the number of returned clusters deviates from the correct number of clusters. We penalize by multiplying the clustering precision by a penalizing factor. This factor is computed by finding the sizes of C, G or M and dividing lowest by the highest size. We take this penalized clustering precision as the main precision-based score to evaluate our clustering.

Results and Lessons Learned

We will first evaluate the effectiveness of the individual row similarity metrics, and afterwards take a look at the effect of different aggregation methods as well as the blocking.

Table 7 shows the average performance of various row clustering methods using the third aggregation method, which combines random forest and weighted average. The first row contains the results when using only the LABEL metric. For every following row we aggregate one additional similarity metric. The last column of the table shows the metric importance, which is the average of the relative importance of the metric inside the learned random forest regression tree and the weights in the learned weighted average function. The importance scores shown are derived for the method that aggregates all metrics, i.e. the one that corresponds to the last row of the table.

The table shows that the similarity of row labels is the best indicator if two rows describe the same instance, as it has the highest average metric importance of 0.33 and with it we are able to achieve a moderate F1 of 0.76. At the same time, it alone is not enough and all other similarity metrics positively impact the row clustering performance when aggregated. This applies especially to the metrics BOW, ATTRIBUTE and IMPLICIT_ATT, which increase the F1 score by 2 percentage points each.

Both PHI and SAME_TABLE have smaller effects, as both only increase precision by 1 percentage point without an effect on recall. PHI likely achieves a low impact because it does not measure the similarity of two rows directly, but rather compares their tables. On the other hand, the same applies to IMPLICIT_ATT and it has a significantly higher impact. This shows the likely benefit of utilizing the knowledge base as background knowledge.

From the overall results, we can conclude that the best approach is to aggregate multiple metrics, thereby combining the different signals exploited by the individual metrics. The LABEL method utilizes the output of the label attribute detection, while the ATTRIBUTE method utilizes the knowledge base as background knowledge to semantically understand the attributes of the table. The IMPLICIT_ATT also exploits a knowledge base, but to assign semantic property-value combinations to its rows. Finally, the BOW method includes all information of a row, potentially covering information that couldn't be mapped to a schema.

The last row in Table 7 shows the clustering method that aggregates all metrics using a combination of random forest and weighted average. Applying both aggregation methods separately would have achieved an F1 score of 0.81 for weighted average and 0.82 for random forest.

Finally, the blocking yields no decrease in F1, which shows that it is an effective approach with minimal loss in recall.

3.3 Entity Creation

The entity creation component receives clusters of rows and transforms each cluster into an entity. First, an entity consists of one or more labels, which we extract from the label attribute of the entity's rows. More importantly, an entity contains a set of values mapped to the properties of the knowledge base. Given that at the row-level, each row can have multiple values matched to certain knowledge base properties, and that we have multiple rows in a cluster, there are likely to be multiple candidate values for one property when creating an entity. We therefore apply the following four-step method to fuse candidate values:

(1) **Scoring:** We score candidate values using one of the three alternative approaches described below.
(2) **Grouping:** We group equal values together. This is done using the data type specific similarity functions.
(3) **Selection:** We then select the group with the highest sum of individual candidate value scores.
(4) **Fusion:** We fuse a group into a fused value by using data type specific fusers. For text and instance reference types we utilize the majority value in a group, whereas for quantity and date types we use a weighted median approach. For nominal string and nominal integer, no fusion is necessary, as all values in a group will be equal.

We test three different scoring approaches. VOTING assigns all candidate values equal scores of 1.0. In the KBT [13] approach we measure for a certain table attribute the correctness of its overlapping values, i.e. those matched to an existing fact in the knowledge base, to estimate the trustworthiness of the whole attribute. Finally, the MATCHING approach utilizes the scores attached to a column by the attribute-to-property component. We measure the effect of the scoring approach using the output at the end of the pipeline. The results are discussed in Section 4.2.

The methods presented here are similar to those in our earlier works [22, 23, 27]. In this work, we additionally apply scores derived from the schema matching component for fusion.

3.4 New Detection

After creating entities from row clusters, we now determine whether a created entity describes a new instance, not yet present in the knowledge base. This is done by attempting to match the entities to existing instances by exploiting various features through entity-to-instance similarity metrics. If there are no instances found or the distance between an entity and an instance is large enough, the entity is determined to be new.

Additionally, for entities not classified as new, we attempt to match them to an existing instance in the knowledge base. These correspondences to existing instances are fed back into a second iteration of the pipeline to refine the schema mapping.

Our new detection approach consists of three steps:

Candidate Selection: We find a list of candidate instances from the knowledge base using a Lucene index built from the labels of knowledge base instances. To search candidates for an entity we utilize the labels attached to the entity in the entity creation component. Additionally candidates found must be of the class of the created entity or share one parent class.

Similarity Score Computation: We compute a score to measure the similarity between the created entity and a candidate instance. Multiple entity-to-instance similarity metrics are implemented and tested below.

Classification: If the highest similarity for any candidate instance is lower than a learned threshold, we classify the entity as new. Otherwise we find the candidate instance with the highest similarity score, and in case its score is higher than another threshold, the entity is classified as existing and a correspondence from the entity to that instance is generated.

In earlier work we presented methods that are solely concerned with matching rows to existing instances of a knowledge base, whereas with the methods presented here, we also determine whether rows have a match at all. Additionally, we do not match rows directly, but first create entities from row clusters, which allows us to exploit more information for matching.

Entity-To-Instance Similarity Metrics

As described above, the following metrics compute a similarity score between a created entity, and a one candidate instance of the knowledge base. We implement overall six different metrics:

- **LABEL:** We compute the similarity between the labels of the created entity and the labels of the candidate instance using Monge-Elkan with Levenshtein as the inner similarity function.

- **TYPE:** In DBpedia every class is part of a hierarchy with a certain number of parent classes. We compute the overlap of the classes of the candidate instance with the class of the entity and its parent classes.
- **BOW:** We create a bag-of-words binary term vector for the entity by combining the vectors of all its rows, which themselves are created as described in the row clustering approach. We then create a vector for the candidate instance in the knowledge base, using its labels, abstract and facts. We return the cosine similarity of both vectors.
- **ATTRIBUTE:** For each property, where a fact exists in both the created entity and the candidate instance in the knowledge base, we determine if the fused fact is equal to the fact in the knowledge base. As there could be multiple overlapping properties, we return an average similarity and a corresponding confidence score, which equals the number of overlapping properties.
- **IMPLICIT_ATT:** We utilize the implicit attributes derived for tables, as described in Section 3.2, to derive implicit attributes for a created entity. We sum up the confidence scores of equal implicit attributes for the tables of all rows in the entity and divide by the total number of rows to compute an entity-level confidence score. We then compare these property-value combinations at the entity level with overlapping facts of a candidate instance.
- **POPULARITY:** We use a dataset of Wikipedia page links to rank all candidate instances of an entity by their number of incoming page links. A similarity score is assigned to each candidate based on its rank. If an entity has only one candidate instance, we assign it a score of 1.0.

Similarity Score Aggregation

We aggregate various similarity scores using the same aggregation approaches utilized for row clustering.

Evaluation

We evaluate the new detection component using the clusters annotated in the gold standard. Before we run new detection on those clusters, we create entities from them as outlined in Section 3.3 above. From the gold standard we know whether a certain created entity describes a new instance or not. In case it describes an existing instance, we additionally know from the gold standard the exact instance it describes.

When running the new detection component on those entities, we receive a set of entities classified as new, and another set classified as existing with additional correspondences to existing instances in the knowledge base. We can now use the gold standard to determine the accuracy of those classifications, which equals the fraction of correctly classified entities. Existing entities must additionally be matched to the correct instance in the knowledge base to be counted as correctly classified.

As the accuracy measures the classification performance for both the new and existing instances, we additionally evaluate both separately using F1. The precision of the new entities equals the fraction of entities returned with a new classification that were correctly classified as new, whereas recall is equal to the fraction of total new entities in the gold standard that were correctly classified as new. The same applies to the existing entities, with a second condition that the entity must be matched to the correct instance in the knowledge base as well.

Table 8: Average performance and metric importance scores for alternative new detection methods.

Run	ACC	$F1_{\text{Existing}}$	$F1_{\text{New}}$	MI
LABEL	0.69	0.66	0.67	0.20
+ TYPE	0.79	0.75	0.82	0.26
+ BOW	0.85	0.84	0.83	0.17
+ ATTRIBUTE	0.85	0.86	0.84	0.20
+ IMPLICIT_ATT	0.88	0.87	0.89	0.11
+ POPULARITY	0.89	0.88	0.88	0.06

Results and Lessons Learned

Table 8 shows the performance of various new detection methods. All numbers in table are averages of all classes and folds. The first row shows a method that only utilizes the label. For each following row we aggregate an additional similarity metric into the method using the combined aggregation approach. The metric importance shown in the last column reflects a score derived from the random forest and the weights in a method that aggregates all metrics, i.e., the method described in the last row.

From the table we can see that with an accuracy of 0.89, the final aggregated method performs quite well. It achieves a performance considerably better than the LABEL method, which only has an accuracy of 0.69. Additionally we can see that all similarity metrics are important and contribute positively to the overall performance. This shows that the combined approach is able to leverage the different features exploited by the individual metrics. The LABEL metric does however have a high importance score, even though the candidate selection already only returns candidates with similar labels.

The later a metric is aggregated, the more difficult it is to yield a large absolute increase in performance. As such, the metrics TYPE and BOW increase accuracy by 10 and 6 percentage points respectively, which is much larger than for metrics added later. At the same time we see, that ATTRIBUTE, which has a higher importance score than BOW, does not increase accuracy at all. It does however increase the individual F1 scores.

Noticeable is also the increase achieved by the IMPLICIT_ATT metric. It is able to improve the accuracy by further 3 percentage points, even though it is the second to last metric to be aggregated. This means, that we are successfully able to leverage the knowledge base as background knowledge to derive semantically relevant property-value combinations per table and entity.

The POPULARITY metric only impacts performance for the Settlement class. This means that, given just the name of a settlement, it is safe to assume that the most well-known settlement is meant. This makes sense, as this assumption is typically made when speaking about cities in general.

The last row shows the performance of a new detection method that aggregates all metrics using a combined approach of weighted average and random forest. When using the aggregation methods separately, we achieve an accuracy of 0.85 and 0.86 respectively. The combined approach is therefore able to exploit both aggregation methods to achieve a higher performance.

4 OVERALL RESULTS ON THE GOLD STANDARD

In this section, we choose the best methods for clustering and new detection, and evaluate the output of a complete run of our system using our gold standard. We will first evaluate how

Table 9: Results of new instances found evaluation.

Class	Clust.	New Det.	P	R	F1
GF-Player	GS	ALL	0.89	0.95	0.91
GF-Player	ALL	ALL	0.82	0.95	0.87
Song	GS	ALL	0.92	0.88	0.90
Song	ALL	ALL	0.72	0.72	0.72
Settlement	GS	ALL	0.84	0.90	0.87
Settlement	ALL	ALL	0.74	0.87	0.80
Average	ALL	ALL	0.76	0.85	0.80

many of the new instances were correctly found, while in the second part, we will evaluate how many correct facts were found. Throughout this evaluation we utilize three fold cross-validation.

4.1 New Instances Found Evaluation

To evaluate how well new instances were found, we utilize precision and recall. First, we determine the number of new instances annotated in the testing sets, for which an entity was correctly returned by the system. For this, three conditions must be met. First, a majority of the rows of an entity must correspond to the same new instance in the gold standard, while at the same time the entity must also contain the majority of the rows that actually describe that instance. Lastly, the entity must be classified as new by the new detection component. Based on this, recall is defined as the fraction of new instances in the gold standard for which a correct entity was returned. Precision, on the other hand, is the fraction of entities returned by the system as new, that correctly match an instance in the gold standard.

Table 9 shows the performance of our system for the three classes separately. To evaluate the individual impact of row clustering and new detection, we once evaluate using the clustering from the gold standard, denoted GS, and once with the aggregated clustering method containing all similarity metrics, denoted ALL. For new detection we run in both cases the aggregated method containing all similarity metrics, also denoted ALL.

Generally, we achieve good performance for football players and settlements, while for songs the performance is less convincing. This is likely, because for songs, the homonym problem is much larger. It is much more likely that there exist songs of the same name by various artists. Sometimes these homonyms even represent cover versions, so that they are highly similar in their descriptions, e.g. in runtime or writer.

When investigating how much performance is lost by the individual components, we find that for football players and settlements the new detection component is causing a larger decrease than the row clustering. More specifically, the drop is mainly caused by classifying entities as new even though they should be matched to existing instances. This is confirmed by the recall being higher than precision. For songs, the clustering causes a much larger decrease in performance, showing that the clustering task is more difficult for songs, and that we require more sophisticated clustering methods.

4.2 Facts Found Evaluation

In this section we evaluate how well we can generate facts from web tables for new entities. Again, we need a mapping between entities returned and instances in the gold standard, for which we utilize the approach described above. For wrongly created entities, or entities incorrectly determined to be new, i.e. they could not be mapped to a new cluster in the gold standard, their facts are counted as wrong and therefore reduce precision. To determine if returned facts for matched entities are correct, they are compared to the facts in the gold standard using data type specific similarity functions and a learned tolerance range. To measure recall, we utilize the number of annotated facts for which a correct value is present in the web tables, as seen in Table 5.

Table 10: Results of the facts found evaluation.

		New	F1	F1	F1
Class	Clust.	Det.	`VOTING`	`KBT`	`MATCHING`
GF-Player	GS	GS	0.82	0.82	0.82
GF-Player	GS	ALL	0.81	0.81	0.81
GF-Player	ALL	ALL	0.81	0.81	0.81
Song	GS	GS	0.80	0.81	0.81
Song	GS	ALL	0.74	0.73	0.74
Song	ALL	ALL	0.67	0.69	0.68
Settlement	GS	GS	0.98	0.98	0.98
Settlement	GS	ALL	0.93	0.93	0.93
Settlement	ALL	ALL	0.91	0.91	0.91
Average	ALL	ALL	0.80	0.80	0.80

Table 10 shows fusion performance per class. In order to measure the individual impact of the new detection and the row clustering on the overall performance, we again perform multiple runs. For the first run, we utilize for both components the correct annotations from the gold standard. In the following run we use our new detection methods, while for the third run we additionally use our clustering methods, in both cases using the methods that aggregate all similarity metrics. Additionally we test performance for the different fusion scoring methods, `VOTING`, `KBT` and `MATCHING`, described in Section 3.3.

From the table we can see that for football players and songs we lose 18 and 19 percentage points of F1 score even when row clustering and new detection are perfect. We looked at a sample of errors and were able to identify two main causes. The largest amount of errors is due to the attribute-to-property matching component, where the proportion of errors caused by wrong or missing column matches makes up 43 % of all errors. This is followed by 35 % of errors that occurred as a result of wrong or outdated data in the tables.

In addition, we evaluate various fusion scoring approaches. We find that all performances are very close, so that the choice of scoring approach is of low relevance.

Finally, we can deduce from the table the individual impacts of the pipeline components on the performance. The largest negative impact is due to errors in finding facts as described above, of which the attribute-to-property matching is a large contributor. Not as large are the individual impacts of the row clustering and new detection components, but they are still significant ranging from 1 to 13 percentage points. Overall, the way errors compound throughout the pipeline shows the difficult nature of the task at hand. Every individual component has to perform very well for there to be good performance at the end of the pipeline.

5 LARGE-SCALE PROFILING

In this section we try to estimate the potential of web tables for extending knowledge bases with new instances, by running our system on not only the tables of the gold standard, but on all tables of a specific class within the whole corpus (see Table 4). We are especially interested in how many new instances we can correctly add per class and how that compares to the number of existing instances in the knowledge base. We additionally are interested in the descriptions of these new instances, the number and accuracy of facts, and property densities of the new instances.

Evaluation

From the entities returned as new by the system, we pull a stratified sample of 50 entities for each class. We group the returned entities by the number of facts generated for each entity. We then pull from each group a number of entities proportional to the size of the group in relation to the total number of new entities.

The accuracy of new entities equals the fraction of entities that were correctly identified as new when compared to the 2014 release of DBpedia, while the accuracy of facts equals the proportion of facts within those new entities that are correct.

Results and Lessons Learned

Table 11 shows the results of the large-scale profiling per class. The second column lists the number of rows of all tables matched to the given class. The three columns afterwards describe existing entities found, to how many unique instances in the knowledge base they were matched, and the ratio of the two numbers. The remaining columns contain the number of new entities, their facts, the relative increases when compared to Table 1 and the accuracies of new entities and facts of the extracted sample.

First of all, we find that the ratio of existing entities to matched instances in the knowledge base differs by class. While for players and settlements the number is good, it is less so for songs. Song was the class with the worst performance at row clustering, i.e. identifying the exact number of unique instances. This shows, that we need to implement more sophisticated row clustering methods or, alternatively, perform deduplication after clustering.

For the class Song we have a very large number of new entities and facts, even if we would correct the number of new entities by the ratio in the fifth column. For Settlement, there are in comparison very few new entities. When considering that only 26 % of them are correct, we would actually achieve a relative increase in knowledge base instances of 0.3 %. The difference can be explained by understanding the notability rules of Wikipedia.

There are a very large number of obscure songs. It is very common, even for well-known artists, to release for example only a few songs from an album as singles, which are the only ones that become popular. And here the notability rules compound the issue, as songs only receive their own Wikipedia article if they are notable, e.g. because they were independently released.

For Settlement, almost the opposite is true. While there are many small villages, they are never irrelevant, as there are always enough people living in them, who might contribute to a Wikipedia article. More importantly, Wikipedia deems any place notable if it has legal recognition. As a result, Wikipedia covers a lot of settlements, and it is difficult to find new ones.

Football players are in the middle of both classes. There are not as many obscure football players, as, theoretically speaking, the number of teams is limited, but there are many that are obscure enough, not to be covered in a Wikipedia article. And while the absolute number of newly added players is not high, compared to the number of existing instances in the knowledge base, we achieve an increase of 67 % for instances and 32 % for facts.

Table 12 shows the property densities for new entities. As one would expect, the properties are not as dense as in Table 2. More importantly, the distribution of densities differs significantly. For football players, personal properties like birthDate and birthPlace have a very low density for new instances, but high for the knowledge base. This might be, because in Wikipedia one is interested in describing a person, whereas in web tables, the games, teams and drafts are more in focus. For those tables, a property like position might be more relevant, which explains why its density is even higher than in the knowledge base.

For songs, the properties writer, genre, and record label have very low densities compared to the knowledge base. It is likely that for genre, this is a column matching issue, as song genres are not always objectively defined. For writer and recordLabel there could be two causes. First, they might be uninteresting properties, and secondly, there are often multiple correct facts. The record label might even differ by country. This makes these properties difficult to match, and, more importantly, unlikely to be included in a table. We can confirm the latter, as these properties occurred very rarely in the tables we annotated for the gold standard.

When looking at the accuracies of new entities we also find differences per class. We achieve a moderate accuracy for songs, a sub-par accuracy for players and a low accuracy for settlements.

The primary reason for the low accuracy for settlements are conflicting values in an entity of an existing instance and the instance in the knowledge base. This includes outdated population numbers, but also isPartOf values, where the values in the entity and in the knowledge base are both correct, but different, preventing the entity from matching. This problem makes up 36 % of all errors. 25 % of errors are because the new entity does not describe a settlement, but a different place, like a region or a mountain. This error is caused by incorrect table-to-class matching. These problems are magnified because there are so few new entities to begin with, so that these corner cases make up a huge proportion of the new entities returned.

For GF-Player, the sources of errors include bad column-to-attribute matching, entities not being football players due to bad table-to-class matching, and incomplete information in DBpedia. The latter happened primarily when a football athlete was not assigned the correct class in DBpedia. The accuracy for entities with a higher number of values is however much higher. If we do not consider entities with one value, the accuracy of new entities rises to 0.72. If we further do not consider entities with two values, we achieve an accuracy of 0.85. This would mean excluding 6,360 entities, but also that with an accuracy of 0.85 we can add 7,623 entities with 34,922 facts to the knowledge base, an increase of 37 % for instances, and 25 % for facts.

For songs, the sources of errors are versatile. The main contributors are bad new detection, incorrect table-to-class matching, and bad clustering. The latter meaning that an entity was incorrectly detected as new, as a result of being created from rows that describe different instances.

We generally notice that the performance does not correlate with the performance on the gold standard. This might indicate that the gold standard either does not completely reflect the nature of the task, or the gold standard is not large enough. On the other hand, we achieve a consistently high accuracy for new facts, similar to the high performance on the gold standard, as seen in Section 4.2. This means that when it comes to finding descriptions, our performance is quite good, even if the density is lower when compared to the knowledge base.

Table 11: Results and evaluation of a system run on all tables matched to a class.

Class	Total Rows	Existing entities	Matched KB instances	Matching Ratio	New Entities	New Facts	N. Entities Accuracy	N. Facts Accuracy
GF-Player	648,741	30,074	24,889	1.21	13,983 (+67%)	43,800 (+32%)	0.60	0.95
Song	2,173,536	40,455	29,140	1.39	186,943 (+356%)	393,711 (+125%)	0.70	0.85
Settlement	1,472,865	28,628	27,365	1.05	5,764 (+1%)	7,043 (+0%)	0.26	0.94

Table 12: Property densities for new entities returned by the full run.

Class	Property	Facts	Density
GF-Player	position	9,204	65.82%
GF-Player	team	7,637	54.62%
GF-Player	college	6,849	48.98%
GF-Player	weight	5,915	42.30%
GF-Player	height	4,253	30.42%
GF-Player	number	2,951	21.10%
GF-Player	birthDate	2,537	18.14%
GF-Player	draftPick	2,404	17.19%
GF-Player	draftRound	1,538	11.00%
GF-Player	draftYear	386	2.76%
GF-Player	birthPlace	126	0.90%
Song	musicalArtist	143,656	76.84%
Song	runtime	115,652	61.86%
Song	album	52,664	28.17%
Song	releaseDate	47,377	25.34%
Song	genre	23,814	12.74%
Song	recordLabel	10,278	5.50%
Song	writer	270	0.14%
Settlement	isPartOf	2,889	50.12%
Settlement	postalCode	1,605	27.85%
Settlement	country	1,232	21.37%
Settlement	populationTotal	1,214	21.06%
Settlement	elevation	103	1.79%

Overall we find that for some classes there is high potential for finding new instances using web tables. Additionally, we also find that the performance of our system for these classes is generally good. Yet, it is clear that more sophisticated approaches are necessary for row clustering, new detection and table-to-class matching.

6 RELATED WORK

This section compares our method to the related work. As we investigate a new problem, we compare to research on similar tasks as well as on specific subtasks, including slot filling, set expansion, schema matching and identity resolution.

Slot Filling

Many works that exploit web table data for knowledge base augmentation [11, 25–29] focus on the task of slot filling, i.e. adding missing facts for existing instances. One prominent state of the art work by Dong et al. [11] introduces a probabilistic approach that exploits background knowledge, in their case Freebase, to construct a large knowledge base using web data, including web tables. The extracted facts however only describe instances that already exist in Freebase [11, 12].

While slot filling is a different task, we can still generally compare the numbers of generated facts. In a previous work, where we use web tables to perform slot filling for DBpedia [27], we are able to find 378, 892 facts, 64, 237 of which are new facts for existing instances. We reach an F1 score of 0.71. Compared to that work, we are able to achieve better numbers and accuracy. In the work by Dong et al., the authors are able to find 271 M facts for instances in Freebase with an expected correctness higher than 90 %. Of those facts, 90 M are new facts for existing instances. While the amount of facts that we discover are much smaller, we are only dealing with three classes and looking at facts only for new instances. Additionally we only use web tables to extract new facts, while Dong et al. also use free text, HTML DOM trees and schema.org annotations. Our average accuracy of 0.91 for facts of new entities is comparable.

Set Expansion

Set expansion is a task, where new instances are retrieved to complete a set [24, 31, 32]. Set expansion methods, however, only focus on finding the labels of new instances. The methods rely on seeds from that set to perform set expansion. Both, the complete sets and the number of seeds, are often small. In contrast, we focus on a scenario in which large sets of entities, already contained in the knowledge base, are extended with potentially large sets of new instances. Finally, most set expansion methods make use of ranked evaluation, where the precision of the top k instances is measured. In contrast, our evaluation not only focuses on precision, but also considers recall.

One set expansion method exploits a corpus of relational tables to augment an incomplete relational table with new instances and their descriptions [33]. The methodology differs significantly from ours. To find more instances, the method uses sets of 1 to 5 seed instances to first search for candidates in the tables. For this, it exploits the labels of the seeds and the caption of the seed table. Candidates are then ranked based on how often they co-occur with the seeds and how similar their tables' captions are. Similarly, the method searches for candidate columns in the corpus and ranks them based on how well they fit the seed table. The method then returns a fixed number of entities, where the authors use 256 as their cut-off. While this approach does generate descriptions, it does not resolve any of the following problems of set expansion. Their approach still ranks candidate entities based on their similarity to the seeds, and, more importantly, always returns a fixed number of instances. Especially the latter makes this approach not applicable to our task, as we are interested in generating as many new instances as possible.

To compare our work with works of set expansion, we need to utilize ranked evaluation and therefore need to implement a ranking algorithm for new entities. We rank based on the similarity scores returned by the new detection. These scores measure the distance between one or more existing instance in the knowledge base, and an entity generated from the web tables. We rank new entities higher, the higher their lowest distance to the closest existing instance is. Using this, we achieve a MAP, with a cut-off at 256, of 0.88, while related works achieve 0.63 [33], 0.95 [32] and 0.78 [31]. For precision at 5 and 20 we achieve 0.84 and 0.78 respectively, while a related work achieves 0.94 and 0.91 [33]. We find that our performance is comparable, even though the task we are solving is more difficult.

Schema Matching and Identity Resolution

Throughout the components of the pipeline, we apply approaches for which a large corpus of related work exists. This includes schema matching methods, which are surveyed in [3]. For row clustering and new detection we essentially exploit identity resolution methods, which are extensively surveyed in [9, 14].

For the specific use case of matching web table attributes to DBpedia properties, authors from our research group were able to achieve an F1 score of 0.81 [25]. While our performance of 0.92 is higher, we consider a smaller number of classes and properties.

There exists a large corpus of research on the task of matching web table rows to existing knowledge base instances. While this task is not a primary objective of this paper, we are able to evaluate our pipeline by comparing how well we are able to perform this task. We achieve an average F1 score of 0.83, compared to 0.80 [25] and 0.87 [34] in the related work, and we achieve an accuracy of 0.78, compared to 0.83 [21] and 0.93 [4] in the related work. While for F1, our performance is comparable to the related work, it is lower when it comes to accuracy.

7 CONCLUSION

This paper explored the potential of web table data for extending a cross-domain knowledge base with new long tail entities and their descriptions according to the schema of the knowledge base. To the best of our knowledge, this specific task has to this date not been handled in related research. For this task, we present and evaluate a complete system. It consists of a pipeline with multiple components, including schema matching, row clustering, entity creation and new detection.

We evaluated our pipeline using a manually annotated gold standard of web tables. We find that the task is non-trivial, as it requires good performance in all steps of the process. For all components of the pipeline we implemented and evaluated multiple alternative methods. We find that aggregating the similarity scores of multiple metrics that exploit different features yields the best results. We also find that metrics that make use of label similarity, while highly important, are not sufficient to yield a good performance. Additionally, we are able to show that metrics that use the knowledge base as background knowledge, e.g. to semantically understand cell values or to derive semantic information about web tables, have a positive impact on performance. Finally, we are able to utilize the output of the pipeline in a second iteration to achieve a large improvement in schema matching performance, while any further iteration has negligible impact.

We are successfully able to utilize our pipeline and our proposed implementations of the pipeline's components to find new instances and their descriptions from the web tables. At the same time, there remains room to further improve the quality of the generated data.

Finally we run the method on the complete web table corpus to profile the overall potential of web tables in augmenting a knowledge base class with new instances. We find that this potential differs per class, but at the same time, we find that for some classes a large number of instances and facts with a high accuracy can successfully be added to the knowledge base.

ABSTRACT

Today machine learning is entering many business and scientific applications. The life cycle of machine learning applications consists of data preprocessing for transforming the raw data into features, training a model using the features, and deploying the model for answering prediction queries. In order to guarantee accurate predictions, one has to continuously monitor and update the deployed model and pipeline. Current deployment platforms update the model using online learning methods. When online learning alone is not adequate to guarantee the prediction accuracy, some deployment platforms provide a mechanism for automatic or manual retraining of the model. While the online training is fast, the retraining of the model is time-consuming and adds extra overhead and complexity to the process of deployment.

We propose a novel continuous deployment approach for updating the deployed model using a combination of the incoming real-time data and the historical data. We utilize sampling techniques to include the historical data in the training process, thus eliminating the need for retraining the deployed model. We also offer online statistics computation and dynamic materialization of the preprocessed features, which further reduces the total training and data preprocessing time. In our experiments, we design and deploy two pipelines and models to process two real-world datasets. The experiments show that continuous deployment reduces the total training cost up to 15 times while providing the same level of quality when compared to the state-of-the-art deployment approaches.

1 INTRODUCTION

In machine learning applications, a pipeline, a series of complex data processing steps, processes a labeled training dataset and produces a machine learning model. The model then has to be deployed into a deployment platform where it answers prediction queries in real-time. To properly preprocess the prediction queries, typically the pipeline has to be deployed alongside the model.

A deployment platform must be robust, i.e., it should accommodate many different types of machine learning models and pipelines. Moreover, it has to be simple to tune. Finally, the platform must maintain the quality of the model by further training the deployed model when new training data becomes available.

Online deployment of machine learning models is one method for maintaining the quality of a deployed model. In the online deployment approach, the deployment platform utilizes online learning methods to further train the deployed model [13]. In online learning, the model is updated based on the incoming training data. Online learning adapts the model to the new training data and provides an up-to-date model. However, online learning is sensitive to noise and outliers which may result in an increase in the prediction error rate. Therefore, to guarantee a high level of quality, one has to tune the online learning method to the specific use case [22, 23]. Thus, effective online deployment of machine learning models cannot provide robustness and simplicity.

To solve the problem of degrading model quality, periodical deployment approach is utilized. In the periodical deployment approach, the platform, in addition to utilizing simple online learning, periodically retrains the deployed model using the historical data. One of the challenges in many real-world use cases is the size of the training datasets. Typically, training datasets are extremely large and require hours or days of data preprocessing and training to result in a new model. Despite this drawback, in some applications, retraining the model is still critical, as even a small increase in the quality of the deployed model can have a large impact. For example, in the domain of ads click-through rate (CTR) prediction, even a 0.1% accuracy improvement yields hundreds of millions of dollars in revenue [21]. In the periodical deployment approach, while the model is being retrained, new prediction queries and training data are still arriving at the deployment platform. However, the platform has to answer the prediction queries using the currently deployed model. Moreover, the platform appends the new training data to the historical data. By the time the retraining process is over, enough training data is accumulated which requires the deployment platform to perform another retraining. As a result, the deployed model quickly becomes stale.

Although periodical deployment is robust and easy to tune, it cannot maintain the quality of the deployed model without incurring a high training cost. We propose a deployment platform that eliminates the need for retraining, thus significantly reducing the training cost while achieving the same level of quality as the periodical deployment approach. Our deployment platform is robust, i.e., it accommodates many different types of machine learning models and pipelines. Moreover, similar to the periodical deployment, the tuning process of our deployment platform is simple and requires the same amount of user interaction as the periodical deployment.

Our deployment platform continuously updates the model using a combination of the historical and incoming training data. Similar to existing deployment platforms, our platform also utilizes online learning methods to update the model based on the incoming training data. However, instead of the periodical retraining, our deployment platform performs regular updates to the model based on samples of the historical data. Our deployment platform offers the following two features:

Proactive training. Proactive training is the process of utilizing samples of the data to update the deployed model. First, the deployment platform processes a given sample using the pipeline, then it computes a partial gradient and updates the deployed model based on the partial gradient. The updated model is immediately ready for answering prediction queries. Our experiments show that proactive training reduces the training time by one order of magnitude while providing the same level of quality when compared to the periodical deployment approach.

Online Statistics Computation and Dynamic Materialization. Before updating the model using proactive training, the pipeline has to preprocess the training data. Every component of the pipeline needs to scan the data, updates the statistics (for example the mean and the standard deviation of the standard scaler component), and finally, transform the data. Computing these statistics and transforming the data are time consuming processes. Aside from the proactive training, our deployment platform also employs online

Series ISSN: 2367-2005

10.5441/002/edbt.2019.35

learning methods to update the model in real-time. During the online learning, we compute the required statistics and transform the data. The deployment platform stores the updated statistics for every pipeline component and materializes the transformed features by storing them in memory or disk. In presence of a limited storage capacity, the platform removes the older transformed features, and only re-materializes them when needed (through a process called *dynamic materialization*). By reusing the computed statistics and the materialized features during the proactive training, we eliminate the data preprocessing steps of the pipeline and further decrease the proactive training time.

In summary, our contributions are:

- A platform for continuously training deployed machine learning models and pipelines that adapts to the changes in the incoming data. The platform accommodates different types of machine learning models and pipelines. In our experiments, we design and deploy two different machine learning pipelines.
- Proactive training of the deployed models and pipelines that frequently updates the model using samples of the data which completely eliminates the need for periodical retraining while providing the same level of model quality.
- Efficient pipeline processing and model training by online statistics computation and dynamic materialization, which provides up-to-date models for answering prediction queries.

The rest of this paper is organized as follows: In Section 2, we provide background information on the optimization strategy we utilize in our continuous deployment platform and tuning mechanism of the existing deployment platforms. Section 3 describes the details of our continuous training approach. In Section 4, we introduce the architecture of our deployment platform. In Section 5, we evaluate the performance of our continuous deployment platform. Section 6 discusses the related work. Finally, Section 7 presents our conclusion and the future work.

2 BACKGROUND

To continuously train the deployed model, we compute partial updates based on the current model parameters and a combination of the incoming and existing data. To compute the partial updates, we utilize Stochastic Gradient Descent (SGD) [36]. SGD has several parameters (typically referred to as hyperparameters) and in order to work effectively, they have to be tuned. In this section, we describe the details of SGD and its hyperparameters and discuss the effect of the hyperparameters on training machine learning models.

2.1 Stochastic Gradient Descent

Stochastic Gradient Descent (SGD) is an optimization strategy utilized by many machine learning algorithms for training a model. SGD is an iterative optimization technique where in every iteration, one data point or a sample of the data points is utilized to update the model. SGD is suitable for large datasets as it does not require scanning the entire data in every iteration [5]. SGD is also suitable for online learning scenarios, where new training data becomes available one at a time. Many different machine learning tasks such as classification [23, 36], clustering [6], and matrix factorization [19] utilize SGD in training models. SGD is also the most common optimization strategy for training neural networks on large datasets [12].

To explain the details of SGD, we describe how it is utilized to train a simple linear regression model. In linear regression, the goal is to find the weight vector(w) that minimizes the least-squares cost function ($J(w)$):

$$J(w) = \frac{1}{2}\sum_{i=1}^{N}(x^i w - y^i)^2 \tag{1}$$

where N is the size of the training dataset. To utilize SGD for finding the optimal w, we start from initial random weights. Then in every iteration, we update the weights based on the gradient of the loss function:

$$w^{t+1} = w^t + \eta \sum_{i \in S}(y^i - x^i w)x^i \tag{2}$$

where η is the learning rate hyperparameter and S is the random sample in the current iteration. The algorithm continues until convergence, i.e., when the weight vector does not change after an iteration.

Learning Rate. An important hyperparameter of stochastic gradient descent is the learning rate. The learning rate controls the degree of change in the weights during every iteration. The most trivial approach for tuning the learning rate is to initialize it to a small value and after every iteration decrease the value by a small factor. However, in complex and high-dimensional problems, the simple tuning approach is ineffective [27]. Adaptive learning rate methods such as Momentum [26], Adam [18], Rmsprop [31], and AdaDelta [35] have been proposed. These methods adaptively adjust the learning rate in every iteration to speed up the convergence rate. Moreover, some of the learning rate adaptation methods perform per coordinate modification, i.e., every parameter of the model weight vector is adjusted separately from the others [18, 31, 35]. In many high-dimensional problems, the parameters of the weight vector do not have the same level of importance, therefore each parameter must be treated differently during the training process.

Sample Size. Another hyperparameter of stochastic gradient descent is the sample size (sometimes referred to as the mini-batch size). Given proper learning rate tuning mechanism, SGD eventually converges to a solution regardless of the sample size. However, the sample size can greatly affect the time that is required to converge. Two extremes of the sample size are 1 (every iteration considers 1 data item) and N (similar to batch gradient descent, every iteration scans the entire dataset). Setting the sample size to 1 increases the model update frequency but results in noisy updates. Therefore, more iterations are required for the model to converge. Using the entire data in every iteration leads to more stable updates. As a result, the model training process requires fewer iterations to converge. However, because of the size of the data, individual iterations require more time to complete. A common approach is mini-batch gradient descent. In mini-batch gradient descent, the sample size is selected in such a way that each iteration is fast. Moreover, the training process requires fewer iterations to converge.

2.2 Tuning the Periodical Deployment

Typically, two groups of hyperparameters affect the efficiency of the periodical deployment approach. The first group (the deployment hyperparameters) control the frequency and amount of data for every retraining. The second group (the training hyperparameters) tune the algorithm for retraining procedure. In this work, we are targeting training algorithms based on Stochastic gradient descent. Therefore, the hyperparameters are the learning rate and the sample size.

There are several existing approaches for tuning the training hyperparameters, such as grid search, random search, and sequential model based search [4, 17]. The deployment hyperparameters, however, are typically selected to fit the specific use case. For example, in many of the real-world use cases, one retrains the deployed model using the entire historical data (hyperparameter for the amount of data for every retraining) on a daily basis (hyperparameter for the frequency of the retraining). In the next sections, we describe how we tune the deployment and training hyperparameters of our deployment framework.

3 CONTINUOUS TRAINING APPROACH

In this section, we describe the details of our continuous training approach. Figure 1 shows the workflow of our proposed platform. The platform processes the incoming training data through 5 stages:

1. Discretizing the data: To efficiently preprocess the data and update the model, the platform transforms the data into small chunks and stores them in the storage unit. The platform assigns a timestamp to every chunk indicating its creation time. The timestamp acts as both a unique identifier and an indicator of the recency of the chunk.

2. Preprocessing the data: The platform utilizes the deployed pipeline to preprocess the raw training data chunks and transform them into feature chunks. Then, the platform stores the feature chunks along with a reference to the originating raw data chunk in the storage unit. When the storage unit becomes full, the platform starts removing the oldest feature chunks and only keep the reference to the originating raw data chunks. In case the later stages of the deployment platform request a deleted feature chunk, the platform can recreate the feature chunk by utilizing the referenced raw data chunk. During the preprocessing stage, we utilize *online statistics computation* to compute the required statistics for the different pipeline components. These statistics speed up the data processing in later stages.

3. Sampling the data: A sampler unit samples the feature chunks from the storage. Different sampling strategies are available to address different use-case requirements.

4. Materializing the data: Depending on the size of the storage unit, some preprocessed feature chunks (results of step 2) are not materialized. If the sampler selects unmaterialized feature chunks, the platform recreates these feature chunks by utilizing the deployed pipeline through a process called *dynamic materialization.*

5. Updating the model: By utilizing the preprocessed feature chunks, the platform updates the deployed model through a process called *proactive training.*

In the rest of this section, we first describe the details of the online statistics computation the platform performs during the preprocessing step. Then we introduce the dynamic materialization approach and the effects of different sampling strategies on the materialization process. Finally, we describe the details of the proactive training method.

3.1 Online Statistics Computation

Some components of the machine learning pipeline, such as the standard scaler or the one-hot encoder, require some statistics of the dataset before they process the data. Computing these statistics requires scans of the data. In our deployment platform, we utilize online training as well as proactive training. During the online update of the deployed model, we compute all the necessary statistics for every component. Every pipeline component first reads the incoming data. Then it updates its underlying statistics. Finally, the component transforms and forwards the data to the next component. Online computation of the required statistics eliminates the need to recompute the same statistics during the dynamic materialization and proactive training.

Online statistics computation is only applicable to certain types of pipeline components. The support for stateless pipeline components is trivial as they do not rely on any statistics before transforming the data. For stateful operations, since the statistics update occurs during the online data processing, the platform can only update the statistics that can be computed incrementally. Many of the well-known data preprocessing components (such as standardization and one-hot encoding) require statistics that can be computed incrementally (such as mean, standard deviation, and hash table). However, some pipeline components require statistics that cannot be updated incrementally (such as percentile) or the algorithm utilized by the pipeline component is non-incremental (such as PCA). As a result, our deployment platform does not support such components. Fortunately, recent bodies of work are devoted to developing novel techniques for online feature engineering [32, 33] and approximate machine learning [25] that offer fast and incremental alternatives with theoretical error bounds to non-incremental algorithms.

The platform can also facilitate the online statistics computation for user-defined pipeline components. In Section 4, we describe how users can incorporate this feature into their custom pipeline components.

3.2 Dynamic Materialization

In order to update the statistics of the pipeline components, each component must first transform the data and then forwards the transformed data to the next component. At the end of this process, the pipeline has transformed the data chunks into feature chunks that the model will utilize during the training process. In our continuous deployment platform, we repeatedly sample the data chunks to update the model. Storing the chunks as materialized features greatly reduces the processing time as the entire data preprocessing steps can be skipped during the model update. However, in the presence of a limited storage capacity, one has to consider the effect of storing the materialized feature chunks.

To address the storage capacity issue, we utilize dynamic materialization. While creating the feature chunks, the platform assigns a unique identifier (the creation timestamp) and a reference to the originating raw data chunk. In dynamic materialization, when the size of the stored feature chunks exceeds the storage capacity, the platform removes the content of the oldest materialized feature chunks from the storage and only keeps the unique identifier and the reference to the raw data chunk (similar to cache eviction). The next time the sampler selects one or more of the evicted feature chunks, the platform re-materializes each feature chunk from the raw data chunk by reapplying the deployed pipeline to the raw data chunk. Figure 2 shows the process of dynamic materialization in two possible scenarios. For both scenarios, there are a total 6 data chunks (raw and feature) available in the storage (with timestamps t_0 to t_5). The sampling operation selects the chunks at t_0, t_2, and t_5. In Scenario 1, all the feature chunks are materialized. Therefore, the platform directly utilizes them to update the model. In Scenario 2, the platform has previously evicted some of the materialized feature chunks due to the limit on the storage capacity. In this scenario, the platform first re-materializes the evicted chunks using the deployed pipeline components before updating the model.

It is important to note that the continuous training platform assumes the raw data chunks are always stored and are available for re-materialization. If some of the raw data chunks are not available, the platform ignores these chunks during the sampling operation. A similar issue arises in the periodical deployment approach. If there is not enough space to store all the historical and incoming data, at every retraining, the platform only utilizes the available data in the storage.

3.2.1 Storage requirement for materialized feature chunks. In order to estimate the storage requirement for the preprocessed feature chunks, we investigate the size complexity of different pipeline components in terms of the input size (raw data chunks). Table 1 shows the categories of the pipeline components and their characteristics. Let us assume the total number of the values in a

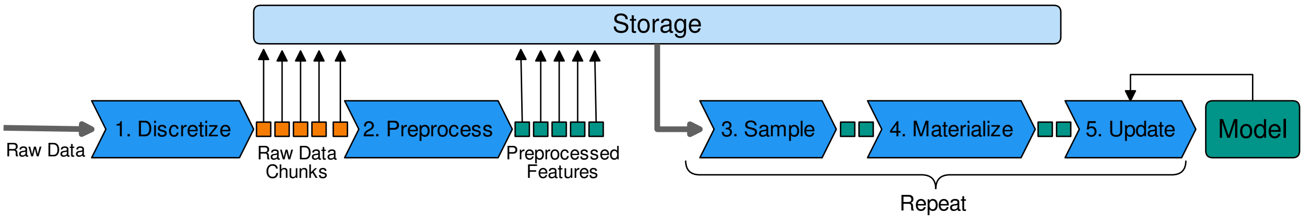

Figure 1: Workflow of our continuous deployment approach. (1) The platform converts the data into small units (2) The platform utilizes the deployed pipeline to preprocess the data and transform the raw data into features and store them in the storage. (3) The platform samples the data from the storage. (4) The platform materializes the sampled data (5) Using the sampled data, the deployment platform updates the deployed model.

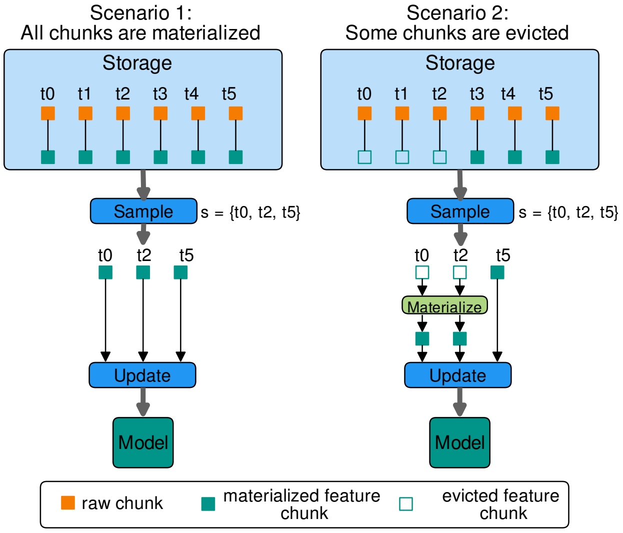

Figure 2: Dynamic Materialization process

Component type	Unit of work	Characteristics
data transformation	data point (row)	filtering or mapping
feature selection	feature (column)	selecting some columns
feature extraction	feature (column)	generating new columns

Table 1: Description of the pipeline component types. Unit of work indicates whether the component operates on a row or a column.

dataset where $\mathcal{R}$ represents the rows and C represents columns is p, where $p = |\mathcal{R}| \times |C|$. Data transformation and feature selection operations either perform a one-to-one mapping (e.g., normalization) or remove some rows or columns (e.g., anomaly filtering and variance thresholding). Therefore, the complexity of data transformation and feature selection operations is linear in terms of the input size ($O(p)$). The case for feature extraction is more complicated as there are different types of feature extraction operations. In many cases, the feature extraction process creates a new feature (column) by combining one or more existing features (such as summing or multiplying features together). This results in a complexity of $O(p)$ as the increase in size is linear with respect to the input size. However, in some case, the feature extraction process generates many features (columns) from a small subset of the existing features. Prominent examples of such operations are one-hot encoding and feature hashing. One-hot encoding converts a column of the data with categorical values into several columns (1 column for each unique value). For every value in the original column, the encoded representation has the value of 1 in the column the value represents and 0 in all the other columns. Consider the case when we are applying the one-hot encoding operation to every column $\forall c \in C$. Furthermore, let us assume $q = \max_{\forall c \in C} |\mathcal{U}(c)|$, where $\mathcal{U}$ is the function that returns the unique values in a column ($\mathcal{U}(x) \in [1, |\mathcal{R}|]$). Thus, the complexity of the one-hot encoding operation is $O(pq)$ (each existing value is encoded with at most q binary values). Based on the value of q, two scenarios may occur:

- if $q \ll |\mathcal{R}| \Rightarrow O(pq) = O(p)$
- if $q \approx |\mathcal{R}| \Rightarrow O(pq) = O(p|\mathcal{R}|) = O(p\dfrac{p}{|C|}) = O(p^2)$

The second scenario represents the worst-case scenario where almost every value is unique and we have very few columns (if the number of columns is large then the complexity is lower than $O(p^2)$). A quadratic growth rate, especially in the presence of large datasets, is not desirable and may render the storage of even a few feature chunks impossible. However, both one-hot encoding and feature hashing produce sparse data where for every encoded data point, only one entry is 1 and all the other entries are 0. Therefore, by utilizing sparse vector representation, we guarantee a complexity of $O(p)$.

Since the complexity is in worst-case scenario linear with respect to the size of the input data and the eviction policy gradually dematerializes the older feature chunks, the platform ensures the size of the materialized features will not unexpectedly exceed the storage capacity.

3.2.2 Effects of sampling strategies on the dynamic materialization. Our platform offers three sampling strategies, namely, uniform, window-based, and time-based (Section 4.2). The choice of the sampling strategy affects the efficiency of the dynamic materialization. Here, we analyze the effects of dynamic materialization in reducing the data processing overhead.

We define N as the maximum number of the raw data chunks, n as the number of existing raw chunks during a sampling operation, m as the maximum number of the materialized feature chunks (corresponds to the size of the dedicated storage for the materialized feature chunks), and s as the sample size (in each sampling operation, we are sampling s chunks out of the available n chunks)[1]. Let us define MS as the number of materialized feature chunks in a sampling operation. The variable MS follows a hypergeometric distribution[2] (sampling without replacement) where the number of success states is m, and the number of draws is s. Therefore, the expected value of MS for a sampling operation with n chunks is:

$$E_n[MS] = s\frac{m}{n}$$

To quantify the efficiency of the dynamic materialization, we introduce the materialization utilization rate with n raw chunks, which indicates the ratio of the materialized feature chunks:

$$\mu_n = \frac{E_n[MS]}{s}$$

Finally, the average materialization utilization rate for the dynamic materialization process is:

$$\mu = \frac{\sum_{n=1}^{N} \mu_n}{N} \tag{3}$$

[1] The value N corresponds to the size of the storage unit dedicated for raw data chunks which bounds the variable n. If we assume n is unbounded, then as $lim_{n \to \infty}$, the probability of sampling materialized feature chunks becomes 0.

[2] https://en.wikipedia.org/wiki/Hypergeometric_distribution

μ indicates the ratio of the feature chunks that do not require re-materialization before updating the model (a μ of 0.5 shows on average half of the sampled chunks are materialized). To simplify the analysis, we assume the platform performs one sampling operation after every incoming data chunk. In reality, a scheduler component governs the frequency of the sampling operation (Section 4.1). Next, we describe how the sampling strategy affects the computation of μ.

Random Sampling: For the random sampling strategy, we compute μ_n as:

$$\mu_n = \begin{cases} 1, & \text{if } n \le m \\ \dfrac{E_n[MS]}{s} = \dfrac{s\frac{m}{n}}{s} = \dfrac{m}{n}, & \text{otherwise} \end{cases}$$

Since for the first m sampling operations the number of raw chunks (n) is smaller than the total size of the materialized chunks (m), μ_n is 1.0 (every sampled chunk is materialized).

$$\begin{aligned} \mu = \frac{\sum\limits_{n=1}^{N} \mu_n}{N} &= \frac{m \times 1.0 + \sum\limits_{n=m+1}^{N} \frac{m}{n}}{N} \\ &= \frac{m + m(\frac{1}{m+1} + \frac{1}{m+2} + \ldots + \frac{1}{N})}{N} \\ &= \frac{m(1 + (H_N - H_m))}{N} \\ &\approx \frac{m(1 + ln(N) - ln(m))}{N} \end{aligned} \tag{4}$$

The highlighted section corresponds to the Harmonic numbers [30]. The t-th harmonic number is:

$$H_t = 1 + \frac{1}{2} + \frac{1}{3} + \ldots + \frac{1}{t} \approx ln(t) + \gamma + \frac{1}{2t} - \frac{1}{12t^2}$$

where $\gamma \approx 0.5772156649$ is the Euler-Mascheroni constant. In our analysis, since t is sufficiently large (more than 1000), we ignore $\frac{1}{2t} - \frac{1}{12t^2}$.

Window-based Sampling: In the window-based sampling, we have an extra parameter w which indicates the number of chunks in the active window. If $m \ge w$ then $\mu = 1$, as all the feature chunks in the active window are always materialized. However, when $m < w$:

$$\mu_n = \begin{cases} 1, & \text{if } n \le m \\ \dfrac{E_n[MS]}{s} = \dfrac{m}{n}, & \text{if } m < n \le w \\ \dfrac{E_w[MS]}{s} = \dfrac{m}{w}, & \text{if } w < n \end{cases}$$

therefore:

$$\begin{aligned} \mu = \frac{\sum\limits_{n=1}^{N} \mu_n}{N} &= \frac{m + \sum\limits_{n=m+1}^{w} \frac{m}{n} + (N-w)\frac{m}{w}}{N} \\ &\approx \frac{m + m(H_w - H_m) + (N-w)\frac{m}{w}}{N} \\ &= \frac{m(1 + ln(w) - ln(m) + \frac{N-w}{w})}{N} \end{aligned} \tag{5}$$

Time-based Sampling: For the time-based sampling strategy, there is no direct approach for computing the expected value of MS (the number of the materialized chunks in the sample). However, we are assigning a higher sampling probability to the recent chunks. As a result, we guarantee the time-based sampling has a higher average materialization utilization rate than the uniform sampling. In the experiments, we empirically show the average materialization utilization rate.

In our experiments, we execute a deployment scenario with a total of 12,000 chunks ($N = 12000$), where each chunk is around 3.5 MB (a total of 42 GB). For the uniform sampling strategy, in order to achieve $\mu = 0.91$, using Formula 4, we set the maximum number of the materialized chunks to 7,200 ($m = 7200$). This shows that, in the worst-case scenario (when uniform sampling is utilized), by materializing around 25 GB of the data, we ensure the deployment platform does not need to re-materialize the data 91% of the time.

3.3 Proactive Training

Updating the model is the last step of our continuous deployment platform. We update the model through the proactive training process. Unlike, the full retraining process that is triggered by a certain event (such as a drop in the quality or certain amount of time elapsed since the last retraining), proactive training continuously updates the deployed model. The proactive training utilizes the mini-batch stochastic gradient descent to update the model incrementally. Each instance of the proactive training is analogous to an iteration of the mini-batch SGD. Algorithm 1 shows the pseudocode of the mini-batch SGD algorithm. In mini-batch SGD, we first initialize the model (Line 1). Then, in every iteration, we randomly sample points from the dataset (Line 3), compute the gradient of the loss function J (Line 4), and finally update the model based on the value of the gradient and the learning rate (Line 5). Since the platform executes the proactive training in arbitrary intervals, we must ensure each instance of the proactive training is independent of the previous instances. According to the mini-batch SGD algorithm, each iteration of the SGD only requires the model (m_{i-1}) and the learning rate (η_{i-1}) of the previous iteration (Lines 4 and 5). Given these parameters, iterations of SGD are conditionally independent of each other. Therefore, to execute the proactive training, the deployment platform only needs to store the model weights and the learning rate. By proactively training the deployed model, the platform ensures the model stays up-to-date and provides accurate predictions.

Algorithm 1 mini-batch Stochastic Gradient Descent

```
Input: $D$ = training dataset
Output: $m$ = trained model
1: initialize $m_0$
2: for $i = 1 \ldots n$ do
3:     $s_i$ = sample from $D$
4:     $g = \nabla J(s_i, m_{i-1})$
5:     $m_i = m_{i-1} - \eta_{i-1} g$
6: end for
7: return $m_n$
```

Proactive training is a form of incremental training [14] which is limited to SGD-based models. In our deployment platform, one can replace the proactive training with other forms of incremental training. However, we limit the platform's support to SGD for two reasons. First, SGD is simple to implement and is used for training a variety of machine learning models in different domains [6, 19, 23]. Second, since the combination of the data sampling and the proactive training is similar to the mini-batch SGD procedure, proactive training provides the same regret bound on the convergence rate as the existing stochastic optimization approaches [18, 36].

4 DEPLOYMENT PLATFORM

Our proposed deployment platform comprises of five main components: pipeline manager, data manager, scheduler, proactive trainer, and execution engine. Figure 3 gives an overview of the architecture of our platform and the interactions among its components. At the center of the deployment platform is the pipeline manager. The pipeline manager monitors the deployed pipeline and model, manages the processing of the training data and prediction queries, and enables the continuous update of the deployed model. The data manager and the scheduler enable the pipeline manager to perform proactive training. The proactive trainer component manages the execution of the iterations of SGD on the deployed model. The execution engine is responsible for executing the actual data transformation and model training components of the pipeline.

4.1 Scheduler

The scheduler is responsible for scheduling the proactive training. The scheduler instructs the pipeline manager when to execute the proactive training. The scheduler accommodates two types of scheduling mechanisms, namely, *static* and *dynamic*. The static scheduling utilizes a user-defined parameter that specifies the interval between executions of the proactive training. This is a simple mechanism for use cases that require constant updates to the deployed model (for example, every minute). The dynamic scheduling tunes the scheduling interval based on the rate of the incoming predictions, prediction latency, and the execution time of the proactive training. The scheduler uses the following formula to compute the time when to execute the next proactive training:

$$T' = S * T * pr * pl \tag{6}$$

where T' is the time in seconds when the next proactive training is scheduled to execute, T is the total execution time (in seconds) of the last proactive training, pl is the average prediction latency (second per item), and pr is the average number of prediction queries per second (items per second). S is the slack parameter. Slack is a user-defined parameter to hint the scheduler about the possibility of surges in the incoming prediction queries and training data. During a proactive training, a certain number of predictions queries arrive at the platform ($T * pr$) which requires $T * pr * pl$ seconds to be processed. The scheduler must guarantee that the deployment platform answers all the queries before executing the next proactive training ($T' > T * pr * pl$). A large slack value (≥ 2) results in a larger scheduling interval, thus allocating most of the resources of the deployment platform to the query answering component. A small slack value ($1 \leq S \leq 2$) results in smaller scheduling intervals. As a result, the deployment platform allocates more resources for training the model.

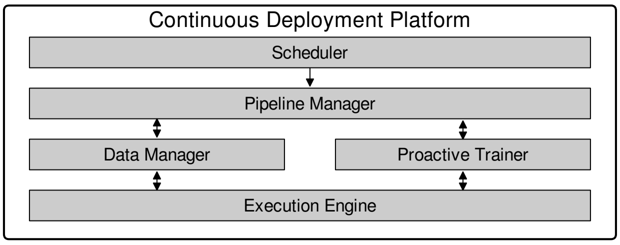

Figure 3: Architecture of the Continuous Deployment Platform

4.2 Data Manager

The data manager component is responsible for the storage of historical data and materialized features, receiving the incoming training data, and providing the pipeline manager with samples of the data. The data manager has four main tasks. First, the data manager discretizes the incoming training data into chunks, assigns a timestamp (which acts as a unique identifier) to them, and stores them in the storage unit. Second, it forwards the data chunks (and the prediction queries) to the pipeline manager for further processing. Third, after the pipeline manager transforms the data into feature chunks, the data manager stores the transformed feature chunks in the storage unit along with a reference to the originating raw data chunk (i.e., the timestamp of the raw data chunk). If the storage unit reaches its limit, the data manager removes old feature chunks. Finally, upon the request of the pipeline manager, the data manager samples the data for proactive training.

During the sampling procedure, the data manager randomly selects a set of chunks by using their timestamp as key. Then, the data manager proceeds as follows. For every sampled timestamp, if the transformed feature chunk exists in the storage, then the data manager forwards it to the pipeline manager. However, if the data manager has previously removed the transformed feature chunks from the storage unit, the data manager forwards the raw data chunk to the pipeline manager and notifies the pipeline manager to re-transform the raw data chunk (i.e., the dynamic materialization process).

The data manager provides three sampling strategies, namely, uniform, time-based, and window-based. The uniform sampling strategy provides a random sample from the entire data where every data chunk has the same probability of being sampled. The time-based sampling strategy assigns weights to every data chunk based on their timestamp such that recent chunks have a higher probability of being sampled. The window-based sampling strategy is similar to the uniform sampling, but instead of sampling from the entire historical data, the data manager samples the data from a given time range. Based on the specific use-case, the user chooses the appropriate sampling strategy. In many real-world use cases (e.g., e-commerce and online advertising), the deployed model should adapt to the more recent data. Therefore, the time-based and window-based sampling provide more appropriate samples for training. However, in some use cases, the incoming training data is not time-dependent (e.g., image classification of objects). In these scenarios, the window-based and the time-based sampling strategies may fail to provide a non-biased sample. In Section 5, we evaluate the effect of the sampling strategy on both the total deployment cost and the quality of the deployed model.

4.3 Pipeline Manager

The pipeline manager is the main component of the platform. It loads the pipeline and the trained model, transforms the data into features using the pipeline, enables the execution of the proactive training, and exposes the deployed model to answer prediction queries.

Each pipeline component must implement two methods: *update* and *transform*. Furthermore, every pipeline component has an internal state for storing the statistics (if needed). During the online training, when new training data becomes available, the pipeline manager first invokes the *update* method which enables the component to update its internal statistics using the incoming data. Then, the pipeline manager invokes the *transform* method, which transforms the data. After forwarding the data through every component of the pipeline, the pipeline manager sends the transformed features to the data manager for storage.

When the scheduler component informs the pipeline manager to execute proactive training, the pipeline manager requests the data manager to provide it with a sample of the data chunks for the next proactive training. If some of the sampled data chunks are not materialized, the pipeline manager re-materializes the chunks by invoking the transform methods of the pipeline components. Then, it provides the proactive trainer with the current model parameters and the materialized sample of the features. Once the proactive training is over, the pipeline manager receives the updated model.

The data manager also forwards the prediction queries to the pipeline manager. Similar to the training data, the pipeline manager sends the prediction queries through the pipeline to perform the necessary data preprocessing (by only invoking the *transform* method of every pipeline component). Using the same pipeline to process both the training data and the prediction queries guarantees that the same set of transformations are applied to both types of data. As a result, the pipeline manager prevents inconsistencies between training and inference that is a common problem in the deployment of machine learning pipelines [3]. Finally, the pipeline manager utilizes the deployed model to make predictions.

4.4 Proactive Trainer

The proactive trainer is responsible for training the deployed model by executing iterations of SGD. In the training process, the proactive trainer receives a training dataset (sampled materialized features) and the current model parameters from the pipeline manager. Then, the proactive trainer performs one iteration of SGD and returns the updated model to the pipeline manager. The proactive trainer utilizes advanced learning rate adaptation techniques such as Adam, Rmsprop, and AdaDelta to dynamically adjust the learning rate parameter when training the model.

In order for the proactive training to update the deployed model, the machine learning model component of the deployed pipeline must implement an *update* method, which is responsible for computing the gradient. To provide support for other types of incremental training approaches, one needs to implement the training logic in the *update* method of the model. However, as described in Section 3.3, the proactive training with data sampling can guarantee convergence only when the SGD optimization is utilized.

4.5 Execution Engine

The execution engine is responsible for executing the SGD and the prediction answering logic. In our deployment platform, any data processing platform capable of processing data both in batch mode (for proactive training) and streaming mode (online learning and answering prediction queries) is a suitable execution engine. Platforms such as Apache Spark [34], Apache Flink [7], and GoogleDataFlow [2] are distributed data processing platforms that support both stream and batch data processing.

5 EVALUATION

To evaluate the performance of our deployment platform, we perform several experiments. Our main goal is to show that the continuous deployment approach maintains the quality of the deployed model while reducing the total training time. Specifically, we answer the following questions:
1. How does our continuous deployment approach perform in comparison to online and periodical deployment approaches with regards to model quality and training time?
2. What are the effects of the learning rate adaptation method, the regularization parameter, and the sampling strategy on the continuous deployment?
3. What are the effects of online statistics computation and dynamic materialization optimizations on the training time?

To that end, we first design two pipelines each processing one real-world dataset. Then, we deploy the pipelines using different deployment approaches.

5.1 Setup

Pipelines. We design two pipelines for all the experiments.

URL pipeline. The URL pipeline processes the URL dataset for classifying URLs, gathered over a 121 days period, into malicious and legitimate groups [22]. The pipeline consists of 5 components: input parser, missing value imputer, standard scaler, feature hasher, and an SVM model. To evaluate the SVM model, we compute the misclassification rate on the unseen data.

Taxi Pipeline. The Taxi pipeline processes the New York taxi trip dataset and predicts the trip duration of every taxi ride [8]. The pipeline consists of 5 components: input parser, feature extractor, anomaly detector, standard scaler, and a Linear Regression model. We design the pipeline based on the solutions of the top scorers of the New York City (NYC) Taxi Trip Duration Kaggle competition[3]. The input parser computes the actual trip duration by first extracting the pickup and drop off time fields from the input records and calculating the difference (in seconds) between the two values. The feature extractor computes the haversine distance[4], the bearing[5], the hour of the day, and the day of the week from the input records. Finally, the anomaly detector filters the trips that are longer than 22 hours, smaller than 10 seconds, or the trips that have a total distance of zero (the car never moved). To evaluate the model, we use the Root Mean Squared Logarithmic Error (RMSLE) measure. RMSLE is also the chosen error metric for the NYC Taxi Trip Duration Kaggle competition.

Deployment Environment. We deploy the URL pipeline on a single laptop running a macOS High Sierra 10.13.4 with 2,2 GHz Intel Core i7, 16 GB of RAM, and 512GB SSD and the Taxi pipeline on a cluster of 21 machines (Intel Xeon 2.4 GHz 16 cores, 28 GB of dedicated RAM per node). In our current prototype, we are using Apache Spark 2.2 as the execution engine. The data manager component utilizes the Hadoop Distributed File System (HDFS) 2.7.1 for storing the historical data [28]. We leverage the SVM, LogisticRegression, and the GradientDescent classes of the machine learning library in Spark (MLlib) to implement the proactive training logic. We represent both the raw data and the feature chunks as RDDs. Therefore, we can utilize the caching mechanism of Apache Spark to simply materialize/dematerialize feature chunks.

Datasets. Table 2 describes the details of the datasets such as the size of the raw data for the initial training, and the amount of data for the prediction queries and further training after deployment. For the URL pipeline, we first train a model on the first day of the data (day 0). For the Taxi pipeline, we train a model using the data from January 2015. For both datasets, since the entire data fits in the memory of the computing nodes, we use batch gradient descent (sampling ratio of 1.0) during the initial training. We then deploy the models (and the pipelines). We use the remaining data for sending prediction queries and further training of the deployed models.

Dataset	size	# instances	Initial	Deployment
URL	2.1 GB	2.4 M	Day 0	Day 1-120
Taxi	42 GB	280 M	Jan15	Feb15 to Jun16

Table 2: Description of Datasets. The Initial and Deployment columns indicate the amount of data used during the initial model training and the deployment phase (prediction queries and further training data)

Evaluation metrics. For experiments that compare the quality of the deployed model, we utilize the prediction queries to compute the cumulative prequential error rate of the deployed models over time [11]. For experiments that capture the cost of the deployment, we measure the time the platforms spend in updating the model, performing proactive training (retraining for the periodical deployment scenario), and answering prediction queries.

Deployment process. The URL dataset does not have timestamps. Therefore, we divide every day of the data into chunks of 1 minute which results in a total of 12000 chunks, each one with the size of roughly 200KB. The deployment platform first uses the chunks for prequential evaluation and then updates the deployed

[5] https://en.wikipedia.org/wiki/Bearing_(navigation)

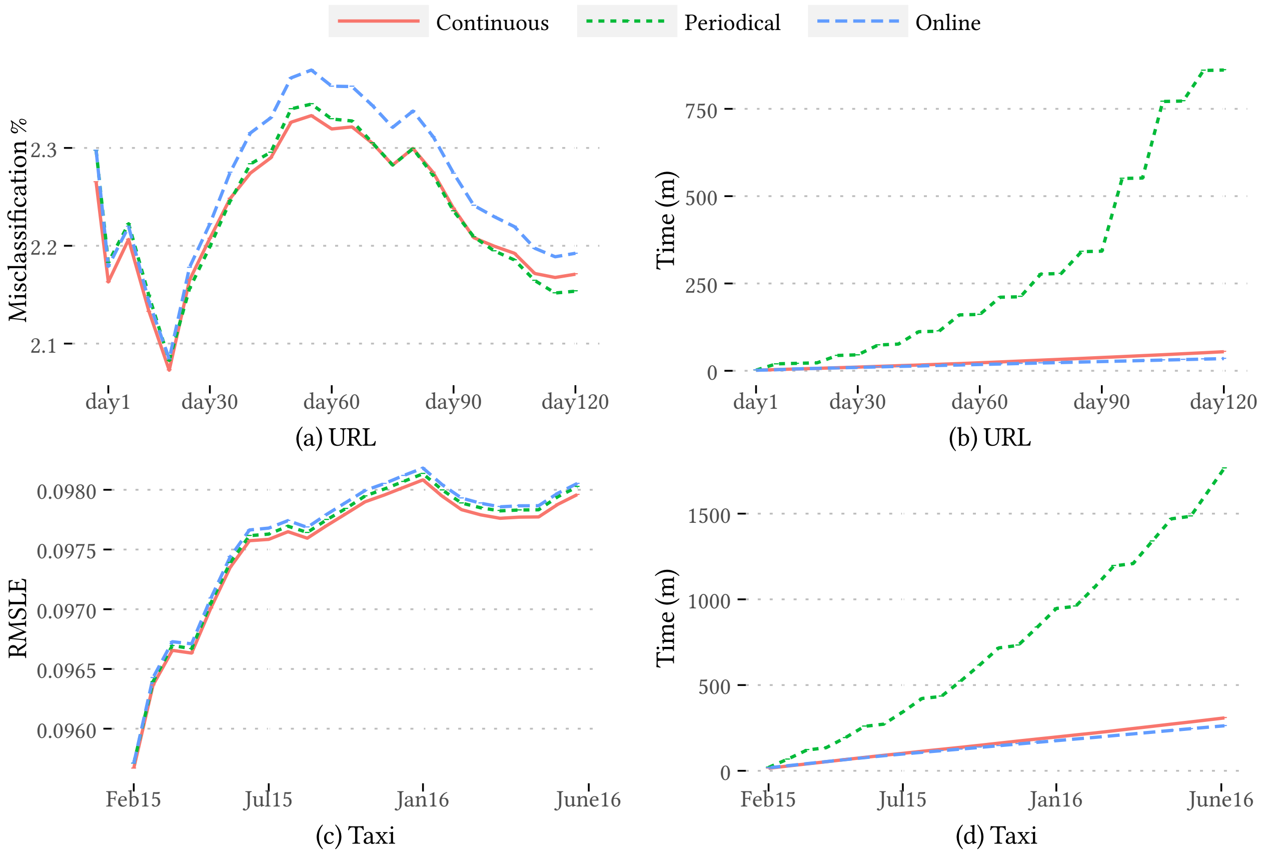

Figure 4: Model Quality and Training cost for different deployment approaches

model. The Taxi dataset includes timestamps. In our experiments, each chunk of the Taxi dataset contains one hour of the data, which results in a total of 12382 chunks, with an average size of 3MB per chunk. The deployment platform processes the chunks in order of the timestamps (from 2015-Feb-01 00:00 to 2016-Jun-30 24:00, an 18 months period).

5.2 Experiment 1: Deployment Approaches

In this experiment, we investigate the effect of our continuous deployment approach on model quality and the total training time. We use 3 different deployment approaches.

- Online: deploy the pipeline, then utilize online gradient descent with Adam learning rate adaptation method for updating the deployed model.
- Periodical: deploy the pipeline, then periodically retrain the deployed model.
- Continuous: deploy the pipeline, then continuously update the deployed model using our platform.

The periodical deployment initiates a full retraining every 10 days and every month for URL and Taxi pipelines, respectively. Since the rate of the incoming training and prediction queries are known, we use static scheduling for the proactive training. Based on the size and rate of the data, our deployment platform executes the proactive training every 5 minutes and 5 hours for the URL and Taxi pipelines, respectively. To improve the performance of the periodical deployment, we utilize the warm starting technique, used in the TFX framework [3]. In warm starting, each periodical training uses the existing parameters such as the pipeline statistics (e.g., standard scaler), model weights, and learning rate adaptation parameters (e.g., the average of past gradients used in Adadelta, Adam, and Rmsprop) when training new models.

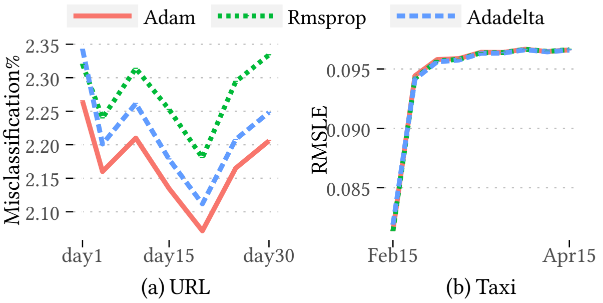
Figure 4 (a) and (c) show the cumulative error rate over time for the different deployment approaches. For both datasets, the continuous and the periodical deployment result in a lower error rate than the online deployment. Online deployment visits every incoming training data point only once. As a result, the model updates are more prone to noise. This results in a higher error rate than the continuous and periodical deployment. In Figure 4 (a), during the first 110 days of the deployment, the continuous deployment has a lower error rate than the periodical deployment. Only after the final retraining, the periodical deployment slightly outperforms the continuous deployment. However, from the start to the end of the deployment process, the continuous deployment improves the average error rate by 0.3% and 1.5% over the periodical and online deployment, respectively. In Figure 4 (c), for the Taxi dataset, the continuous deployment always attains a smaller error rate than the periodical deployment. Overall, the continuous deployment improves the error rate by 0.05% and 0.1% over the periodical and online deployment, respectively.

When compared to the online deployment, periodical deployment slightly decreases the error rate after every retraining. However, between every retraining, the platform updates the model using online learning. This contributes to the higher error rate than the continuous deployment, where the platform continuously trains the deployed model using samples of the historical data.

In Figure 4 (b) and (d), we report the cumulative cost over time for every deployment platform. We define the deployment cost as the total time spent in data preprocessing, model training, and performing prediction. For the URL dataset (Figure 4 (b)), online deployment has the smallest cost (around 34 minutes) as it only scans each data point once (around 2.4 million scans). The continuous deployment approach scans 45 million data points. However, the total cost at the end of the deployment is only 50% larger than the online deployment approach (around 54 minutes). Because of the online statistics computation and the dynamic materialization optimizations, a large part of the data preprocessing time is avoided. For the periodical deployment approach, the cumulative deployment cost starts similar to the online deployment approach. However, after every offline retraining, the deployment cost substantially increases. At the end of the deployment process, the total cost for the periodical deployment is more than 850 minutes which is 15 times more than the total cost of the continuous deployment approach. Each data point in the URL dataset has more than 3 million features. Therefore, the convergence time for each retraining is very high. The high data-dimensionality and repeated data preprocessing contribute to the large deployment cost of the periodical deployment.

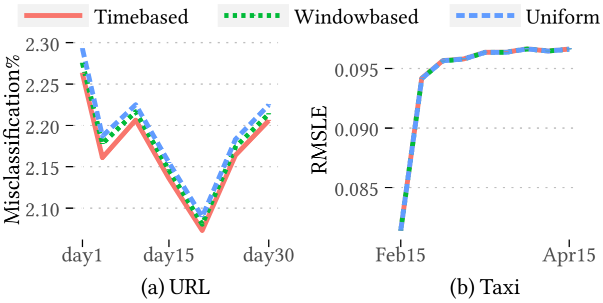
For the Taxi dataset (Figure 4 (d)), the cost of online, continuous, and periodical deployments are 262, 308, and 1765 minutes, respectively. Similar to the URL dataset, continuous deployment only adds a small overhead to the deployment cost when compared with the online deployment. Contrary to the URL dataset, the feature size of the Taxi dataset is 11. Therefore, offline retraining converges faster to a solution. As a result, for the Taxi dataset, the cost of the periodical deployment is 6 times larger than the continuous deployment (instead of 15 times for URL dataset).

5.3 Experiment 2: System Tuning



(a) URL (b) Taxi

Figure 5: Result of hyperparameter tuning during the deployment



(a) URL (b) Taxi

Figure 6: Effect of different sampling methods on quality

In this experiment, we investigate the effect of different parameters on the quality of the models after deployment. As described in Section 3.3, proactive training is an extension of the stochastic gradient descent to the deployment phase. Therefore, we expect the set of hyperparameters with the best performance during the initial training also performs the best during the deployment phase.

Proactive Training Parameters. Stochastic gradient descent is heavily dependent on the choice of learning rate and the regularization parameter. To find the best set of hyperparameters for the initial training, we perform a grid search. We use advanced learning rate adaptation techniques (Adam, Adadelta, and Rmsprop) for both initial and proactive training. For each dataset, we divide the initial data (from Table 2) into a training and evaluation set. For each configuration, we first train a model using the training set and then evaluate the model using the evaluation set. Table 3 shows the result of the hyperparameter tuning for every pipeline. For the URL dataset, Adam with regularization parameter $1E$-3 yields the model with the lowest error rate. The Taxi dataset is less complex than the URL dataset and has a smaller number of feature dimensions. As a result, the choice of different hyperparameter does not have a large impact on the quality of the model. The Rmsprop adaptation technique with the regularization parameter of $1E$-4 results in a slightly better model than the other configurations.

After the initial training, for every configuration, we deploy the model and use 10 % of the remaining data to evaluate the model after deployment. Figure 5 shows the results of the different hyperparameter configurations on the deployed model. To make the deployment figure more readable, we avoid displaying the result of every possible combination of hyperparameters and only show the result of the best configuration for each learning rate adaptation technique. For the URL dataset, similar to the initial training, Adam with regularization parameter $1E$-3 results in the best model. For the Taxi dataset, we observe a similar behavior to the initial training where different configurations do not have a significant impact on the quality of the deployed model.

This experiment confirms that the effect of the hyperparameters (learning rate and regularization) during the initial and proactive training are the same. Therefore, we tune the parameters of the proactive training based on the result of the hyperparameter search during the initial training.

Sampling Methods. The choice of the sampling strategy also affects the proactive training. Each instance of the proactive training updates the deployed model using the provided sample. Therefore, the quality of the model after an update is directly related to the quality of the sample. We evaluate the effect of three different sampling strategies, namely, time-based, window-based, and uniform, on the quality of the deployed model. The sample size is similar to the sample size during the initial training ($16k$ and $1M$ for URL and Taxi data, respectively). Figure 6 shows the effect of different sampling strategies on the quality of the deployed model. For the URL dataset, time-based sampling improves the average error rate by 0.5% and 0.9% over the window-based and uniform sampling, respectively. As new features are added to the URL dataset over time, the underlying characteristics of the dataset gradually change [22]. A time-based sampling approach is more likely to select the recent items for the proactive training. As a result, the deployed model performs better on the incoming prediction queries. The underlying characteristics of the Taxi dataset are known to remain static over time. As a result, we observe that different sampling strategies have the same effect on the quality of the deployed model. Our experiments show that for datasets that gradually change over time, time-based sampling outperforms other sampling strategies. Moreover, time-based sampling performs similarly to window-based and uniform sampling for datasets with stationary distributions.

5.4 Experiment 3: Optimizations Effects

In this experiment, we analyze the effect of the system optimizations, i.e., online statistics computation and the dynamic materialization on the total deployment cost. We define the materialization rate (i.e., $\frac{m}{n}$, as described in Section 3.2) as the ratio of the number of materialized chunks over the total number of chunks (both URL and Taxi have around 12,000 chunks in total). For both datasets, the materialization rates of 0.0, 0.2, 0.6, and 1.0 indicates that 0, 2400,

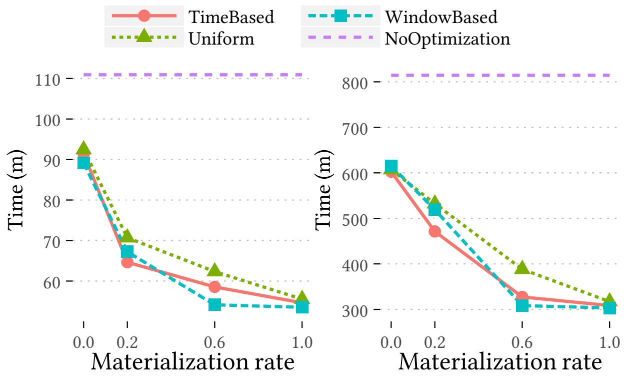
	URL			Taxi		
Adaptation	1E-2	1E-3	1E-4	1E-2	1E-3	1E-4
Adam	0.030	**0.026**	0.035	0.09553	0.09551	**0.09551**
RMSProp	0.030	**0.027**	0.034	0.09552	0.09552	**0.09550**
Adadelta	0.029	**0.028**	0.034	**0.09609**	0.09610	0.09619

Table 3: Hyperparameter tuning during initial training (bold numbers show the best results for each adaptation techniques)

7200, and 12000 chunks are materialized. For the window-based sampling strategy, we set the window size to 6,000 chunks (half of the total chunks). In this experiment, we assume the raw data is always stored in memory. The total size of the datasets after materialization is 5.2 GB and 59 GB for the URL and Taxi datasets, respectively. Therefore, when setting the materialization rate to a specific value, we must ensure we have enough memory capacity to store both the materialized and the raw data. Table 4 shows the empirical values and theoretical estimates of μ for different settings. For both the uniform and time-based sampling, the empirical and analytical computation yield similar values. Moreover, the empirical computation shows that the time-based strategy performs better than the uniform sampling strategy. When the number of materialized feature chunks is 0 or 12000, the design of the deployment platform guarantees that μ is 0.0 and 1.0, respectively. Therefore, we do not report those results in the table.

	URL		Taxi	
Sampling	$\frac{m}{n}$=0.2	$\frac{m}{n}$=0.6	$\frac{m}{n}$=0.2	$\frac{m}{n}$=0.6
Uniform	0.52 (**0.52**)	0.91 (**0.91**)	0.51 (**0.52**)	0.90 (**0.91**)
Window-based	0.58 (**0.58**)	1.0 (**1.0**)	0.57 (**0.58**)	1.0 (**1.0**)
Time-based	0.68	0.97	0.65	0.97

Table 4: Empirical computation and theoretical estimates (bold numbers) of μ for different sampling strategies and materialization rates ($\frac{m}{n}$). We omit the materialization rates 0.0 and 1.0 since both the empirical and theoretical estimates of μ are 0.0 and 1.0 for every sampling strategy.



(a) URL (b) Taxi

Figure 7: Effect of the online statistics computation and dynamic materialization on the deployment cost

To examine the effect of μ on the deployment cost, we plot the total deployment cost using different sampling strategies and materialization rates ($\frac{m}{n}$) for the URL and Taxi deployment scenarios in Figure 7. When the materialization rate is 0.0 or 1.0, the sampling strategies have similar effects on the deployment cost. Therefore, the total deployment cost for every sampling strategy is 90 minutes for URL and 600 minutes for Taxi deployment scenario, when the materialization rate is 0.0. Similarly, the deployment cost is 54 minutes for URL and 308 minutes for Taxi, when the materialization rate is 1.0 (an improvement of 40% for URL and 49% for Taxi deployment scenarios).

For the URL deployment scenario, when the materialization rate is 0.2, time-based, window-based, and uniform sampling improve the deployment cost by 30%, 25%, and 23% in comparison with the materialization rate of 0.0. Similarly, in the Taxi deployment scenario, time-based, window-based, and uniform sampling improve the deployment cost by 22%, 16%, and 12%, respectively. Time-based sampling performs better since it has a higher μ value than the other two sampling strategies (Table 4). When the materialization rate is 0.2, the rate of the decrease in the deployment cost for the URL scenario is greater than the Taxi scenario. We attribute this difference in the decrease in the deployment cost to two reasons. First, the number of sampled chunks in the Taxi deployment scenario is larger than the URL (720 for Taxi and 100 for URL). Before updating the model, we utilize the *context.union* operation of Spark, to combine all the non-materialized and materialized chunks. The union operation incurs a larger overhead when the number of underlying chunks is bigger. Second, we execute the URL deployment scenario on a single machine with SSD. Since materializing data that resides on an SSD is faster than an HD, we observe a larger decrease in the deployment cost.

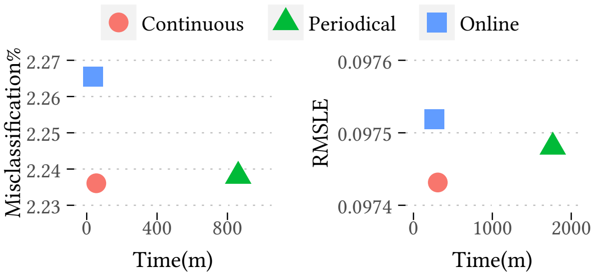
When the materialization rate is 0.6, window-based sampling has the best performance. Since the size of the window is smaller than the number of the materialized feature chunks, every sampled feature chunk is materialized. For the URL deployment scenario, window-based, time-based, and uniform sampling improves the performance by 40%, 36%, and 33%, respectively. For the Taxi deployment scenario, window-based, time-based, and uniform sampling improves the performance by 49%, 46%, and 37%, respectively. Similar phenomena explain the difference in performance improvement at materialization rate of 0.6 between the Taxi and the URL deployment scenarios. At materialization rate of 0.6, more than 90% of the chunks are materialized. Therefore, the Taxi deployment scenario gains relatively more than the URL deployment scenario from a smaller number of disk I/O operations.

To analyze the effect of the online statistics computation on the deployment cost, we also execute the deployment scenarios without the online statistics computation and the dynamic materialization optimizations. In this case, the deployment platform first accesses the sampled raw data chunk directly from the disk. Then, the platform recomputes the required statistics of every component by scanning the data. Finally, it transforms the raw data chunk into the preprocessed feature chunks by utilizing the deployed pipeline. Without the optimizations, the choice of the sampling strategy does not affect the total deployment time (similar to the materialization rate of 0.0). Therefore, when the optimizations are disabled, we only show the results for the time-based sampling (depicted as NoOptimization in Figure 7). The extra disk access and data processing result in an increase of %110 for the URL (Figure 7a) and %170 for the Taxi deployment scenarios (Figure 7b) when compared with a fully optimized execution (with online statistics computation and materialization rate of 1.0). Similar to the dynamic materialization case, we observe a larger increase in the deployment cost of the Taxi deployment scenario due to the larger overhead of disk I/O.

The result of this experiment shows that even under limited storage we can benefit from the dynamic materialization, especially for the time-based and window-based sampling strategies. Furthermore, online statistics computation can improve the total deployment cost, especially when the expected amount of incoming data is large.

5.5 Discussion

Trade-off between quality and training cost. In many real-world use cases, even a small improvement in the quality of the deployed model can have a significant impact [21]. Therefore, one can employ more complex pipelines and machine learning training algorithms to train better models. However, during the deployment where prediction queries and training data become available at a high rate, one must consider the effect of the training time. To ensure the model is always up-to-date, the platform must constantly update the model. Long retraining time may have a negative impact on the prediction accuracy as the deployed model becomes stale. Figure 8 shows the trade-off between the average quality and the total cost of the deployment. By utilizing continuous deployment, we reduce the total cost of the deployment 6 to 15 times when compared with the periodical deployment, while providing the same quality (even slightly outperforming the periodical deployment by 0.05% and 0.3% for the Taxi and URL datasets, respectively.)



(a) URL (b) Taxi

Figure 8: Trade-off between average quality and deployment cost

Staleness of the model during the periodical deployment. In the experiments of the periodical deployment approach, we pause the inflow of the training data and prediction queries. However, in real-world scenarios, the training data and the prediction queries constantly arrive at the platform. Therefore, the periodical deployment platform pauses the online update of the deployed model and answers the prediction queries using the currently deployed model (similar to how Velox operates [9]). As a result, the error rate of the deployed model may increase during the retraining process. However, in our continuous deployment platform, the average time for the proactive training is small (200 ms for the URL dataset and 700 ms for the Taxi dataset). Therefore, the continuous deployment platform always performs the online model update and answers the predictions queries using an up-to-date model.

6 RELATED WORK

Traditional machine learning systems focus solely on training models and leave the task of deploying and maintaining the models to the users. It has only been recently that some platforms, for example LongView [1], Velox [9], Clipper [10] , and TensorFlow Extended [3] have proposed architectures that also consider model deployment and query answering.

LongView integrates predictive machine learning models into relational databases. It answers predictive queries and maintains and manages the models. LongView uses techniques such as query optimization and materialized view selection to increase the performance of the system. However, it only works with batch data and does not provide support for real-time queries. As a result, it does not support continuous and online learning. In contrast, our platform is designed to work in a dynamic environment where it answers prediction queries in real-time and continuously updates the model.

Velox is an implementation of the common periodical deployment approach. Velox supports online learning and can answer prediction queries in real-time. It also eliminates the need for the users to manually retrain the model offline. Velox monitors the error rate of the model using a validation set. Once the error rate exceeds a predefined threshold, Velox initiates a retraining of the model using Apache Spark. However, Velox has four drawbacks. First, retraining discards the updates that have been applied to the model so far. Second, the process of retraining on the full dataset is resource intensive and time-consuming. Third, the platform must disable online learning during the retraining. Lastly, the platform only deploys the final model and does not support the deployment of the machine learning pipeline. Our approach differs from Velox as it exploits the underlying properties of SGD to integrate the training process into the platform's workflow. Our platform replaces the offline retraining with proactive training. As a result, our deployment platform maintains the model quality with a small training cost. Moreover, our deployment platform deploys the machine learning pipeline alongside the model.

Clipper is another machine learning deployment platform that focuses on producing high-quality predictions by maintaining an ensemble of models. For every prediction query, Clipper examines the confidence of every deployed model. Then, it selects the deployed model with the highest confidence for answering the prediction query. However, it does not update the deployed models, which over time leads to outdated models. On the other hand, our deployment platform focuses on maintenance and continuous update of the deployed models.

TensorFlow Extended (TFX) is a platform that supports the deployment of machine learning pipelines and models. TFX automatically stores new training data, performs analysis and validation of the data, retrains new models, and finally redeploys the new pipelines and models. Moreover, TFX supports the warm starting optimization to speed up the process of training new models. TFX aims to simplify the process of design and training of machine learning pipelines and models, simplify the platform configuration, provide platform stability, and minimize the disruptions in the deployment platform. For use cases that require months to deploy new models, TFX reduces the time to production from the order of months to weeks. Although TFX uses the term "continuous training" to describe the deployment platform, it still periodically retrains the deployed model on the historical dataset. On the contrary, our continuous deployment platform performs more rapid updates to the deployed model. By exploiting the properties of SGD optimization technique, our deployment platform rapidly updates the deployed models (seconds to minutes instead of several days or weeks) without increasing the overhead. Our proactive training component can be integrated into the TFX platform to speed up the process of pipeline and model update.

Weka [15], Apache Mahout [24], and Madlib [16] are systems that provide the necessary toolkits to train machine learning models. All of these systems provide a range of training algorithms for machine learning methods. However, they do not support the management and deployment of machine learning models and pipelines. Our platform focuses on continuous deployment and management of machine learning pipelines and models after the initial training.

MLBase [20] and TuPaq [29] are model management systems. They provide a range of training algorithms to create machine learning models and mechanism for model search as well as model management. They focus on training high-quality models by performing automatic feature engineering and hyper-parameter search. However, they only work with batch datasets. Moreover, the users have to manually deploy the models and make them available for answering prediction queries. On the contrary, our deployment platform focuses on the continuous deployment of pipelines and models.

7 CONCLUSIONS

We propose a deployment platform for continuously updating machine learning pipelines and models. After a machine learning pipeline is designed and initially trained on a dataset, our platform deploys the pipeline and makes it available for answering prediction queries. To ensure that the model maintains an acceptable error rate , existing deployment platforms periodically retrain the deployed model. However, periodical retraining is a time-consuming and resource-intensive process. As a result of the lengthy training process, the platform cannot produce fresh models. This results in model-staleness which may decrease the quality of the deployed model.

We propose a training approach, called proactive training, that utilizes samples of the historical data to train the deployed pipeline. Proactive training replaces the periodical retraining, which provides the same level of model quality without the lengthy retraining process. We also propose online statistics computation and dynamic materialization of the preprocessed features which further decreases the training time. We propose a modular design that enables our deployment platform to be integrated with different scalable data processing platforms.

We implement a prototype using Apache Spark to evaluate the performance of our deployment platform. In our experiments, we develop two pipelines with two machine learning models to process two real-world datasets. We discuss how to tune the deployment platform based on the available historical data. Our experiments show that our continuous deployment reduces the total deployment cost by a factor of 6 and 15 for the Taxi and URL datasets, respectively. Moreover, continuous deployment platform provides the same level of quality for the deployed model when compared with the periodical deployment approach.

Currently, we provide support for anomaly and concept drift detection through components of the machine learning pipeline. However, given the large impact of the concept drift and anomalies on the performance of a deployed model, in the future work, we plan to extend our platform to provide native support for both concept drift and anomaly detection and alleviation. Furthermore, we plan to integrate more complex machine learning pipelines and models (e.g., neural networks) into our deployment platform.

ABSTRACT

A relevant task in the exploration and understanding of large datasets is the discovery of hidden relationships in the data. In particular, functional dependencies have received considerable attention in the past. However, there are other kinds of relationships that are significant both for understanding the data and for performing query optimization. Order dependencies belong to this category. An *order dependency* states that if a table is ordered on a list of attributes, then it is also ordered on another list of attributes. The discovery of order dependencies has been only recently studied. In this paper, we propose a novel approach for discovering order dependencies in a given dataset. Our approach leverages the observation that discovering order dependencies can be guided by the discovery of a more specific form of dependencies called *order compatibility dependencies.* We show that our algorithm outperforms existing approaches on real datasets. Furthermore, our algorithm can be parallelized leading to further improvements when it is executed on multiple threads. We present several experiments that illustrate the effectiveness and efficiency of our proposal and discuss our findings.

1 INTRODUCTION

In the big data era, the volume and complexity of available datasets has grown so much that data engineers are having a hard time interpreting the information contained in them. In such a reality, the ability to discover hidden dependencies in some automatic way is fundamental. Dependencies across different parts of the data play a significant role in query optimization, since redundant information may be ignored making the query evaluation faster. Furthermore, parts of the data may be replaced with others that are easier to manipulate, without affecting the final result. Data profiling may help with data quality since it highlights constraints that may exist in the data but are not fully satisfied and have not been enforced when designing the database.

Dependency discovery is not a new challenge. Functional and inclusion dependencies are the most common type of dependencies and have been studied extensively [14]. A *functional dependency* states that if two different data elements sharing a common structure have the same part A, then some other part B should also have the same value. An *inclusion dependency* states that the values of the data elements in some part A must be a subset of the values in a subpart B of some other portion of the dataset.

An example of functional dependency can be seen in Table 1, that shows a relational table with data regarding yearly incomes, savings and taxes. Assume that the tax system is a progressive one that categorizes the different incomes into brackets, each of them characterized by a tax percentage. Thus, there is a functional dependency from the income amount to the tax brackets, i.e., `income` → `bracket`. Since for every income range the percentage is fixed, there are two other functional dependencies from the income to the tax amount and vice-versa, i.e., `income` → `tax` and `tax` → `income`. Using the transitive property of functional dependencies a new one can be inferred, i.e., `tax` → `bracket`.

A closer look at Table 1 can illustrate another, stronger, form of dependency: as the income is increasing, bracket and tax amount are increasing as well. In other words, if we were to order the table based on the income column, each one of the bracket and the tax amount columns will also end up being ordered. This form of dependency is known as an *order dependency* and is typically noted with the ↦ symbol, i.e., `income` ↦ `tax`, which is read as: `income` *orders* `tax`.

The knowledge encoded by order dependencies can be applied to various tasks during the entire data life-cycle [3]: in the design phase, order dependencies can be exploited to assist schema design [21] or for selecting indexes [7]; if data are extracted from unstructured sources, order dependencies can aid knowledge discovery, to find hidden properties of the data; in the context of data profiling [13], data integration and cleansing [5], order dependencies can be used to describe a dataset; for data quality [8], order dependencies can be used as requirements or constraints [1].

The most important application of order dependencies is their use in the optimization of queries; in particular, they can be used to rewrite the `ORDER BY` clauses in SQL queries in ways similar to that of functional dependencies for the `GROUP BY` statements [17, 22]. Consider the following query:

```
SELECT income, bracket, tax
FROM TaxInfo
ORDER BY income, bracket, tax
```

TaxInfo

name	income	savings	bracket	tax
T. Green	35,000	3,000	1	5,250
J. Smith	40,000	4,000	1	6,000
J. Doe	40,000	3,800	1	6,000
S. Black	55,000	6,500	2	8,500
W. White	60,000	6,500	2	9,500
M. Darrel	80,000	10,000	3	14,000

Table 1: A relational table with financial information.

Given that the order dependencies `income` ↦ `tax` and `income` ↦ `bracket` hold, the query optimizer can infer that sorting by `income` makes the ordering on the other two columns redundant, so the `ORDER BY` clause can be simplified to `ORDER BY income`.

The concept of order dependency in the context of database systems first appeared under the name of *point-wise order* [9–11]. A point-wise ordering specifies that a *set* of columns orders another *set* of columns. In the example of Table 1, the point-wise order dependency `income,tax` ⇝ `bracket` holds because if both of the tuples (`income`, `tax`) and (`tax`, `income`) are lexicographically ordered, then the column `bracket` is ordered in the same way. A new definition for order dependency was later introduced [21] to represent an order-preserving mapping between *lists* of attributes. In contrast to point-wise ordering, the new definition was distinguishing tuples with attributes in different order, thus having lists of attributes instead of sets.

There are cases where two lists of attributes order each other when taken together. This property is known as *order compatibility* and is denoted with the symbol ~. In Table 1, e.g., it holds that

$$(\texttt{income}, \texttt{savings}) \mapsto (\texttt{savings}, \texttt{income}) \qquad \text{and}$$
$$(\texttt{savings}, \texttt{income}) \mapsto (\texttt{income}, \texttt{savings})$$

and thus `income` ~ `savings`. Another way to see an order compatibility dependency between two columns is that their values are both monotonically non-decreasing when they are considered pairwise.

Dependencies are typically derived from design specifications, from the context of queries or from other known dependencies using inference rules. Discovering dependencies by analyzing the data is a process known as *dependency discovery* [14]. It conceptually requires to check for all potential dependencies if they hold in the database instance under examination, which may be time consuming. Thus, there is interest in developing strategies that limits the number of combinations to be checked. The task becomes even more challenging in the case of order dependencies, where the order of attributes matters, leading to a search space much larger than that of functional dependencies.

In this work we study ways for efficiently discovering order dependencies. We follow a bottom-up approach in which we start by checking short lists of columns and progressively check longer and longer lists. In this process, once an order dependency between two lists of attributes is found not to hold, we prune the search space by ignoring larger lists that include them. In this way, many of the combinations that would have normally been checked are avoided.

We advocate that this whole process can be significantly improved by framing the discovery of order dependencies in the context of order compatibility dependencies. This is based on a recently introduced theorem [21] that established that an order dependency holds if and only if a functional and an order compatibility dependency hold between the two attribute lists of the order dependency. We illustrate in details how the order compatibility dependencies can be exploited to find order dependencies and propose a new algorithm for finding them.

Recently, two algorithms to automatically detect order dependencies in relational data have been proposed: ORDER, proposed by Langer and Naumann [13], and FASTOD proposed by Szlichta et al. [18]. ORDER explores a lattice of order dependency candidates, in a level-wise fashion reminiscent of the TANE algorithm [12]. After building a dependency candidate, ORDER checks its validity against the data and then it applies pruning rules to reduce the search space over the lattice. ORDER has been shown to be incomplete [18], i.e. it does not find the complete set of order dependencies. In particular, this approach is unable to discover dependencies with repeated attributes, for example, the order dependency (`income`, `savings`) ↦ `savings` of Table 1 cannot be discovered. Dependencies of this form, however, may not be inferred from other dependencies and are useful in the case of queries that involve ordering with multi-column indexes. In the example of Table 1, an index over (`income`, `savings`) can be used to simplify the clause `ORDER BY savings`. FASTOD [18] is based on a different axiomatization of order dependencies that allows mapping dependencies between lists of attributes to dependencies between sets of attributes written in a canonical form. In this way, several order dependencies are mapped to the same set-based canonical form. FASTOD explores the space of order dependencies of this set-based canonical form, still retaining the ability to find a complete set of dependencies. While we have reproduced the results presented in the original work, we have found that an implementation error of the original work produces wrong results over simple datasets, this vitiates the validity of their results and the comparison with our approach.

The approach we present in this paper is able to provide a complete set of dependencies that is based on the idea that the whole process of order dependency discovery could be performed through the search of *order compatibility dependencies.* While our approach has a higher worst-case complexity than FASTOD, it outperforms all the state-of-the-art approaches [13, 18] when tested over real datasets.

In particular, our contributions are the following:

- we introduce a definition of minimality for a set of order compatibility dependencies that we show being complete in the sense that it can recover all valid order compatibility dependencies that hold over a given instance of relational data;
- we propose a novel algorithm for finding order dependencies that is complete and can perform the detection of order dependencies in parallel.
- we perform an exhaustive experimental evaluation that shows the performance of our algorithm in comparison with existing works, including a study of its scalability over big datasets and multiple threads.
- we discuss possible solutions for the discovery of the most important order dependencies in the case of dataset that could not be managed (too many columns) in a reasonable amount of time.

The paper is structured as follows: in Section 2 we review the relevant definitions and theorems that formalize the connection between order dependencies and order compatibility dependencies. In Section 3 we prove that order dependency discovery can be guided by order compatibility dependencies without losing completeness. Our novel algorithm is presented in Section 4, while Section 5 contains the discussion of our experimental evaluation. Finally, a thorough review of the related work can be found in Section 6 and we present our conclusions in Section 7.

2 BACKGROUND

To provide the background of our problem, we first review the definition of order dependency and its axiomatization, then we describe the formal relation between order dependencies (ODs), functional dependencies (FDs) and order compatibility dependencies (OCDs).

2.1 Notational Conventions and Definitions

We adopt the notational conventions summarized in Table 2, consistently with the literature [21]. Let $\boldsymbol{R}$ be a relation over the set of attributes $\mathcal{U}$ and $\boldsymbol{r}$ be a table instance of $\boldsymbol{R}$, i.e. a set of tuples under $\boldsymbol{R}$'s schema. A tuple p can be projected over a single attribute A, over a set of attributes $\mathcal{X}$ and over a list of attributes $\mathbf{X}$ by subscripting the tuple as follows: $p_A, p_{\mathcal{X}}, p_{\mathbf{X}}$.

We assume that a total ordering is defined over each of the attributes, denoted $\leq_A$; in the following, however, we will drop the attribute specification and use $\leq$, as the attribute will be always clear from the context. Order dependencies are defined based on the operator $\preccurlyeq$, which is equivalent to a lexicographical ordering over a list of attributes, and is defined by:

Definition 2.1 (operator $\preccurlyeq$). Given a list of attributes $\mathbf{X} := [A|\mathbf{T}]$ and two tuples $p, q \in \boldsymbol{r}$, the operator $\preccurlyeq$ (and its associated operator $\prec$) are defined as follows:

$$
\begin{aligned}
p_{\mathbf{X}} \preccurlyeq q_{\mathbf{X}} \quad &\Leftrightarrow \quad \big(p_A < q_A\big) \vee \\
&\qquad \big((p_A = q_A) \wedge (\mathbf{T} = [\cdot] \vee p_{\mathbf{T}} \preccurlyeq q_{\mathbf{T}})\big) \qquad (1) \\
p_{\mathbf{X}} \prec q_{\mathbf{X}} \quad &\Leftrightarrow \quad p_{\mathbf{X}} \preccurlyeq q_{\mathbf{X}} \wedge p_{\mathbf{X}} \neq q_{\mathbf{X}}
\end{aligned}
$$

The $\preccurlyeq$ operator reproduces the ordering clause `ORDER BY ASC` in SQL [21].

Based on the comparison operator of Definition 2.1, we can introduce the concept of *order dependency* [21].

Definition 2.2 (Order dependency (OD)). Given a relation $\boldsymbol{R}$ and two lists $\mathbf{X}$ and $\mathbf{Y}$, $\mathbf{X} \mapsto \mathbf{Y}$ is an *order dependency* if, for any instance $\boldsymbol{r}$ of $\boldsymbol{R}$ and for every pair of tuples $p, q \in \boldsymbol{r}$, the following implication holds:

$$p_{\mathbf{X}} \preccurlyeq q_{\mathbf{X}} \Rightarrow p_{\mathbf{Y}} \preccurlyeq q_{\mathbf{Y}} \qquad (2)$$

If both $\mathbf{X} \mapsto \mathbf{Y}$ and $\mathbf{Y} \mapsto \mathbf{X}$ hold, we say that $\mathbf{X}$ and $\mathbf{Y}$ are *order equivalent* and we write $\mathbf{X} \leftrightarrow \mathbf{Y}$. If $\mathbf{XY} \leftrightarrow \mathbf{YX}$ we say that $\mathbf{X}$ and $\mathbf{Y}$ are *order compatible* and we write $\mathbf{X} \sim \mathbf{Y}$. We will discuss the latter relation in Section 2.2.

Order dependencies satisfy the set of axioms $\mathcal{J}_{\mathrm{OD}}$, introduced by Szlichta et al. [21], which are reported in Table 3. These axioms are analogous to the Armstrong axioms for functional dependencies [2].

Relations:

- $\boldsymbol{R}$, written as a capital letter in bold italics, is a *relation* over a set of attributes $\mathcal{U}$;
- $\boldsymbol{r}$, written as a lowercase letter in bold italics, is a *table instance* over $\boldsymbol{R}$, i.e. a *set of tuples*;
- Single *attributes* are represented with capital letters: A, B, and C;
- *Tuples* are represented with lowercase letters: p, q, s, and t.

Lists:

- Bold capital letters are *lists* of attributes: $\mathbf{X}$,$\mathbf{Y}$, and $\mathbf{Z}$. they can represent the empty list $[\cdot]$;
- A list is denoted with square brackets $[A,B,C]$. A list $[A|\mathbf{T}]$ is composed by a *head* A and a *tail* $\mathbf{T}$;
- $\mathbf{XY}$ is a shorthand for $\mathbf{X} \circ \mathbf{Y}$, $\mathbf{X}A$ and $A\mathbf{X}$ are shorthands for $\mathbf{X} \circ [A]$ and $[A] \circ \mathbf{X}$ respectively, AB denotes $[A,B]$.

Table 2: Notational conventions

Table 3: The set of axioms $\mathcal{J}_{\mathrm{OD}}$ for order dependencies [21]

2.2 Decomposing Order Dependencies

We show how an order dependency can be decomposed in a pair composed of one functional dependency and one order compatibility dependency.

Functional dependencies. Functional dependencies encode the fact that, in a relation, one attribute determines completely another attribute.

Definition 2.3 (Functional dependency (FD)). Given a relation $\boldsymbol{R}$ and two sets of attributes $\mathcal{X}$ and $\mathcal{Y}$, $\mathcal{X} \rightarrow \mathcal{Y}$ is a *functional dependency* if, for any instance $\boldsymbol{r}$ of $\boldsymbol{R}$ and for every pair of tuples $p, q \in \boldsymbol{r}$, the following implication holds:

$$p_{\mathcal{X}} = q_{\mathcal{X}} \Rightarrow p_{\mathcal{Y}} = q_{\mathcal{Y}} \qquad (3)$$

Order Compatibility Dependencies. Order compatibility dependencies encode the fact that in a relation two lists of attributes show the same monotonicity. If we order either combination of the lists in non-decreasing order, they end up both ordered such their values are both monotonically non-decreasing.

Definition 2.4 (order compatibility dep. (OCD)). Given a relation $\boldsymbol{R}$ and two lists of attributes $\mathbf{X}$ and $\mathbf{Y}$ in $\boldsymbol{R}$, $\mathbf{X} \sim \mathbf{Y}$ is a *order compatibility dependency* if, for any instance $\boldsymbol{r}$ of $\boldsymbol{R}$ and for every pair of tuples $p, q \in \boldsymbol{r}$, the following implications hold:

$$p_{\mathbf{XY}} \preccurlyeq q_{\mathbf{XY}} \Leftrightarrow p_{\mathbf{YX}} \preccurlyeq q_{\mathbf{YX}} \qquad (4)$$

Order dependencies are a stricter relation between two attributes with respect to functional and order compatibility dependencies; furthermore, when an order dependency between two lists of attributes $\mathbf{X}$ and $\mathbf{Y}$ holds, an order compatibility dependency between $\mathbf{X}$ and $\mathbf{Y}$ holds as well. In this sense, order dependencies combine the fact that an attribute functionally determines and have the same monotonicity of another when ordered together.

We present previous results [21] that formally highlight the nature of the relationship between these dependencies, showing that when an order dependency does not hold there are only two possible scenarios called *split* and *swap*. When $\mathbf{X}$ does not order $\mathbf{Y}$, i.e. when the order dependency between $\mathbf{X}$ and $\mathbf{Y}$ does not hold, we write $\mathbf{X} \not\mapsto \mathbf{Y}$.

	A	B
t_1	1	4
t_2	2	5
t_3	3	6
t_4	3	7
t_5	4	1

Table 4: A relational table containing both a split and a swap between the two attributes *A* and *B*.

Split. A split indicates the case where there exists a pair of tuples that have the same values when projected over the attributes X, but have different values over the attributes Y. Formally:

Definition 2.5 (Split). Two tuples s,$t \in \boldsymbol{r}$ form a split over two lists of attributes X, Y iff $s_{\mathrm{X}} = t_{\mathrm{X}}$ but $s_{\mathrm{Y}} \neq t_{\mathrm{Y}}$, or equivalently:

$$\exists s, t \in \boldsymbol{r} \,:\, s_{\mathrm{X}} = t_{\mathrm{X}} \wedge s_{\mathrm{Y}} > t_{\mathrm{Y}}$$

When an OD between two attribute lists is valid, then a FD is valid as well (Theorem 15, [21])

Theorem 2.6 (ODs subsume FDs). *For every instance* $\boldsymbol{r}$ *of relation* $\boldsymbol{R}$*, if the OD* $\mathrm{X} \mapsto \mathrm{Y}$ *holds, then the FD* $\mathcal{X} \to \mathcal{Y}$ *holds.*

Whereas if there is a split between two lists of attributes X and Y, there is no guarantee that ordering data will result in ordered tuples over Y and XY; in other words, both the ODs $\mathrm{X} \mapsto \mathrm{Y}$ and $\mathrm{X} \mapsto \mathrm{XY}$ do not hold. Furthermore, a split falsifies the functional dependency $\mathcal{X} \to \mathcal{Y}$ as well.

The relationship between order and functional dependencies is formalized as follows (Theorem 13, [21]):

Theorem 2.7 (FD and OD correspondence). *For every instance* $\boldsymbol{r}$ *of a relation* $\boldsymbol{R}$*, the functional dependency* $\mathcal{X} \to \mathcal{Y}$ *holds iff* $\mathrm{X} \mapsto \mathrm{XY}$ *holds for all lists* X *that order the attributes of* $\mathcal{X}$ *and all lists* Y *that order the attributes of* $\mathcal{Y}$.

In Table 4, tuples t_3 and t_4 form a split for the attributes A and B, thus $A \not\mapsto B$ and $A \not\mapsto AB$. The functional dependency $A \to B$ is not valid, as well.

Swap. A *swap* indicates the case where there exists a pair of tuples whose values projected over two lists of attributes X and Y are swapped, i.e. they are sorted differently when they are ordered with respect to X or Y. Formally:

Definition 2.8 (Swap). Two tuples s,$t \in \boldsymbol{R}$ form a swap over two list of attributes X and Y, iff $s_{\mathrm{X}} \prec t_{\mathrm{X}}$ but $t_{\mathrm{Y}} \prec s_{\mathrm{Y}}$, or equivalently:

$$\exists s, t \in \boldsymbol{r} \,:\, s_{\mathrm{X}} \prec t_{\mathrm{X}} \wedge s_{\mathrm{Y}} \succ t_{\mathrm{Y}}$$

Swaps between X and Y falsify the ODs of the form $\mathrm{X} \mapsto \mathrm{Y}$, $\mathrm{Y} \mapsto \mathrm{X}$, and $\mathrm{XY} \leftrightarrow \mathrm{YX}$. For example, tuples t_1 and t_5 in Table 4 form a swap for attributes A and B, thus $A \not\mapsto B$, $AB \not\mapsto B$, and $AB \not\mapsto BA$.

Splits and swaps establish a correspondence between order dependencies, functional dependencies and order compatibility dependencies, as in the following theorem (Theorem 15, [21]):

Theorem 2.9 (OD = FD + OCD). $\mathrm{X} \mapsto \mathrm{Y}$ *holds iff* $\mathcal{X} \to \mathcal{Y}$ *(*$\mathrm{X} \mapsto \mathrm{XY}$*) and* $\mathrm{X} \sim \mathrm{Y}$ *(*$\mathrm{XY} \leftrightarrow \mathrm{YX}$*) hold.*

In summary, when an order dependency between two lists of attributes X and Y holds:

- a functional dependency $\mathcal{X} \to \mathcal{Y}$ holds, which implies the absence of split conditions;
- an order compatibility dependency between X and Y holds, which implies the absence of swap conditions.

We exploit this relation to guide our discovery algorithm as established in Section 4.2.

3 ORDER DEPENDENCY THROUGH ORDER COMPATIBILITY

This section introduces the concepts that lay the foundations to our approach.

3.1 Minimality of Discovered Dependencies

Similarly to what has been done for functional dependencies, we introduce the notion of minimality of a set of order compatibility dependencies. In principle, minimality is the property for which a set of dependencies equipped with inference rules can recover all the dependencies that are valid in a given instance of relational data. Axioms AX1-AX6 presented in Table 3 provide inference rules for order dependencies.

The concept of minimality for order dependencies, as for other types of dependencies, has several uses. First of all, it allows reasoning about the validity of pruning rules, e.g., to show that they do not lead to loss of information about valid dependencies in the relation.

Minimality serves also the purpose of compressing information to a manageable size: in fact, if we take a relation with n attributes, in the worst case where each of which is order equivalent to every other, the minimal set of ODs would contain $n - 1$ dependencies ($A \leftrightarrow B, A \leftrightarrow C$, etc.), while the set of all valid dependencies would contain $\mathcal{O}((n!)^2)$ elements: all the possible combinations of attributes on the left-hand and right-hand sides, a prohibitively large number.

Finally, real applications may not need the whole list of dependencies: for example, in knowledge discovery, redundant dependencies do not add value to the properties discovered and too many dependencies can cause the most important ones to be missed; in query optimization, the only useful dependencies are those that can be applied to the queries to be performed.

Any pruning rule applied by a dependency discovery algorithm needs to respect minimality, in the sense that it should allow the recovery of the full set of valid dependencies. A complete algorithm must find at least all *minimal* order dependencies over an instance $\boldsymbol{r}$ of a relation $\boldsymbol{R}$.

To introduce the concept of minimality for ODs, we start by presenting the concepts of closure and equivalence of sets of order dependencies.

Definition 3.1 (Closure). The *closure* of the set of ODs $\mathcal{M}$, denoted $\mathcal{M}^+$, is the set of ODs that are logically implied from $\mathcal{M}$ by the axioms $\mathcal{J}_{\mathrm{OD}} = \{\mathrm{AX1} - \mathrm{AX6}\}$ defined in Table 3.

$$\mathcal{M}^+ = \{\mathrm{X} \mapsto \mathrm{Y} \mid \mathcal{M} \vdash_{\mathcal{J}_{\mathrm{OD}}} \mathrm{X} \mapsto \mathrm{Y}\}$$

Definition 3.2 (Equivalence of sets of ODs). Two sets $\mathcal{M}_1$ and $\mathcal{M}_2$ of order dependencies are *equivalent* if and only if they have the same closure $\mathcal{M}_1^+ = \mathcal{M}_2^+$.

The closure of a set of minimal dependencies is the set of all the dependencies that are valid over $\boldsymbol{r}$. We build this definition first showing which lists of attributes are in minimal form and then when an OCD is minimal. Finally, we prove that our definition of minimality is complete.

Order compatibility dependencies employ attribute lists instead of attribute sets, thus we introduce the concepts of *minimal* attribute list. An attribute list is minimal if it has no embedded order dependency, i.e., the list of attributes is the shortest possible.

Definition 3.3 (minimal attribute list). An attribute list $\mathbf{X}$ is minimal if there is no other list $\mathbf{X}'$ such that:

- $\mathbf{X}'$ is smaller than $\mathbf{X}$, and
- $\mathbf{X}$ and $\mathbf{X}'$ are order equivalent.

For example, the attribute list *ABA* is never minimal, in fact, by the Normalization axiom (AX3) we know that $ABA \leftrightarrow AB$ and *AB* is a shorter list than *ABA*. Instead, *AB* is a minimal attribute list, unless $A \leftrightarrow B$.

An OCD is minimal if both sides are given as minimal attribute lists and there are no repeated attributes:

Definition 3.4 (minimal OCD). An OCD $\mathbf{X} \sim \mathbf{Y}$ is minimal if:

- $\mathbf{X}$ and $\mathbf{Y}$ are minimal attribute lists;
- $\mathcal{X} \cap \mathcal{Y} = \varnothing$.

In the following theorem, we show that OCDs with repeated attributes can be derived from OCDs without repeated attributes:

Theorem 3.5 (Completeness of minimal OCD). *Order compatibility dependencies with repeated attributes can be derived from OCD without repeated attributes.*

Proof. The proof of this theorem is split in three cases:

(1) OCDs of the form $\mathbf{XY} \sim \mathbf{XZ}$ can be derived from $\mathbf{Y} \sim \mathbf{Z}$;
(2) OCDs of the form $\mathbf{XY} \sim \mathbf{MY}$ can be derived from $\mathbf{XY} \sim \mathbf{M}$ and $\mathbf{X} \sim \mathbf{MY}$;
(3) OCDs of the form $\mathbf{XY} \sim \mathbf{MYN}$ can be derived from $\mathbf{X} \sim \mathbf{M}$, $\mathbf{XY} \sim \mathbf{M}$, $\mathbf{X} \sim \mathbf{MY}$ and $\mathbf{XY} \sim \mathbf{MN}$;

which are covered respectively by Theorems 3.10, 3.11 and 3.12 which are presented separately for clarity in Section 3.3. □

The following result extends the Downward Closure theorem (Theorem 12, [21]):

Theorem 3.6. *Downward closure for OCD*

$$\frac{\mathbf{XY} \sim \mathbf{Z}V}{\mathbf{X} \sim \mathbf{Z}}$$

Theorems 3.5 and 3.6 provide the justification for the structure of the search tree used in our approach, as explained in Section 4.2. In particular, we derive the following pruning rule:

Theorem 3.7 (Pruning rule for OCD).

$$\frac{\mathbf{X} \nsim \mathbf{Z}}{\mathbf{XY} \nsim \mathbf{Z}V}$$

Proof. This theorem is the contronominal preposition of Theorem 3.6. □

Theorem 3.5 justifies the reduction of the search space that we highlight in the following section.

3.2 Dimension of the Search Space

The number of valid ODs over a relation $\boldsymbol{R}$ is vast: in fact, if $\boldsymbol{R}$ has n attributes, then all permutations of length k of n elements must be considered both for the left-hand side and the right-hand side of the OD. We address a limitation of the previous work by Langer and Naumann [13] and we show that some order dependencies with repeated attributes cannot be derived from other dependencies without repeated attributes.

For example, in Table 5 (a) we have that $AB \not\mapsto B$, instead in Table 5 (b) we have $AB \mapsto B$ and $A \sim B$. For both tables the dependencies $A \not\mapsto B$ and $B \not\mapsto A$ do not hold, thus the validity of $AB \mapsto B$ and $A \sim B$, in this case, cannot be inferred from shorter ODs.

	(a)		(b)	
	A	B	A	B
t_1	1	4	1	4
t_2	2	5	2	5
t_3	3	6	3	6
t_4	3	7	3	7
t_5	4	1	4	7

Table 5: Two relations where the ODs $A \not\mapsto B$ and $B \not\mapsto A$ do not hold; furthermore in (a) $AB \not\mapsto B$ while in (b) $AB \mapsto B$ and $A \sim B$.

Finding all valid order dependencies thus requires, in principle, the need for checking all combinations $\mathbf{X} \mapsto \mathbf{Y}$ where both $\mathbf{X}$ and $\mathbf{Y}$ can be permutations of length k of the n attributes in $\boldsymbol{R}$ with $1 \leq k \leq n$. If we denote with $S(n)$ the number of k-permutations of n elements we have:

$$S(n) = \lfloor e \cdot n! \rfloor - 1$$

Excluding trivial ODs of the form $\mathbf{X} \mapsto \mathbf{X}$, the number of candidates that needs to be checked would be:

$$C(n) = \big(S(n) - 1\big) \cdot \big(S(n) - 1\big) - \big(S(n) - 1\big) \propto \mathcal{O}\big((n!)^2\big) \quad (5)$$

With $n = 10$, there are more than $97 \cdot 10^{12}$ candidates ODs.

In contrast to general order dependencies, OCDs candidates with repeated attributes, i.e., $\mathbf{X} \rightarrow \mathbf{Y}$ or $\mathbf{X} \sim \mathbf{Y}$ where $\mathcal{X} \cap \mathcal{Y} \neq \varnothing$, are redundant in the sense that their validity can be inferred from the validity of other dependencies of the same type without repeated attributes and with shorter attribute lists.

Theorem 3.8. $\mathbf{X} \sim \mathbf{Y}$ *iff* $\mathbf{XY} \mapsto \mathbf{Y}$

Proof. We prove the implication in each direction:

⇒ By definition $\mathbf{X} \sim \mathbf{Y}$ implies that both the order dependencies $\mathbf{XY} \mapsto \mathbf{YX}$ and $\mathbf{YX} \mapsto \mathbf{XY}$ are valid. By Reflexivity (AX1) $\mathbf{YX} \mapsto \mathbf{Y}$ and thus by Transitivity (AX4) the order dependency $\mathbf{XY} \mapsto \mathbf{Y}$ is valid.

⇐ Conversely, if $\mathbf{XY} \mapsto \mathbf{Y}$, by Suffix (AX5) $\mathbf{XY} \mapsto \mathbf{YXY}$ and Normalization (AX3) $\mathbf{XY} \mapsto \mathbf{YX}$. □

□

This means that ODs of the form $\mathbf{XY} \mapsto \mathbf{Y}$ and OCDs of the form $\mathbf{X} \sim \mathbf{Y}$ are equivalent. We are thus enabled to solve the problem by considering only OCDs without repeated attributes, and thus the dimension of the search space is reduced to $\mathcal{O}(n!)$.

As shown in Theorem 2.9, if $\mathbf{X} \mapsto \mathbf{Y}$ then $\mathbf{X} \sim \mathbf{Y}$ is valid; we can thus derive the following theorem, which will provide the foundation for the pruning rules detailed in Section 4.2.1.

Theorem 3.9.

$$\frac{\mathbf{X} \mapsto \mathbf{Y}}{\mathbf{XZ} \sim \mathbf{Y}} \quad (6)$$

Proof. By the Augmentation theorem [21], $\mathbf{X} \mapsto \mathbf{Y}$ implies $\mathbf{XZ} \mapsto \mathbf{Y}$. By Theorem 2.9 of Section 2.2, $\mathbf{XZ} \mapsto \mathbf{Y}$ implies $\mathbf{XZ} \sim \mathbf{Y}$. □

3.3 Completeness of Minimal OCD

We divide the proof of the completeness of our definition of minimality for OCDs in three parts: first, in the following theorem we prove that attribute lists with repeated attributes at the beginning are redundant:

Theorem 3.10 (Completeness of minimal OCD - 1).

$$\frac{\mathbf{Y} \sim \mathbf{Z}}{\mathbf{XY} \sim \mathbf{XZ}}$$

Proof. By the Shift theorem [21] and the fact that $\mathbf{X} \leftrightarrow \mathbf{X}$ by Reflexivity (AX1):

$$\frac{\begin{array}{c}\mathbf{YZ} \mapsto \mathbf{ZY} \\ \mathbf{X} \leftrightarrow \mathbf{X}\end{array}}{\mathbf{XYZ} \mapsto \mathbf{XZY}}$$

by Normalization (AX3) and Replace [21] $\mathbf{XYXZ} \mapsto \mathbf{XZXY}$. Analogously by the Shift theorem [21] starting from $\mathbf{ZY} \mapsto \mathbf{YZ}$ we obtain $\mathbf{XZXY} \mapsto \mathbf{XYXZ}$. Thus $\mathbf{XYXZ} \leftrightarrow \mathbf{XZXY}$, i.e., $\mathbf{XY} \sim \mathbf{XZ}$ □

The following theorem proves that attribute lists with repeated attributes at the end are also redundant:

Theorem 3.11 (Completeness of minimal OCD - 2).

$$\frac{\begin{array}{c}\mathbf{X} \sim \mathbf{Y} \\ \mathbf{XZ} \sim \mathbf{Y} \\ \mathbf{X} \sim \mathbf{YZ}\end{array}}{\mathbf{XZ} \sim \mathbf{YZ}}$$

Proof.
(1) using $\mathbf{XY} \leftrightarrow \mathbf{YX}$ and $\mathbf{XZY} \leftrightarrow \mathbf{YXZ}$, by Normalization (AX3) $\mathbf{XZY} \leftrightarrow \mathbf{XZYZ}$ and by Replace [21] $\mathbf{YXZ} \leftrightarrow \mathbf{XZYZ}$;
(2) using $\mathbf{XY} \leftrightarrow \mathbf{YX}$ and $\mathbf{XYZ} \leftrightarrow \mathbf{YZX}$, by Normalization (AX3) $\mathbf{YZX} \leftrightarrow \mathbf{YZXZ}$, by Replace [21] $\mathbf{YXZ} \leftrightarrow \mathbf{YZX}$ and by Transitivity (AX4) $\mathbf{YXZ} \leftrightarrow \mathbf{YZXZ}$;

By Transitivity (AX4) $\mathbf{YXZ} \leftrightarrow \mathbf{XZYZ}$ and $\mathbf{YXZ} \leftrightarrow \mathbf{YZXZ}$ imply $\mathbf{XZYZ} \leftrightarrow \mathbf{YZXZ}$, i.e., $\mathbf{XZ} \sim \mathbf{YZ}$. □

Finally, the following theorem proves that attribute lists with repeated attributes in the middle are redundant:

Theorem 3.12 (Completeness of minimal OCD - 3).

$$\frac{\begin{array}{c}\mathbf{X} \sim \boldsymbol{M} \\ \mathbf{XY} \sim \boldsymbol{M} \\ \mathbf{X} \sim \boldsymbol{MY} \\ \mathbf{XY} \sim \boldsymbol{MN}\end{array}}{\mathbf{XY} \sim \boldsymbol{MYN}}$$

Proof.

(1) from $\mathbf{XY} \sim \mathbf{MN}$, by Normalization (AX3) $\mathbf{XYMYN} \leftrightarrow \mathbf{MNXY}$;
(2) from $\mathbf{XY} \sim \mathbf{M}$ and $\mathbf{X} \sim \mathbf{MY}$, using $\mathbf{X} \sim \mathbf{M}$ and Replace [21] we get $\mathbf{MYX} \leftrightarrow \mathbf{XYM}$ and $\mathbf{MXY} \leftrightarrow \mathbf{MYX} \leftrightarrow \mathbf{XYM}$;
(3) from (2), by the Shift theorem [21] with $\mathbf{MY} \leftrightarrow \mathbf{MY}$ and $\mathbf{MNXY} \leftrightarrow \mathbf{XYMMYN}$ we get $\mathbf{MYMNXY} \leftrightarrow \mathbf{MYXYMMYN}$;
(4) by Normalization (AX3) $\mathbf{MYMNXY} \leftrightarrow \mathbf{MYNXY}$;
(5) from $\mathbf{MYXYMMYN}$, using $\mathbf{MYX} \leftrightarrow \mathbf{XYM}$ and Normalization (AX3) we get $\mathbf{XYMYMYN}$ and finally $\mathbf{XYMYN}$;

From points (3), (4) and (5) we finally get $\mathbf{MYNXY} \leftrightarrow \mathbf{XYMYN}$, i.e., $\mathbf{XY} \sim \mathbf{MYN}$. □

4 THE OCDDISCOVER ALGORITHM

We present now the details of our algorithm, called ocddiscover, by first examining its search strategy to cover all the possible combinations and then presenting an implementation in pseudocode.

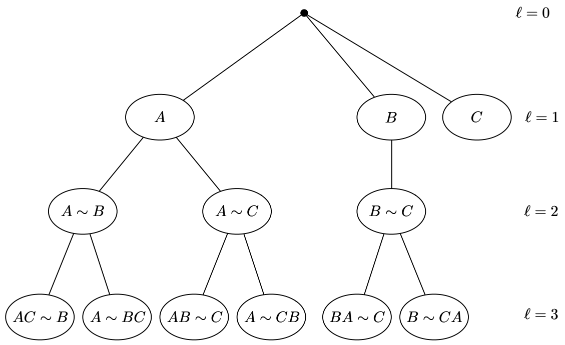

Figure 1: Permutation tree for a table with $n = 3$ attributes.

4.1 Column Reduction

Given that the search space grows with the number of columns, we start our discovery algorithm focusing on the columns showing special properties and we perform two operations: (a) the removal of constant columns; (b) the reduction of order-equivalent columns. The dependencies provided by these operations are an integral part of the results provided by our algorithm.

Removal of constant columns. Constant columns generate a huge amount of ODs; in fact, over an instance $\boldsymbol{r}$ a constant column C is ordered by any other attribute list $\mathbf{X}$.[1] Thus, we remove all constant columns and we collect the corresponding dependencies.

Reduction of order-equivalent columns. Order-equivalent columns as $A \leftrightarrow B$ describe a relation in which both the directions of the order dependency hold. By the Replace theorem (Theorem 6, [21]), we can replace any order dependency where A appears with another dependency with any instance of A replaced with B, that is:

$$\mathbf{X}A\mathbf{Y} \mapsto \mathbf{M}A\mathbf{N} \Leftrightarrow \mathbf{X}B\mathbf{Y} \mapsto \mathbf{M}B\mathbf{N}$$

We check any combination of order-equivalent dependencies, i.e. for all $A, B \in \mathcal{U}$ we verify the validity of $A \mapsto B$ and $B \mapsto A$, and we build the equivalence classes of columns using the Tarjan algorithm [25].

We choose a representative from each of these equivalence classes; we then remove all other columns. We store this information to later recover the redundant dependencies.

4.2 Search Tree

We use a breadth-first search strategy for identifying OCD relations in $\boldsymbol{r}$; in this way, shorter minimal dependencies are discovered before longer ones. At the first level, we consider the set of all pairs of single attributes. Given that OCDs are commutative, we build this set by enumerating all the attributes with $A_1, A_2, \ldots, A_n$ and taking all the pairs (A_i, A_j) such that $\{(A_i, A_j) \mid A_i, A_j \in \mathcal{U}, i < j\}$.

Figure 1 shows the tree $\mathcal{T}$ of generated candidates for a relation $\boldsymbol{r}$ with attributes $\mathcal{U} = \{A,B,C\}$ where all possible candidates are generated.

Each OCD candidate $\mathbf{X} \sim \mathbf{Y}$ is checked for order compatibility; we are then confronted with two possibilities:

[1] If C is constant column, the following property holds for any tuple $\boldsymbol{p}$, $\boldsymbol{q}$ in any instance $\boldsymbol{r}$ of $\boldsymbol{R}$: $p_{\mathbf{X}} \leq q_{\mathbf{X}} \Rightarrow p_C = q_C$, where the second part of the implication is always true by definition of constant column.

- if the candidate is not order compatible, we do not generate any other candidate starting from it, as stated by Theorem 3.7 in Section 3.1;
- if the candidate is order compatible, we generate new OCD candidates in the following way: for each attribute not already present in the OCD, for each $A \in \mathcal{U} \setminus \{\mathcal{X} \cup \mathcal{Y}\}$, we add it to the right of each attribute list, i.e. $\mathbf{X}A \sim \mathbf{Y}$ and $\mathbf{X} \sim \mathbf{Y}A$, then we apply further pruning rules as explained in Section 4.2.1.

4.2.1 Pruning Rules. When we find a new OCD $\mathbf{X} \sim \mathbf{Y}$, we further check the validity of the OD $\mathbf{X} \mapsto \mathbf{Y}$ and $\mathbf{Y} \mapsto \mathbf{X}$.

From Theorem 3.9 we derive the following pruning rules:

- if $\mathbf{X} \mapsto \mathbf{Y}$ we do not generate the candidates of the form $\mathbf{XZ} \overset{?}{\sim} \mathbf{Y}$, i.e. the left-hand children candidates of $\mathbf{X} \sim \mathbf{Y}$ are pruned;
- if $\mathbf{Y} \mapsto \mathbf{X}$, we do not generate the candidates of the form $\mathbf{X} \overset{?}{\sim} \mathbf{YZ}$, i.e. the right-hand children candidates of $\mathbf{X} \sim \mathbf{Y}$ are pruned;

If both dependencies are valid we prune all the subtree from the given OCD candidate.

With reference to Figure 1, if the order compatible dependency $A \sim B$ is valid:

- if $A \mapsto B$, the children candidate $AC \overset{?}{\sim} B$ is pruned;
- if $B \mapsto A$, the children candidate $A \overset{?}{\sim} BC$ is pruned.

4.2.2 Parallelizability. ocddiscover explores the tree of candidates breadth-first. Each branch of the tree can be visited independently since each OCD candidate is independent from the others; furthermore, a candidate is generated for each level if and only if its father in the tree was a valid order dependency. We exploit this structure to parallelize the execution of ocddiscover by assigning candidates from different branches to different queues; each queue is then processed by a different thread. With reference to Algorithm 1, if we have K cores available, we can have K independent subtrees $\mathcal{T}_\ell^1, \mathcal{T}_\ell^2, \ldots, \mathcal{T}_\ell^K$ (lines 7 — 12) each one containing the OCD candidates belonging to a different branch of the tree. The number of queues used by the algorithm can be chosen as a run-time parameter provided by the user.

4.3 Order Checking

One of the most important steps in our approach is the check of order compatibility candidates.

Single check. Given an OCD candidate in the form $\mathbf{X} \overset{?}{\sim} \mathbf{Y}$, we need to verify if it holds. The general definition of order compatibility states that $\mathbf{X} \sim \mathbf{Y} \equiv \mathbf{XY} \leftrightarrow \mathbf{YX}$, i.e. $\mathbf{X}$ and $\mathbf{Y}$ are order compatible if $\mathbf{XY} \mapsto \mathbf{YX}$ and $\mathbf{YX} \mapsto \mathbf{XY}$; however, with the following theorem, we can reduce the problem of checking the validity of an OCD to a single check.

Theorem 4.1. $\mathbf{XY} \mapsto \mathbf{YX}$ *is valid iff* $\mathbf{X} \sim \mathbf{Y}$.

Proof.

$\Rightarrow$ we have to prove that $\mathbf{XY} \mapsto \mathbf{YX} \Rightarrow \mathbf{YX} \mapsto \mathbf{XY}$. If, by contradiction, $\mathbf{YX} \not\mapsto \mathbf{XY}$, then:

$$\exists\, p,q \mid p_{\mathrm{YX}} \le q_{\mathrm{YX}} \Rightarrow p_{\mathrm{XY}} > q_{\mathrm{XY}} \tag{7}$$

thus since $p_{\mathrm{XY}} > q_{\mathrm{XY}}$ we can distinguish two cases:

– if $p_{\mathrm{X}} > q_{\mathrm{X}}$, we can conclude that:

$$q_{\mathrm{XY}} < p_{\mathrm{XY}} \Rightarrow q_{\mathrm{YX}} > p_{\mathrm{YX}}$$

thus $\mathbf{XY} \not\mapsto \mathbf{YX}$;

– if $p_{\mathrm{X}} = q_{\mathrm{X}} \wedge p_{\mathrm{Y}} > q_{\mathrm{Y}}$, we always obtain a contradiction with the condition expressed in Eq. 7;

thus both $\mathbf{XY} \mapsto \mathbf{YX}$ and $\mathbf{YX} \mapsto \mathbf{XY}$ are valid and $\mathbf{X} \sim \mathbf{Y}$;

$\Leftarrow$ by definition if $\mathbf{X} \sim \mathbf{Y}$ then both $\mathbf{YX} \mapsto \mathbf{XY}$ and $\mathbf{XY} \mapsto \mathbf{YX}$ are valid;

□

Checking with Indexes. To compute if an order dependency candidate holds, we sort the relation by the left-hand side attributes of the candidate. We build an index that contains only the position of each tuple in the order in which it appears. Then, we iterate over the tuples following this index, and we check if the attributes on the right-hand side violate the ordering, specifically if we detected a pair of tuples forming a swap. We break the detection loop as soon as we find a violation and return true otherwise. In the worst case, the number of comparisons to be made is $O(m + m \log m)$ where m is the total number of tuples in the relation.

`NULL` Values. In real-world datasets, and in many of the test cases that will be analyzed in Section 5, data contains `NULL` values, which destroy the total ordering assumption because they can not be compared with the other values. We use the standard SQL semantics given by `set ansi nulls ON`, i.e. `NULL` equals `NULL`, and `NULLS FIRST` for sorting.

4.4 Description of the Algorithm

Algorithm 1 is the main algorithm that implements our approach. The input is given by the instance of relational data $\boldsymbol{r}$ and its set of attributes $\mathcal{U}$.

Algorithm 1 ocddiscover

```
Input: r: a relational instance
Input: U: the set of attributes associated with r
 1: function ocddiscover(r, U)
 2:     $\ell \leftarrow 2$
 3:     $\mathcal{U}' \leftarrow$ columnsReduction($\mathcal{U}$)
 4:     $\mathcal{T}_1 \leftarrow \{(A,B) \mid A,B \in \mathcal{U}', B > A\}$
 5:     while $\mathcal{T}_\ell \neq \emptyset$ do                          ▷ Main loop
 6:         $\mathcal{T}_{\ell+1} \leftarrow \emptyset$
 7:         for each $(\mathrm{X},\mathrm{Y}) \in \mathcal{T}_\ell$ do
 8:             if checkCandidate(XY, YX, r) then
 9:                 emit $\mathrm{X} \sim \mathrm{Y}$
10:                 $\mathcal{T}_{\ell+1} \leftarrow \mathcal{T}_{\ell+1} \cup$ generateNextLevel($\mathrm{X}, \mathrm{Y}, \mathcal{U}'$)
11:             end if
12:         end for
13:         $\ell \leftarrow \ell + 1$
14:     end while
15: end function
```

In Line 3, function columnReduction() (not shown here) is called to apply the operations described in Section 4.1: the removal of constant attributes and the reduction of order-equivalent columns. This function prints a list of order-equivalence relations and a list of constant attributes and returns a reduced set of attributes $\mathcal{U}'$ where (a) the constant columns are removed; and (b) for each class of order-equivalent attributes, one representative is chosen.

The initial tree of OCD candidates is built in Line 4; by the commutativity of OCDs, only half of the combinations are added.

Figure 1 shows that the second level of the tree ($\ell = 2$) contains only the initial candidates $A \overset{?}{\sim} B$, $A \overset{?}{\sim} C$ and $B \overset{?}{\sim} C$.

Then, the algorithm continues with the main loop where each OCD candidate $\mathbf{X} \overset{?}{\sim} \mathbf{Y}$ is tested against the data in $\boldsymbol{r}$ in the form of an OD candidate $\mathbf{XY} \overset{?}{\mapsto} \mathbf{YX}$ using the function checkCandidate(), which is described in Algorithm 2.

The function checkCandidate() iterates over the index built on the left-hand side of the candidate with generateIndex() and checks that the values over the attributes in the right-hand side are in the same order. The loop is terminated early if a violation is detected.

Algorithm 2 checkCandidate

```
Input: X, Y: an OD candidate
Input: r: the instance of relational data
Output: true if $\mathbf{X} \mapsto \mathbf{Y}$, false otherwise.
function checkCandidate(X, Y, r)
    $l_r \leftarrow$ len(r)
    $index \leftarrow$ generateIndex(X,Y,r)
    for $i \leftarrow 1$ to $l_r - 1$ do
        for each $A \in \mathbf{Y}$ do
            if $r[index[i], A] > r[index[i+1], A]$ then
                return false
            else if $r[index[i], A] < r[index[i+1], A]$ then
                return true
            end if
        end for
    end for
    return true
end function
```

If the candidate is a valid OCD, we emit it as a result and generate the new candidates through generateNextLevel(), which is described in Algorithm 3.

The function generateNextLevel() builds a set containing all the OCD candidates of the form $\mathbf{X}A \sim \mathbf{Y}$ and $\mathbf{X} \sim \mathbf{Y}A$, where A is an attribute that does not already belong to the lists $\mathbf{X}$ and $\mathbf{Y}$, this corresponds to creating a new level of the tree presented in Section 4.2 using the pruning rules of Section 4.2.1. The function further checks if the ODs $\mathbf{X} \overset{?}{\mapsto} \mathbf{Y}$ or $\mathbf{Y} \overset{?}{\mapsto} \mathbf{X}$ hold. If so, it applies the pruning rules and returns the remaining candidates. We emit the valid ODs found in Lines 9 and 16 of Algorithm 3.

The new candidates are added to the queue of candidates to check for the next level in line 10 of Algorithm 1. The loop terminates when there are no candidates left.

5 EXPERIMENTAL EVALUATION

In this section, we evaluate the results of our approach, with particular emphasis on its scalability in the number of rows and columns, and we compare it with previous work on order dependency detection. We analyze the results of ocddiscover over 6 real-world datasets and 5 synthetic datasets.

Our algorithm is implemented in Java 1.7 and is designed to work on the Metanome data profiling framework [15] as a multi-threaded program.

All experiments were run on a `i686` Intel Xeon E52440 2.40 GHz machine with 12 cores in hyper-threading and 128 GB RAM, over a Linux kernel `v4.15.0`. The execution environment is a 64-bit Oracle JDK version `1.8.0_171`, with the JVM heap space limited to 110 GB.

Algorithm 3 generateNextLevel

```
Input: X, Y: an OCD candidate
Input: $\mathcal{U}'$: the set of reduced attributes of relation R
Output: C: the candidate OCD generated from $\mathbf{X} \sim \mathbf{Y}$
 1: function generateNextLevel(X, Y, $\mathcal{U}'$)
 2:     $C \leftarrow \varnothing$
 3:     $\mathcal{A}^+ \leftarrow \mathcal{U}' -$ set(X) $-$ set(Y)
 4:     if ¬checkCandidate(X, Y, r) then                 ▷ $\mathbf{X} \not\mapsto \mathbf{Y}$
 5:         for each $A \in \mathcal{A}^+$ do
 6:             $C.add((\mathbf{X}A, \mathbf{Y}))$
 7:         end for
 8:     else                                             ▷ $\mathbf{X} \mapsto \mathbf{Y}$
 9:         emit $\mathbf{X} \mapsto \mathbf{Y}$
10:     end if

5.1 Datasets

We use the datasets provided by the Information Systems Group of Hasso-Plattner-Institut.[2] These datasets are the same used by the previous work on order dependency discovery by Langer and Naumann [13]. We have also created three simple additional synthetic datasets, called `YES`, `NO`, and `NUMBERS` created to highlight the differences of our approach with previous works. In particular, `YES` and `NO` reproduce, respectively, the examples in Tables 5 (a) and 5 (b), while `NUMBERS` is shown in Table 7.

Table 6 presents the datasets and their properties; for each dataset, the table reports: the dataset name, the number of rows $|\boldsymbol{r}|$, the number of attributes $|\mathcal{U}|$, the number of functional dependencies discovered by the fastfds algorithm [26] $|\mathcal{F}_d|$, the number of ODs discovered $|\mathcal{O}_d|$ by order. For fastod we provide: (a) the number of FDs discovered $|\mathcal{F}_d|$, (b) the number of ODs discovered $|\mathcal{O}_d|$. For ocddiscover we provide: (a) the number of OCDs discovered $|\mathcal{O}_c|$, which are missed by order [13], since they are order dependencies with repeated attributes; (b) the number of ODs discovered $|\mathcal{O}_d|$; and (c) the total number of dependency candidates checked during the execution of the algorithm.

Execution time is averaged across 5 independent runs and we set a time threshold at 5 hours. When the time limit is reached, for order, and fastod we are unable to present the number of dependencies discovered so far, while for ocddiscover we report the number of dependencies discovered and the number of checks made until the limit.

5.2 Comparison with Previous Work

We discuss the results of the extensive comparison with the previous state-of-the-art algorithms for detecting order dependencies. The code used for the comparison has been provided by the respective authors.[3]

[2] https://hpi.de/naumann/projects/repeatability/data-profiling/fd-algorithms.html

[3] the source code for order is available at: https://hpi.de/naumann/projects/repeatability/data-profiling/fds.html#c168192 while the source of fastod has been provided to us by the authors through direct communication.

Table 7: NUMBERS dataset.

To compare our algorithm with ORDER and FASTOD we need to transform OCDs back to ODs. In fact, in a relation $\boldsymbol{R}$ over attributes A, B and C where $A \leftrightarrow B$, $A \sim C$ and $B \sim C$, the set of OCDs $\mathcal{O} = \{A \sim B, A \sim C, B \sim C\}$ is minimal following Definition 3.4. However, COLUMNSREDUCTION() would discover the order-equivalence $A \leftrightarrow B$ and choose one attribute as a representative, e. g. A. Thus OCDDISCOVER would return as valid OCDs only $\mathcal{O} = \{A \sim C\}$. From this information, we infer the remaining dependency $B \sim C$ using the axioms $\mathcal{J}_{\text{OD}}$. We perform this expansion and compare the results produced by OCDDISCOVER, ORDER and FASTOD. The function performing the expansion is not shown in Algorithm 1, but the times reported in Table 6 include it. This step did not impact the running time of OCDDISCOVER.

5.2.1 Comparison with Langer and Naumann [13]. For ORDER, dependencies are considered to be *completely non-trivial*, if their left- and right-hand side attribute lists are disjoint. However, we argue that limiting the discovery of order dependencies to candidates where the left-hand side and the right-hand side are completely disjoint gives incomplete results. Our algorithm, instead, is complete.

Following Theorem 3.8 in Section 3.2, order dependencies of the form $\mathbf{XY} \mapsto \mathbf{Y}$ can be inferred from order compatibility dependencies of the form $\mathbf{X} \sim \mathbf{Y}$. Note that these dependencies have repeated attributes between its left- and right-hand sides.

We show the difference between our approach and previous work with the YES and NO datasets. As reported in Table 6, the ORDER algorithm does not find any order dependency in either of the YES and NO datasets. OCDDISCOVER, instead, finds correctly the order compatibility dependency $A \sim B$, i.e., the order equivalence $AB \leftrightarrow BA$, in YES.

Our approach detects all the dependencies found by ORDER, and additional dependencies on HEPATITIS, NCVOTER_1K, and HORSE. For FLIGHT_1K and NCVOTER_ALLC we found several dependencies but we were not able to compare the results with ORDER because the latter does not report the discovered dependencies when the time limit is reached.

Provided that the order compatibility dependencies found by OCDDISCOVER are translated to the corresponding OD in the form $\mathbf{XY} \mapsto \mathbf{Y}$, OCDDISCOVER effectively discovers a minimal set of ODs even following the definition of minimality provided by Langer and Naumann [13].

When a candidate dependency is found to be false, pruning rules are applied. For this reason, notwithstanding the factorial dimension of the search space, datasets with several columns, such as datasets HEPATITIS and HORSE, are successfully and completely tested. When pruning cannot be applied, the generation of candidates grows – e.g., more than 7 million candidates are generated in FLIGHT_1K. For this dataset, OCDDISCOVER detects more than 32 million ODs. In this particular case, the number of checks is smaller than the number of discovered dependencies because we also count the dependencies inferred from constant and order-equivalent columns reported by the COLUMNSREDUCTION() function.

Furthermore, Table 6 shows that using order compatibility dependencies does not hinder the performance of the detection. In all dataset tested, the performance of our algorithm with respect to the execution time is comparable to order; in some cases, we obtain significant speedups up to a factor of 75, e.g. in HORSE.

5.2.2 Comparison with Szlichta et al. [18]. As shown in Table 6, ocddiscover and fastod compute a different number of order dependencies. We claim that this difference, which also affects also the results published in [18], is due to an implementation error in the code. Table 7 presents an instance of a relational table where the implementation of fastod we received finds several order dependencies that are not actually present in the data, e.g. $[B] \mapsto [AC]$. Other datasets were also affected by this issue, but, unfortunately, we were not able to isolate and resolve the root cause of this incorrect behavior. In addition, fastod considers all columns as if they contain data of type `String`, thus using a lexicographical ordering, while order and ocddiscover perform type inference over the datasets provided, and use the natural ordering for real and integer numbers. We have also implemented for ocddiscover the possibility of forcing lexicographical ordering, i.e., treat all data as if they were of type `String`, but we do not report these results since this change does not affect the execution time of our approach.

Furthermore, the scalability experiments reported by Szlichta et al. [18] used trimmed-down versions of the datasets. For the row scalability experiments, the datasets were reduced to 1,000 rows, while for the column scalability experiments columns were chosen at random. For this reason, we report in Table 6 both the DBTESMA and DBTESMA_1K datasets, which are respectively the full dataset with 250,000 rows, and a trimmed-down version with the first 1,000 rows. For column scalability, we tested ocddiscover and fastod against HEPATITIS, FLIGHT_1K, and NCVOTER_1K, which were used in full, so we were able to compare the performance of the two algorithms.

As shown in Table 6, ocddiscover gains significant speed-ups. This highlights the fact that, while the worst-case complexity of ocddiscover is $(O)(|\boldsymbol{r}|!)$, which is greater than that of fastod, $O(2^{|\boldsymbol{r}|})$, the execution time depends on the actual number of dependencies contained in the dataset.

5.3 Performance

In the following, we analyze the scalability of our approach with respect to the number of rows, the number of columns, and the number of parallel threads used.

5.3.1 Scalability in the number of rows. We performed our analysis on the synthetic dataset LINEITEM with 6,001,215 rows and 16 columns. We also test the algorithm on the NCVOTER dataset. This dataset has 938,084 rows and 94 columns, but since our algorithm did not terminate on the full datasets, we consider only a subset of 20 randomly chosen columns. Figure 2 shows the results for the scalability experiment on LINEITEM and NCVOTER. Ten samples of the original dataset have been created, ranging from 10% to 100% of the rows with a step of 10%. Five repetitions have been performed for each of the samples and the average is reported. Variance is very small and thus not shown.

The experiments show that the algorithm scales almost linearly with the number of rows, and it is able to find a complete set of OCDs over datasets with millions of rows.

The execution time would be expected to grow log-linearly with respect to the number of rows, due to the indexing phase; but an increasing number of rows may correspond to a smaller number of dependencies; thus, the pruning phase could reduce the number of checks to be computed.

Previous work, instead, has shown the ability to scale linearly on the number of rows performing the check of dependency candidates with sorted partitions computed from the data. This method could have been re-implemented in our approach as well, but it would have been out of the scope of this paper.

5.3.2 Scalability in the number of columns. Scalability over columns is the key challenge in detecting dependencies in relational data since in many cases the dimension of the search scales with the number of columns.

We choose the HORSE and HEPATITIS datasets, that are well-suited to evaluate the influence of an increasing number of columns, given that their execution completes. We also consider FLIGHT_1K that has a very high number of columns and does not terminate.

The evaluation approach is as follows: we start with two random columns from each dataset, and we incrementally add more randomly-chosen columns, until the total number of columns in the dataset is reached.

To avoid skewing the results, we generate 50 samples of each dataset with the process described above and we run our algorithm over these samples. We average the execution time of ocddiscover of each sample with c columns over all the 50 samples.

Figures 3 and 4 show the results of the column scalability experiment on the HEPATITIS and HORSE datasets.

Figure 5 shows how the algorithm behaves when the number of dependencies discovered in the data grows on a single run. Times on the y-axis are in logarithmic scale. ocddiscover is very susceptible to columns that are quasi-constant, i.e., attributes with very few distinct values, but not constant. In this case, ocddiscover cannot eliminate these columns during the column-reduction phase. As argued in Section 4.1, constant columns are ordered by any other attribute; quasi-constant columns are associated with a large number of valid OCDs and consequently the size of the tree to be explored grows enormously.

In fact, the slowdown corresponding to the sample with 28 columns in Figure 5 is caused by the addition of a column with 3 distinct values. This column appears on the right-hand side of more than 94% of the dependencies found in that sample.

5.3.3 Scalability over parallel threads. As described in Section 4.2.2, ocddiscover can be run over multiple threads.

Figure 6 shows the results of the multithreading scalability experiments on the LETTER, LINEITEM, and DBTESMA datasets. On the y-axis times are normalized to the runtime over a single thread, which is the maximum for each case. Table 8 reports the executions times.

	Time (s) vs number of threads			
Dataset	**1**	**2**	**4**	**8**
LETTER	5.7	4.6	3.6	3.4
LINEITEM	2,848.8	1,770.0	1,243.5	1,040.0
DBTESMA	2,228.9	1,240.0	686.0	414.0

Table 8: Execution time of ocddiscover versus number of threads.

As it is shown in Figure 6, using multiple parallel threads shortens the execution time of our dependency discovery algorithm.

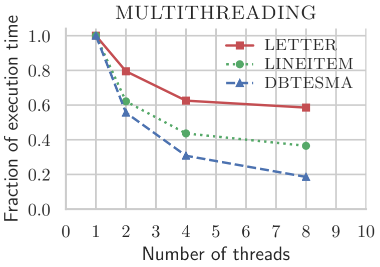

Figure 6: Execution times for `LETTER` (red straight line), `LINEITEM` (green dotted line), `DBTESMA` (blue dashed line), when executed over multiple threads, normalized over the runtime over a single thread.

The amount of this improvement varies based on the characteristics of each dataset and in particular, depends on the of OCD candidates checked.

If we compare `LETTER` and `LINEITEM`, we see that while the number of checks performed on each dataset is comparable (272 for `LETTER` versus 255 for `LINEITEM`), the number of their rows differ by several orders of magnitude (~ $20k$ lines for `LETTER`, versus ~ $6M$ for `LINEITEM`). This implies that checking the validity of an OCD candidate for `LINEITEM` takes longer than checking a candidate for `LETTER`. Thus the relative gain when splitting the work over multiple threads is greater for `LINEITEM`.

Instead, comparing `LINEITEM` and `DBTESMA` we can see that for the latter dataset the number of checks performed is much higher, thus the workload of candidate checking can be spread over multiple threads, leading to greater relative improvements.

5.4 Quasi-constant Columns

The quasi-constant column scenario is challenging for our algorithm. We further develop the idea of measuring how varied the values in a column are by measuring its *entropy*.

Definition 5.1 (Entropy). Given an attribute $A \in \mathcal{U}$ of an instance $\boldsymbol{r}$ of a relation $\boldsymbol{R}$, the entropy of A is defined as:

$$H(A) = -\sum_{[a]} p_{[a]} \log\left(p_{[a]}\right) \tag{8}$$

where $[a]$ are the equivalence classes of distinct values in A and $p_{[a]}$ is the probability of extracting an instance of class a, computed as the relative frequency of instances class $[a]$ over the total number of tuples in $\boldsymbol{r}$:

$$p_{[a]} = \frac{|\{t \in \boldsymbol{r} \mid t_A \in [a]\}|}{|\boldsymbol{r}|}$$

For constant columns there is only one equivalence class and $p_{[a]} = 1$, thus $H(A) = 0$. If all values are distinct, for each $[a]$, $|[a]| = 1$ and $p_{[a]} = 1/|\boldsymbol{r}|$:

$$H(A) = -\sum_{[a]} \frac{1}{|\boldsymbol{r}|} \log\left(1/|\boldsymbol{r}|\right) = \log\left(|\boldsymbol{r}|\right)$$

We test the idea that progressively less diverse columns cause the slowdown of OCDDISCOVER by taking the `FLIGHT_1K` dataset and running it over multiple samples build with the following criteria: we calculate the entropy of each column in `FLIGHT_1K` and then we build samples of increasing size in the number of columns by adding progressively the columns with decreasing entropy, i.e., we start with the columns with the greatest number of distinct values and we progressively add columns with less distinct values. Eventually, the constant columns are added.

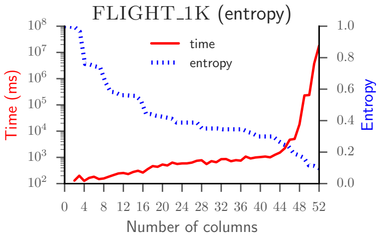

Figure 7: Execution times (red straight line) for the `FLIGHT_1K` when adding columns of decreasing entropy (blue dotted line). On the y-axis, times (left-hand side) are in logarithmic scale, entropy (right-hand side) is normalized with respect to the maximum value over the dataset.

The result of the execution on OCDDISCOVER over this set of samples is reported in Figure 7. With 50 columns the OCDDISCOVER completes in 4 minutes, adding the 51st column the execution time grows by an order of magnitude to over 1 hour. With the addition of the 52nd column, the algorithm reaches the time limit of 5 hours. The 50th, 51st, and 52nd columns have respectively 4, 2, and 2 distinct values respectively.

With respect to applications, this insight could be exploited to develop algorithms that return results for the most diverse columns, which can be the most interesting with respect to other properties of the data such as unique column combinations (UCC). Detection of unique column combinations is usually performed to find primary keys candidates that may be also interesting candidates from the point of view of ordering and query optimization.

In summary, the column scalability experiments show that OCDDISCOVER can find a complete set of ODs over datasets with tens of columns. Furthermore, OCDDISCOVER can be easily adapted to perform the detection over a set of interesting columns, where the interestingness of an attribute can be determined providing a function measuring the properties chosen by the user.

6 RELATED WORK

Functional Dependencies: Theory, Discovery and Applications. Literature on functional dependencies is vast [2, 12, 14, 16]. Applications of functional dependencies span several fields from query optimization [6], to data cleaning [5], to data quality management [8]. Given this variety of applications, several algorithms for the discovery of functional dependencies have been developed. The first algorithm to be proposed was TANE [12], which has served as inspiration for many subsequent efforts [14, 16]. Research on better functional dependency discovery algorithms is still ongoing [15]. Functional dependencies have been extended in several ways: from conditional functional dependencies [4], to approximate (or partial) functional dependencies [14].

Order Dependencies Theory and Applications. In the 1980's, Ginsburg and Hull were the first to consider the idea of analyzing orderings between the attributes of a relation as a kind of dependency [9–11]. They introduced the concept of point-wise ordering [11], that is a relation where a set of attributes orders another set of attributes. Recently, Szlichta et al. introduced the concept of order dependency [21], which is the one used throughout this paper. Order dependencies are defined over lists of attributes, and can be formalized in a similar way to functional dependencies [21, 23]. In this paper we focused on dependencies where the attributes are all ordered in the same direction, also called "unidirectional" order dependencies; however order dependencies can be generalized to "polarized" or "bidirectional" ODs where a different direction of the ordering can be specified for each attribute on either side of the dependency [20]. One of the main theoretical problems concerning dependencies in relational data is the problem of inference. For order dependencies this problem is shown to be co-NP-complete [24].

Applications of Order Dependencies. Notwithstanding their recent theoretical formulation, order dependencies have been already used in several applications, such as query optimization.

Sorting is a fundamental database operation. Since the seminal works [10], research has focused on developing optimization strategies for dealing with queries with an `ORDER BY` clause [17]. Order dependencies can be used for this purpose, as it has been shown with an implementation of a query optimizer in IBM DB2. Optimizing queries with order dependencies yields significant speedups in execution times over the well-known TPC-DS benchmark and on queries taken from real-world scenarios [22].

Discovery Algorithms for Order Dependencies. These applications are driving the need for discovering order dependencies in existing datasets. The first work proposing an algorithm to solve this problem is the one by Langer and Naumann [13]. Their approach, called ORDER, follows the path of TANE, computing the potential order dependency candidates from the permutations of attributes and traversing the lattice in a level-wise, bottom-up manner. Pruning rules are applied to reduce the number of candidates to check, with the caveat of eliminating only redundant relations that can be later inferred from the dependencies discovered together with the axioms. However, as shown in this paper, this approach does not consider all the possible order dependency candidates, discarding repeated attributes. While this gives a significant advantage in execution time, reducing the worst-case time complexity of the algorithm to $O(|\boldsymbol{r}|!)$, its major drawback is the possibility of losing completeness. More recently Szlichta et al. [18] proposed an algorithm called FASTOD that is complete and faster than ORDER. This algorithm exploits a novel polynomial mapping that transforms ODs with lists of attributes into canonical forms of ODs that are established between sets of attributes. FASTOD has exponential worst-case time complexity, $O(2^{|\boldsymbol{r}|})$, in the number of attributes. Recently, this work was extended in order to discover bidirectional order dependencies [19].

7 CONCLUSIONS

In this work, we presented a novel method for discovering order dependencies (ODs). We based our approach on the fact that an order dependency is valid if and only if both a functional dependency (FD) and an order compatibility dependency (OCD) are valid. Thus, we designed a novel and efficient algorithm – called OCDDISCOVER – where the search for ODs is guided by checking the validity of OCDs. Our approach outperforms existing two state-of-the-art algorithms, ORDER [13] and FASTOD [18] with respect to ORDER, we are complete, meaning that we detect order dependencies that are ignored. We have shown that these dependencies cannot be inferred by other detected dependencies. While the worst-case complexity of OCDDISCOVER is greater than FASTOD, the execution time on real datasets depends on the actual number of dependencies found, thus our algorithm outperforms FASTOD. Furthermore, we presented an extensive set of experiments that illustrate that our approach can be executed in parallel over multiple threads. We have also suggested that considering the entropy of attributes can lead to further developments in discovery the most interesting order dependencies. As a future work, we would like to consider dynamic inputs, where additional rows and columns may be added at runtime.

ABSTRACT

Local outlier techniques are known to be effective for detecting outliers in skewed data, where subsets of the data exhibit diverse distribution properties. However, existing methods are not well equipped to support modern high-velocity data streams due to the high complexity of the detection algorithms and their volatility to data updates. To tackle these shortcomings, we propose local outlier semantics that operate at an abstraction level by leveraging kernel density estimation (KDE) to effectively detect local outliers from streaming data. A strategy to continuously detect top-N KDE-based local outliers over streams is designed, called **KELOS** – the first linear time complexity streaming local outlier detection approach. The first innovation of KELOS is the abstract kernel center-based KDE (*a*KDE) strategy. *a*KDE accurately yet efficiently estimates the data density at each point – essential for local outlier detection. This is based on the observation that a cluster of points close to each other tend to have a similar influence on a target point's density estimation when used as kernel centers. These points thus can be represented by one abstract kernel center. Next, the KELOS's inlier pruning strategy early prunes points that have no chance to become top-N outliers. This empowers KELOS to skip the computation of their data density and of the outlier status for every data point. Together *a*KDE and the inlier pruning strategy eliminate the performance bottleneck of streaming local outlier detection. The experimental evaluation demonstrates that KELOS is up to 6 orders of magnitude faster than existing solutions, while being highly effective in detecting local outliers from streaming data.

1 INTRODUCTION

Motivation. The growth of digital devices coupled with their ever-increasing capabilities to generate and transmit live data presents an exciting new opportunity for real time data analytics. As the volume and velocity of data streams continue to grow, automated discovery of insights in such streaming data is critical. In particular, finding *outliers* in streaming data is a fundamental task in many online applications ranging from fraud detection, network intrusion monitoring to system fault analysis. In general, outliers are data points situated away from the majority of the points in the data space. For example, a transaction of a credit card in a physical location far away from where it has normally been used may indicate fraud. Over 15.4 million U.S residents were victims of such fraud in 2016 according to [3]. On the other hand, as more transactions take place in this new location, the previous transaction may appear legitimate as it begins to conform to the increasingly expected behavior exemplified by the new data. Thus, in streaming environments, it is critical to design a mechanism to efficiently identify outliers by monitoring the statistical properties of the data relative to each other as it changes over time.

State-of-the-Art. To satisfy this need, several methods [20, 21] have been proposed in recent years that leverage the concept of *local outlier* [6] to detect outliers from data streams. The local outlier notion is based on the observation that real world datasets tend to be skewed, where different subspaces of the data exhibit different distribution properties. It is thus often more meaningful to decide on the outlier status of a point based on its difference with the points in its local neighborhood as opposed to using a global density [9] or frequency [5] cutoff threshold to detect outliers [11]. More specifically, a point x is considered to be a *local outlier* if the *data density* at x is low *relative* to that at the points in x's local neighborhood. Unfortunately, existing streaming local outlier solutions [20, 21] are not scalable to high volume data streams. The root cause is that they measure the data density at each point x based on the point's distance to its k nearest neighbors (kNN). Unfortunately, kNN is very sensitive to data updates, meaning that the insertion or removal of even a small number of points can cause the kNN of many points in the dataset to be updated [20]. Since the complexity of the kNN search [6] is quadratic in the number of the points, significant resources may be wasted on a large number of unnecessary kNN re-computations. Therefore, those approaches suffer from a high response time when handling high-speed streams. For example, it takes [20, 21] 10 minutes to process just 100k tuples as shown by their experiments. Intuitively, kernel density estimation (KDE) [26], an established probability density approximation method, could be leveraged for estimating the data density at each point [16, 23, 27]. Unlike kNN-based density estimation that is sensitive to data changes, KDE estimates data density based on the statistical properties of the dataset. Therefore, it tends to be more robust to gradual data changes and thus a better fit for streaming environments. However, surprisingly, to date no method has been proposed that utilizes KDE to tackle the local outlier detection problem for data streams.

Challenges. Effectively leveraging KDE in the streaming context comes with challenges. Similar to kNN search, the complexity of KDE is quadratic in the number of points [26]. While the computational costs can be reduced by running the density estimation on kernel centers sampled from the input dataset, sampling leads to a trade-off between accuracy and efficiency. Although a low sampling rate can dramatically reduce the computational complexity, one must be cautious because the estimated data density at each point may be inaccurate due to an insufficient number of kernel centers. On the other hand, a higher sampling rate will certainly lead to a better estimation of the data density. However, the computational costs of KDE increase quadratically with more kernel centers. With a large number of kernel centers, KDE

*This work was partly supported by the National Science Foundation under grants IIS-1815866 and IIS-1560229.

would be at risk of becoming too costly to satisfy the stringent response time requirements of streaming applications. Due to this accuracy versus efficiency trade-off, to the best of our knowledge, no method has successfully adapted KDE to function efficiently on streaming data to date.

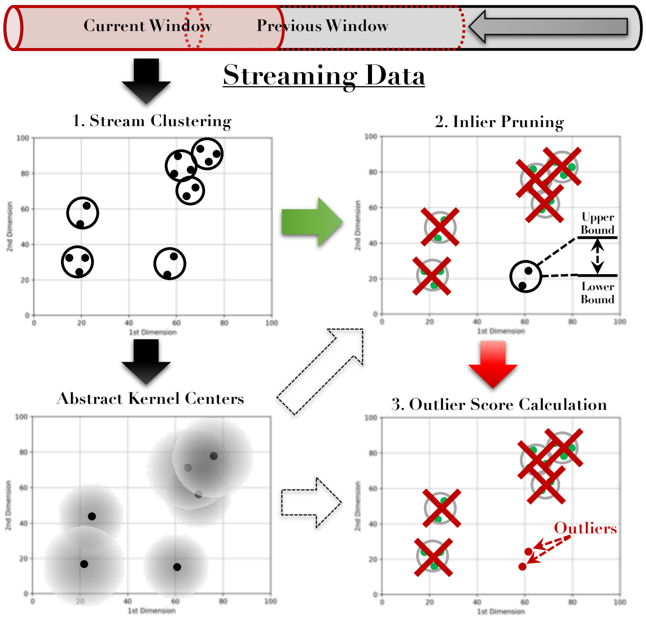

Figure 1: An illustration of KELOS approach.

Proposed Solution. In this work, we propose a scalable KDE-based strategy (Fig. 1) for detecting top-N local outliers over streams, or in short **KELOS**. KELOS provides the first practical solution for local outlier detection on streaming data. Our key contributions are given below.

- New KDE-based semantics are proposed for the continuous detection of the top promising outliers from data streams. This establishes a foundation for the design of a scalable streaming local outlier detection method.
- A notion of the *abstract kernel center* is introduced to solve the accuracy versus efficiency trade-off of KDE. This leverages the observation that kernel centers close to each other tend to have a similar strength of influence on the densities at other points. These nearby points thus can be clustered together and considered as one abstract kernel center weighted by the amount of data it represents. Compared to the traditional sampling-based KDE, our strategy achieves accurate density estimation using *much fewer kernel centers*. This in turn speeds up the quadratic complexity process of local density estimation. This notion of abstract kernel centers by itself could be applied to a much broader class of density estimation related stream mining tasks beyond local outlier detection.
- Unlike existing techniques [20, 21], which detect outliers by computing the data density and then the outlierness score for every data point, KELOS quickly prunes the vast majority of the data points that have no chance to become outliers. The more expensive KDE method itself is only used thereafter to evaluate the remaining much smaller number of potential outlier candidates.
- Putting these optimizations together, we obtain the first linear time complexity streaming local outlier detection approach that outperforms the state-of-the-arts by up to 6 orders of magnitudes in speed confirmed by our experiments on real world datasets.

2 PRELIMINARIES

2.1 Local Outlier

Given a point x_i, it is a *local outlier* if the *data density* at x_i (e.g. inverse of average distances to its kNN) is significantly lower than the densities at x_i's neighbors.

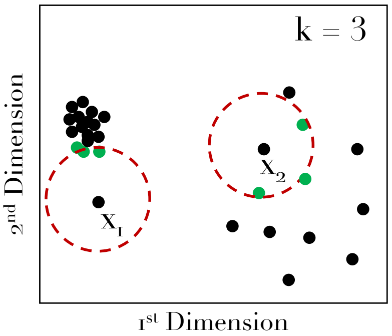

Figure 2: Local outlier detection using local densities.

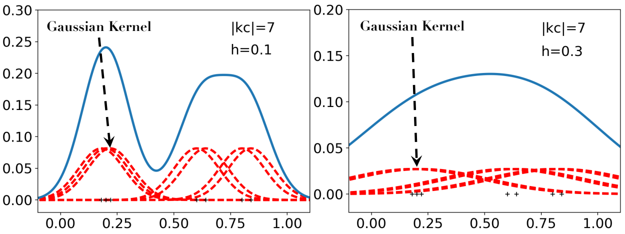
As illustrated in Fig. 2, although the densities at x_1 and x_2 are both low, the density at x_1 is quite different than the densities at the locations of its neighbors. However, the densities at the neighbors of x_2 is similar to x_2. Therefore, x_1 is more likely to be an outlier than x_2 due to its *relatively low density* in contrast to those at its neighbors. Therefore, conceptually measuring a point x_i's status of being a **local outlier** corresponds to the two-steps:
(1) Estimate the density at x_i and the densities at its neighbors;
(2) Compute the outlierness score of x_i based on the deviation of the density at x_i in contrast to those at its neighbors.

2.2 Kernel Density Estimation



(a) Bandwidth h = 0.1 **(b) Bandwidth h = 0.3**

Figure 3: An example of univariate kernel density estimator using Gaussian kernel with different bandwidth.

Kernel density estimation (KDE) is a non-parametric method to estimate the probability density function (PDF) of a dataset $X = \{x_1, \cdots, x_n\}$. Given a point x_i, the kernel density estimator of X computes how likely x_i is drawn from X. This computed probability can be interpreted as the "data density" at x_i in X.

The density at x_i in X is:

$$\tilde{f}(x_i) = \frac{1}{m} \sum_{j=1}^{m} K_h(|x_i - kc_j|). \tag{1}$$

Kernel Centers. $kc_j \in \mathbb{KC}$ where $1 \leq j \leq m$ are called the kernel centers in the estimator. Typically, kc_j is a point sampled from X. The selected set of kernel centers must be sufficient to represent the data distribution of X [26]. Each kernel center kc_j carries a kernel function K_h. The *density contribution* by a kernel center kc_j is calculated based upon the distance from kc_j to the target point x_i. The density at x_i is estimated by the average density contribution by all kernel centers. For example, in Fig. 3(a), there are 7 kernel centers. Each of them carries a kernel function (red dashed curve). The shape of the overall density function across all kernels is represented by the blue solid line. Given a dataset X with n points and m kernel centers, the time complexity of computing the densities of all $x_i \in X$ is $O(nm)$.

Kernel Function. A wide range of kernel functions can be used in kernel density estimation [26]. The most commonly used ones are the *Gaussian* and *Epanechnikov* kernel functions [11]. In this study, we adopt the *Gaussian* kernel:

$$K_{gauss}(u) = \frac{1}{(\sqrt{2\pi})h} e^{(-\frac{1}{2}\frac{u^2}{h^2})}, \tag{2}$$

$$K_{epanechnikov}(u) = \frac{3}{4h}\left(1 - \frac{u^2}{h^2}\right), \tag{3}$$

where u represents the distance from a kernel center kc_j to the target point x_i and h is an important smoothing factor, called *bandwidth*. The *bandwidth h* controls the smoothness of the shape of the estimated density function. The greater the value h, the smoother the shape of the density function $\tilde{f}$. As shown in Figs. 3(a) and (b), using the same set of kernel centers but different bandwidth values, the estimated PDFs (the blue lines) are significant different from each other. Therefore, an appropriate bandwidth is critical to the accuracy of the density estimation.

Balloon Kernel. In *balloon kernel* [30], when estimating the density at a target point x_i, only the k nearest kernel centers of x_i denoted as kNN(x_i,$\mathbb{KC}$) are utilized in the estimator. This provides each point x_i a customized kernel density estimator that adapts to the distribution characteristics of x_i's surrounding area, hence also called *local density*. Therefore, Balloon kernel fits the local outlier that detects outliers based on the local distribution properties as shown in [23]:

$$\tilde{f}(x_i) = \frac{1}{k}\sum_{j=1}^{k} K_h(|x_i - kc_j|) \text{ where } kc_j \in k\text{NN}(x_i, \mathbb{KC}). \tag{4}$$

Multi-dimensional Kernel. We adopt the *product kernel* [24] as the form of the kernel function. The product kernel is typical in density estimation for multi-dimensional data. Given a d dimensional target point x_i and a kernel center kc_j, for each dimension l the product kernel (Eq. 5) first computes the density contribution of kc_j to x_i based on the distance on dimension l. The final density contribution by kc_j to x_i is the product of the density contributions by kc_j on all dimensions, so called product kernel. As we will show in Sec. 7, this creates opportunities for the design of constant time density update operation in the streaming context. Moreover, product kernel allows the bandwidth to be customized for each dimension, resulting in more accurate estimation [24].

$$\tilde{f}(x_i) = \sum_{j=1}^{k}\prod_{l=1}^{d} K_{h^l}(|x_i^l - kc_j^l|) \text{ where } kc_j \in k\text{NN}(x_i, \mathbb{KC}). \tag{5}$$

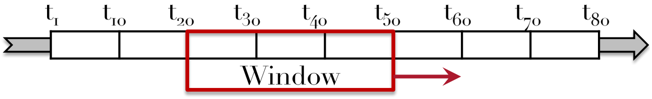


Figure 4: A data stream in the form of sliding windows.

3 PROPOSED OUTLIER SEMANTICS

Next, we propose our semantics of KDE-based streaming local outliers. We first introduce the notion of top-N local outliers that captures the most extreme outliers in the input dataset. We then apply this concept to sliding windows to characterize outliers in data streams.

3.1 Top-N KDE-based Local Outliers

We first define a new outlierness measure, KDE-based local outlierness measure (KLOME). The goal is to reduce the computation costs of the existing KDE-based outlier semantics [23], while still effective in detecting outliers.

Definition 3.1. **KLOME.** Given a set of data points $X = \{x_1, \cdots, x_n\}$ and a set of kernel centers $\mathbb{KC} = \{kc_1, \cdots, kc_m\}$, the KLOME score of a target point $x_i \in X$ is defined as KLOME(x_i) = *z-score*($\tilde{f_b}(x_i)$, $\{\tilde{f_b}(kc_j) \mid \forall kc_j \in k\text{NN}(x_i, \mathbb{KC})\}$).

Here *z-score*$(s, S) = (s$ - $\bar{S})/\sigma_S$ [33] indicates how many standard deviations a value s is above or below the mean of a set of values S. In this definition, KLOME(x_i) measures how different the local density at x_i is from the average local density at x_i's nearest kernel centers denoted as kNN(x_i, $\mathbb{KC}$). A negative KLOME score of a target point x_i indicates that the local density at x_i is smaller than the local densities at its neighbors' locations. The *smaller* the KLOME score of a point x_i is, the *larger* the possibility that x_i is an outlier.

The key property of our KLOME semantics is that the density at x_i is compared against the densities at its kNN in the kernel center set $\mathbb{KC}$ (kNN(x_i, $\mathbb{KC}$)) instead of its actual kNN in the dataset.

The intuition is as below. The kernel centers sufficient to recover the distribution of the original dataset can well capture every local phenomenon. The density at x_i is estimated based on its location *relative to* the selected kernel centers kc_j $\in k$NN(x_i, $\mathbb{KC}$). Naturally kc_j can serve as the local neighbor of x_i in the density deviation computation of x_i (*z-score*). In other words, kNN(x_i, $\mathbb{KC}$) effectively models the local neighborhood of a point x_i. This in turn significantly reduces the computational complexity compared to working with x_i's kNNs in the much larger input dataset X.

Next, we define the top-N KDE-based local outlier:

Definition 3.2. Given a set of data points $X = \{x_1, \cdots, x_n\}$ and a count threshold N, the **top-N KDE-based local outliers** are a set of N data points, denoted by *Top*-KLOME(X, N) such that $\forall x_i \in$ *Top*-KLOME(X, N) and $\forall x_j \in X \setminus$ *Top*-KLOME(X, N), KLOME(x_i) $\leq$ KLOME(x_j).

3.2 Local Outlier Detection in Sliding Window

We work with periodic sliding window semantics, illustrated in Fig. 4, commonly adopted to model a finite substream of interest from the otherwise infinite data stream [4]. Such semantics can be either time or count-based. Each data point x_i has an associated time stamp denoted by $x_i.time$. The window size and slide size of a stream S are denoted as $S.win$ and $S.slide$ correspondingly.

Each window W_c has a starting time $W_c.T_{start}$ and an ending time $W_c.T_{end} = W_c.T_{start} + S.win$. Periodically the current window W_c slides, causing $W_c.T_{start}$ and $W_c.T_{end}$ to increase by $S.slide$ respectively. For count-based windows, a fixed number (count) of data points corresponds to the window size $S.win$. Accordingly $S.slide$ is also measured by number of data points. $\mathcal{S}^{W_c}$ denotes the set of data points falling into the current window W_c. The local outliers are then always detected in the current active window W_c. An outlier in the current window might turn into an inlier in the next window.

Next, we define the problem of continuously detecting Top-KLOME(X, N) over sliding windows:

Definition 3.3. Given a stream S, a window size $S.win$, a slide size $S.slide$, and an integer N, continuously compute Top-KLOME$(\mathcal{S}^{W_c}, N)$ over sliding windows.

Next, we introduce our KELOS framework for supporting continuous local outlier detection over windows stream with our proposed KLOME semantics.

4 THE KELOS FRAMEWORK

KELOS framework, depicted in Fig. 5, consists of three main components, namely, **stream data abstractor**, **density estimator** and **outlier detector**.

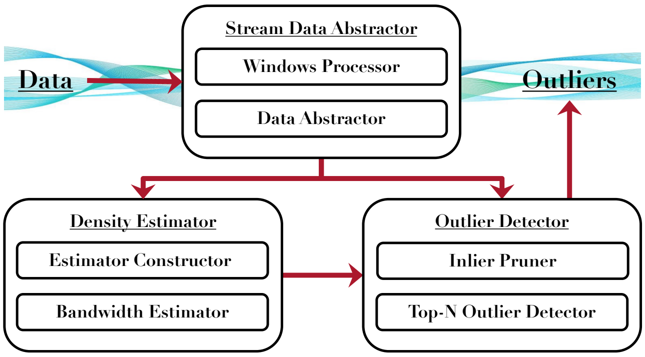

Figure 5: The KELOS framework.

The **stream data extractor** is composed of the *window processor* and the *data abstractor*. The *window processor* feeds the latest data that falls into the current stream window to the system. By leveraging a lightweight stream clustering approach, the *data abstractor* dynamically organizes the data points in each window into evolving clusters based on their affinity. It then generates and maintains statistics that reflect the key distribution properties of each cluster. These statistics are essential to performing density estimation and the inlier pruning during outlier detection.

The *estimator constructor* in the **density estimator** builds kernel density estimators utilizing *abstract kernel centers* where each abstract kernel center represents one data cluster. The *bandwidth estimator* leverages the statistics associated with each cluster to approximate an optimal bandwidth for each density estimator customized for each target. The constant time complexity of the bandwidth estimator ensures that the bandwidth can be continuously updated online to best fit the data.

The **outlier detector** continuously computes the top-N outliers, that is, the N points with the highest outlierness scores. It avoids having to compute the density and the outlierness score for each and every point by pruning clusters that as a whole do not have a chance to contain any outlier. This leverages the *stable density* property of a tight cluster and the characteristics of local outliers (Sec. 6.1).

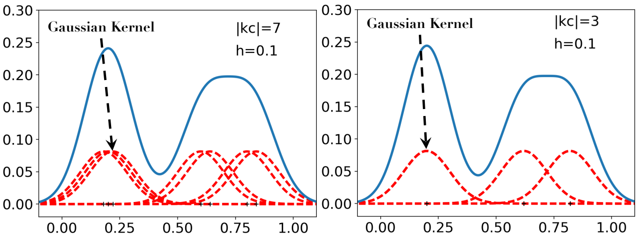
In Sec. 5, we present the key strategies of our **density estimator**, namely abstract kernel center-based KDE. In Sec. 6, we introduce the techniques core to our **outlier detector**. It efficiently identifies and prunes the points that are guaranteed not to be outliers. Finally, in Sec. 7, we introduce our **stream data abstractor**. It features a low complexity dual-purpose clustering algorithm that continuously constructs data clusters, while at the same time generating the statistics needed to support the density estimator and outlier detector.

5 DENSITY ESTIMATOR

In this section, we propose our abstract kernel center-based KDE strategy (*a*KDE). It solves the problem of accurately yet efficiently estimating the density at a given point. In contrast to the traditional sampling-based KDE approach [26], our density estimation is performed on top of a set of clusters (Fig. 1) that succinctly summarize the distribution characteristics of the dataset. This approach is inspired by our *abstract kernel center* observation below.

Abstract Kernel Center Observation. In KDE, the density at a given point x_i is determined by the *additive influences* of the kernel centers, while the influence from one center kc_j is determined by the distance between kc_j and x_i. The centers close to each other tend to have similar influence on the target point x_i. Using them redundantly instead of representing them as a whole perplexes the density estimation by unnecessarily enlarging the center space. To obtain succinct while informative representatives as kernel centers, KELOS first performs a lightweight clustering that groups close points together. The centroid of the cluster weighted by the cluster's data cardinality, called abstract kernel center (AKC) is then selected as a kernel center to perform density estimation.

Fig. 6(b) shows an example estimation using the abstract kernel centers. The original 7 points in Fig. 3(a) are abstracted into three clusters. The estimations (blue line) in Fig. 6(b) with 3 centers and Fig. 6(a) using all 7 points as kernel centers are similar.



(a) All points as kernel centers **(b) Abtract kernel centers**

Figure 6: Local kernel density estimator.

On the performance side, real world data sets tend to be skewed. Therefore, typically most points can be clustered into a small number of tight clusters. Correspondingly, the number of the abstract kernel centers tends to be much smaller than the number of sampled kernel centers that would be sufficient to represent the overall data distribution of the dataset. Since the bottleneck of local density estimation is on the computation of the k nearest kernel centers for each to be estimated point x_i, the small number of abstract kernel centers promises to reduce the complexity of the successive density estimation process.

Furthermore, the abstract kernel centers allow us to use a small k while establishing a diversified neighborhood – hence a comprehensive density estimator for each point. This not only reduces the complexity of the kNN search and kernel density computation, but also alleviates the problem of selecting an appropriate k because of the reduced range of possible k.

Definition 5.1. Given a stream window $S^{W_c} = \{x_1, \cdots, x_n\}$, the abstract kernel centers of S^{W_c} are a set of pairs $\mathbb{AKC}(S^{W_c}) = \{\langle c_{c_1}, |c_1|\rangle, \cdots, \langle c_{c_m}, |c_m|\rangle\}$, where c_{c_i} $(1 \leq i \leq m)$ corresponds to the centroid of the respective data cluster c_i and $|c_i|$ the number of points in c_i. Here $\bigcup_{i=1}^{m} c_i = S^{W_c}$ and $\forall i, j, i \neq j$ $c_i \cap c_j = \emptyset$.

Weighted Kernel Density Estimator. Intuitively, each abstract kernel center represents the centroid of a cluster of points close to each other along with the data cardinality of this cluster. Utilizing these abstract kernel centers, we construct a weighted kernel density estimator [13], where the kernel centers correspond to the centroids in $\mathbb{AKC}(S^{W_c})$ (the first component of $\mathbb{AKC}$) and the weight corresponds to the cardinality of the data cluster represented by the centroid (the second component). Therefore, the weighted kernel density estimator reflects the distribution characteristics of the entire dataset by utilizing only a small number of kernel centers. The formula is shown below:

$$\tilde{f}_{\mathbb{AKC}(S^{W_c})}(x_i) = \sum_{j=1}^{k} \omega(c_{c_j}) \prod_{l=1}^{d} K_{h^l}(|x_i^l - c_{c_j}^l|) \tag{6}$$

where

$$\omega(c_{c_j}) = \frac{|c_j|}{\sum_{m=1}^{k} |c_m|}, \tag{7}$$

and $c_{c_m} \in k\text{NN}(x_i, \mathbb{AKC}(S^{W_c}))$. Here $\tilde{f}_{\mathbb{AKC}(S^{W_c})}(x_i)$ in Eq. 6 corresponds to a weighted product kernel estimator that computes the local density at x_i and $k\text{NN}(x_i, \mathbb{AKC}(S^{W_c}))$ corresponds to the k nearest centroids of x_i in the abstract kernel centers.

Bandwidth Estimation. One additional step required to make the weighted kernel density estimator work is to establish an appropriate bandwidth for the kernel on each dimension. Here we show that the data driven strategy introduced in [25] (Eq. 8) can be efficiently applied here by leveraging the abstract kernel centers.

$$h^l = 1.06\sigma^l k^{-1/(d+1)}. \tag{8}$$

In Eq. 8, d denotes the data dimension. σ^l denotes the weighted standard deviation of the kernel centers on the lth dimension computed by:

$$\sigma^l = \sqrt{\sum_{m=1}^{k} \omega(c_{c_m})(c_{c_m}^l - \mu^l)^2}, \tag{9}$$

where

$$\mu^l = \frac{\sum_{m=1}^{k} \omega(c_{c_m}) c_{c_m}^l}{k}, \tag{10}$$

and $c_{c_m} \in k\text{NN}(x_i, \mathbb{AKC}(S^{W_c}))$.

Efficiency. The time complexity of KDE is $O(nm)$, where n is number of data points and m is the number of kernel centers. Since *a*KDE dramatically reduces the number of kernel centers, it significantly speeds up the KDE computation. On the other hand, data clustering introduces extra computation overhead. In this work, we apply the low complexity *micro-clustering* [2] strategy that processes each point only once. This overhead is significantly outweighed by the saved KDE computation costs. Therefore, overall *a*KDE is much faster than the traditional KDE – as shown in Sec. 8.2.

6 OUTLIER DETECTOR

Our outlier detector fully utilizes the data clusters produced for *a*KDE by leveraging our *stable density* observation described below.

Stable Density Observation. Data points in a tight cluster are close to each other. Therefore, they tend to share the same kernel centers and have similar local densities. By the definition of local outliers, the outlierness score of a point x depends on the relative density at x in contrast to those at its neighbors. Therefore, these points tend to have similar outlierness scores. Since outliers only correspond to small subset of points with the highest outlierness scores, it is likely that most of the data clusters do not contain any outlier.

Assume we have a method to approximate the highest (upper bound) and lowest (lower bound) outlierness scores for the points in each data cluster. Using these bounds, the data clusters that have no chance to contain any outlier can be quickly identified and pruned from outlier candidate set without any further investigation. More specifically, if the upper bound outlierness score of a data cluster c_i is smaller than the lower bound outlierness score of a data cluster c_j, then the whole c_i can be pruned (under the trivial premise that c_j has at least N points). This is so because there are at least N points in the dataset whose outlierness scores are larger than any point in c_i.

Leveraging this observation, we now design an efficient local outlier detection strategy. The overall process is given in Alg. 1. We first rank and then prune data clusters based on their upper KLOME score bounds. As shown in Sec. 3.1, a small KLOME score indicates large outlier possibility. Therefore, the upper KLOME bound corresponds to the lower outlierness score bound. Similarly, the lower KLOME bound corresponds to the upper outlierness score bound. Therefore, if the lower KLOME bound of a cluster c_i is higher than the upper KLOME bound of another cluster c_j, all points in c_i can be pruned immediately. Only the clusters with a small lower KLOME bound (large outlierness score upper bound) are subject to further investigation. The densities and KLOME scores at the data point-level are computed only for the data points in these remaining clusters. Finally, the top-N results are selected among these points by maintaining their KLOME scores in a priority queue.

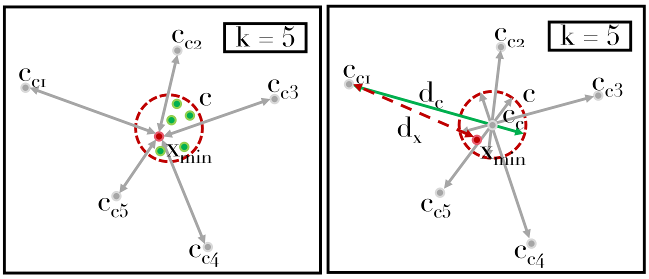
6.1 Bounding the KLOME Scores

Next, we present an efficient strategy to establish the upper and lower KLOME bounds for each given data cluster.

By Def. 3.1, the KLOME score of a point x_i corresponds to *z-score*($\tilde{f}(x_i)$, S), where S refers to the local densities at x_i's kernel centers. Since the points in the same cluster c_i typically share the same kernel centers, the data point $x_{min} \in c_i$ with the minimal density determines the lower bound KLOME score of the entire cluster c_i. Similarly the upper bound is determined by the point x_{max} with the maximal density. Obviously it is not practical to figure out the lower/upper bound by computing the densities at all points and thereafter finding x_{min} and x_{max}.

Algorithm 1 : Top-N Outlier Computation.

```
Input: Clusters $C$.
Output: Top-N Outliers.
$PriorityQueue$<Cluster> $P$ of size $N$ /*by upperbound in ascending order*/
$P \leftarrow$ first $N$ in $C$
for rest of the cluster $c$ in $C$ do
    if $KLOME_{low}(c) > KLOME_{up}(P.peek)$ then
        prune $c$
    else if $KLOME_{up}$(c) < $KLOME_{low}(P.peek)$ then
        $P$.poll & $P$.add($c$)
    else
        $P$.add($c$)
$PriorityQueue$<Data> $R$ of size $N$ /*by $KLOME$ in ascending order*/
for cluster $c$ in $P$ do
    for data $d$ in $c$ do
        compute $KLOME$ of $d$
        $R$.add($d$)
return $R$
```



(a) Lowest KLOME in c **(b) Lower bound of c**

Figure 7: An example of lower KLOME bound.

Lower bound. We now show that by utilizing the statistical property of each data cluster – more specifically the *radius*, the bounds can be derived in constant time. Here we use the lower bound as example to demonstrate our solution (Fig. 7).

Lemma 6.1. *Given a data cluster c_i, its k nearest kernel centers $\{c_{c_1}, \cdots, c_{c_k}\}$ and the data point x_{min} which has the minimum density among all points in c_i, $\tilde{f}_{min}(c_i) \le \tilde{f}(x_{min})$, where $\tilde{f}_{min}(c_i) = \sum_{j=1}^{k} \omega(c_{c_j}) K_h(|c_{c_i} - c_{c_j}| + r)$. Here r is the radius of c_i and c_{c_i} is the centroid of c_i.*

Proof. The density contribution $K_h(|x_i - c_{c_j}|)$ is inversely proportional to the distance between the evaluated point x_i and the kernel center c_{c_j}. The longer the distance, the smaller the density contribution is from the kernel center. The radius r of a cluster c_i is the distance from c_i's centroid c_{c_i} to the furthest possible points in c_i. The longest possible distance from a kernel center c_{c_j} to any point in c_i is denoted as $d_c = |c_{c_i} - c_{c_j}| + r$. The distance from c_{c_1} to x_{min} is denoted as $d_x = |c_{c_j} - x_{min}|$. $d_c \ge d_x$ by the triangle inequality. Therefore $K_h(d_x) \le K_h(d_c)$. This holds for any kernel center c_{c_j}. Therefore $\tilde{f}_{min}(c_i) = \sum_{j=1}^{k} \omega(c_{c_j}) K_h(|c_{c_j} - c_{c_i}| + r) \le \tilde{f}(x_{min})$. □

Intuitively, the density at a data point is measured by the summation of the density contributions of all relevant kernel centers. The summation of the density contribution from each kernel center c_{c_j} to the point x_j that is the point furthest to c_{c_j} in c_i is guaranteed to be smaller or equal to the density at point x_{min}. This is so because the distance from x_{min} to each kernel center c_{c_j} cannot be larger than the distance between c_{c_j} and x_j.

According to Lemma 6.1, given the radius of a data cluster c_i and its k nearest kernel centers $c_{c_1} \cdots c_{c_k}$, the **lower KLOME bound** of cluster c_i is computed as:

$$KLOME_{low}(c_i) = z\text{-}score(\tilde{f}_{min}(c_i), \{\tilde{f}(c_{c_1}) \cdots \tilde{f}(c_{c_k})\}). \quad (11)$$

Upper Bound. Similarly, we can show that the maximal local density at a cluster c_i, denoted by $\tilde{f}_{max}(c_i)$, can be obtained based on the shortest distance from each kernel center to the points in c_i.

$$\tilde{f}_{max}(c_i) = \sum_{j=1}^{k} \omega(c_{c_j}) K_h(|c_{c_j} - c_{c_i}| - r). \quad (12)$$

Accordingly, the upper KLOME bound of each cluster c_i $KLOME_{up}(c_i)$ is derived based on $\tilde{f}_{max}(c_i)$.

$$KLOME_{up}(c_i) = z\text{-}score(\tilde{f}_{max}(c_i), \{\tilde{f}(c_{c_1}) \cdots \tilde{f}(c_{c_k})\}). \quad (13)$$

7 THE EFFICIENT STREAM DATA ABSTRACTOR

The stream data abstractor adapts a lightweight stream clustering algorithm similar to [2, 8] that clusters the extremely close data points together. As the clusters are continuously constructed and incrementally maintained, the statistics needed by both *a*KDE and inlier pruning, namely the *cardinality*, the *centroid*, and the *radius* of the cluster, must also be continuously generated. We thus refer to this as dual-purpose clustering. The dual-purpose clustering is based on two key ideas: *additive meta data* and *pane-based meta data maintenance.*

The **additive meta data** is inspired by *micro-clustering* [2] – a popular stream clustering approach. The idea is that by maintaining meta data that satisfies the additive properties, the statistics required by both the density estimator and the outlier detector can be computed in constant time whenever the window evolves.

Definition 7.1. A **cluster** c_i in a d-dimensional data set $S_{W_c} = \{x_1, \cdots, x_m\}$ corresponding to the data in the current window W_c of stream S is represented as a 4-tuple set $\{M, LS, R_{min}, R_{max}\}$ where M denotes the cardinality of the cluster, $LS =< \sum_{i=1}^{m} x_i^1, \cdots, \sum_{i=1}^{m} x_i^d >$ is the linear sum of the points by dimension, $R_{min} =< x_{min}^1, \cdots, x_{min}^d >$ and $R_{max} =< x_{max}^1, \cdots, x_{max}^d >$ are the minimum and maximum values of the points in each dimension.

Cardinality and Centroids for *a*KDE. In Def. 7.1, M refers to data cardinality of cluster c_i. M is used to compute the *weight* (Eq. 7) and the *centroid* of the abstract kernel center. The linear sum LS is used to compute the *centroid* of cluster $c_i = \frac{LS}{M}$.

The Radius for Inlier Pruning. R_{min} and R_{max} representing the minimal and maximal values in each dimension are utilized to compute the radius of cluster c_i. Radius is a key statistic needed by our outlier detector to quickly prune the clusters from the outlier candidate set.

Since the radius is defined as the distance from the centroid c_{c_i} to its furthest point in cluster c_i, the radius changes whenever the centroid changes. All points in c_i then have to be re-scanned

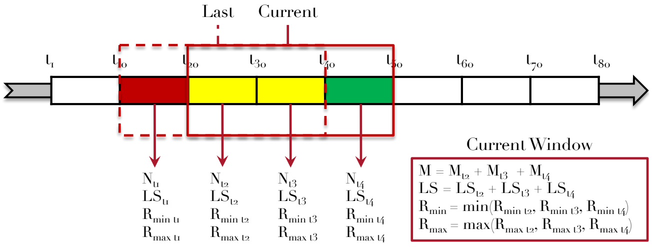


Figure 8: An example of an evolving cluster.

to find the point "furthest" from the new centroid. This, being computational expensive, is not acceptable in online applications.

The remedy comes from our carefully selected product kernel function (Eq. 5). In the product kernel, each dimension has its own customized bandwidth. Accordingly, we only need the radius on each single dimension to estimate the bandwidth instead of the radius over the multi-dimensional data space. Since updating the minimum or maximum value per insertion or deletion to an array is constant cost, the cost of radius maintenance for k separated dimensions (R_{min} and R_{max}) is constant as well.

Pane-based meta data maintenance. The pane-based meta data maintenance strategy [17] is utilized to effectively update the meta data for each cluster as the window slides. Given the window size $S.win$ and slide size $S.slide$, a window can be divided into $\frac{S.win}{gcd(S.win,S.slide)}$ small panes where *gcd* refers to greatest common divisor. The meta data of a cluster c_i is maintained at the pane granularity instead of maintaining one meta data structure for the whole window. Since the data points in the same pane arrive and expire at the same slide pace, the meta data can be quickly computed by aggregating the meta data structures maintained for the unexpired panes as the window moves. This process is illustrated in Fig. 8. Since the meta data satisfies the additive property, the computation can be done in constant time. In this way, no explicit operation is required to handle the expiration of outdated data from the current window. Therefore, our stream clustering algorithm only needs to exclusively deal with the new arrivals.

The Dual-Purpose Stream Clustering Algorithm. Once a new data point x arrives, The algorithm first finds its nearest cluster according to the distance of x to all the centroids. If the distance from x to its nearest cluster c_i denoted as $dist(x, c_{c_i})$ is smaller than a radius threshold θ, x is inserted into c_i. The corresponding *4-tuple* meta data is updated accordingly. On the other hand, if $dist(x, c_{c_i}) > \theta$, a new cluster will be created. This logic is described in Alg. 2.

7.1 Time Complexity Analysis of KELOS

The complexity of the clustering comes from the nearest centroid search. The complexity is $O(mc)$ with m the number of new arrivals and c the number of centroids. In the density estimation step, each point has to find its k nearest kernel centers from the c centroids. Therefore, in worst case the complexity is $O(c)$ for each point. In the outlier detection step, the cluster-based pruning takes $O(c^2)$.

One more pass is required for the remaining points to compute the density and the outlierness score. Assuming the number of remaining points is l, the density computation takes $O(lc)$, while the outlierness score computation takes $O(l \log N)$, where $O(\log N)$ comes from the priority queue operation for maintaining the top-N outlierness score points. Therefore, the overall computation costs for a batch of newly arriving data points is $O(mc) + O(c^2) + O(lc) + O(l \log N)$. In summary, the time complexity of our KDE based outlier detection approach is linear in the number of points. Since typically $N \ll c \ll l \ll m$, the complexity is dominated by the clustering step.

Algorithm 2 : Dual-Purpose Stream Clustering

```
Input: Data batch $\mathcal{D}$ at time $t_i$, window size $S.win$ and threshold $\theta$.
Output: Clusters $C$.
Array<Cluster> C
for every data $d$ in $\mathcal{D}$ do
    $dist_{min} \leftarrow +\infty$
    Cluster $c_n$
    for every cluster $c$ in $C$ do
        $dist \leftarrow distance(d, c.centroid_{t_{i-S.win+1} \rightarrow t_i})$
        if dist $< dist_{min}$ then
            $dist_{min} \leftarrow dist$
            $c_n \leftarrow c$
    if $dist_{min}$ < threshold $\theta$ then
        $c_n$.insert($d$,$t_i$)
    else
        Cluster $c_{new}$
        $c_{new}$.insert($d$,$t_i$)
        $C$.add($c_{new}$)
return $C$
```

8 EXPERIMENTAL EVALUATION

8.1 Experimental Setup & Methodologies

In this section, we compare the efficiency and effectiveness of KELOS against the state-of-art local outlier detection approaches for data streams. All experiments are conducted on an Ubuntu server with 56 Intel(R) Xeon(R) 2.60GHz cores and 512GB memory. Overall, our KELOS is 1-6 orders of magnitude faster, while still at least as accurate as the alternative approaches.

We utilize the public as well as synthetic datasets generated using the data mining framework ELKI [1] to measure the efficiency of KELOS. We also work with real labeled datasets so that we can evaluate the effectiveness of KELOS.

Real Datasets. We work with 3 labeled public datasets. The **HTTP** dataset [10] contains in total 567,479 network connection records with 2,211 among them being outliers. The labeled outliers correspond to different types of network intrusions including DOS, R2L, U2R, etc. Three numerical attributes, namely duration, src_bytes and dst_bytes are utilized in our experiments. The points in the HTTP dataset are ordered by their arrival time. Therefore we can generate a data stream simply by enforcing a sliding window on it.

The Yahoo! Anomaly Dataset (**YAD**) [15] is considered as one of the industry standards for outlier detection evaluation. It is composed of 4 distinct data sets. In this work we utilize Yahoo! A1 and Yahoo! A2. Yahoo! A1 is based on the real production traffic to some of the Yahoo! services. The anomalies are marked by Yahoo! domain experts. Yahoo! A2 is a synthetic data set containing time-series with random seasonality, trend and noise. Yahoo! A1 and Yahoo! A2 contain 94,866 points with 1,669 outliers and 142,101 points with 312 outliers respectively. Each data point has three attributes: timestamp, value, and label.

Synthetic Datasets. We generate synthetic datasets to measure the efficiency of KELOS under various scenarios with different distribution properties. We first create static datasets containing different number of data clusters and then utilize these datasets to simulate windowed streams. For example, to simulate a windowed stream with three clusters and some outliers, we first create a static dataset containing three clusters. The size and shape of the clusters are controlled by different parameter settings in ELKI such as type of distribution, standard deviation, etc. When generating a sliding window data stream, different windows correspond to different datasets with different cluster densities.

Comparative Methods. We compare KELOS against five baselines, namely sLOF, sKDEOS, pKDEOS, iLOF [20] and MiLOF [21]. LOF [6] is the seminal and most popular local outlier detection method. KDEOS [23] leverages KDE in local density estimation which is then used to compute an outlierness score for each point. Since their performance bottleneck is the kNN search, we implemented the skyband stream kNN search algorithm [29] to speed up their outlier detection process for windowed streams and named the modified methods as sLOF and sKDEOS. iLOF [20] and MiLOF [21] are two incremental LOF algorithms specifically designed for *landmark* windows. iLOF computes the LOF score for each inserted data point and update the LOF score of the affected data points following the reverse kNN relationships. MiLOF improves iLOF in a scenario where the memory is limited. When the memory limit is reached, part of the existing data points are summarized into small clusters as references for the future LOF approximation. Since iLOF and MiLOF do not handle data expiration, they have to start from scratch for each new window. In the original KDEOS, every data point in the input dataset is used as kernel center. We also implemented a sampling-based sKDEOS called pKDEOS, since it is the common practice for KDE to use only the data points uniformly sampled from the input dataset as kernel centers. All methods continuously return the N points with the highest outlierness scores as outliers in each window.

Efficiency Measures. We measure the end-to-end execution time.

Effectiveness Measures. We measure the effectiveness using the *Precision@N* (*P@N*) metric typical for the evaluation of outlier detection techniques [7].

$$P@N = \frac{\text{\# of True Outliers}}{N}. \tag{14}$$

Intuitively, $P@N$ measures the true positive of the detected top-N outliers. An ideal $P@N$ equals to 1, where all outliers are found and no inlier is returned as result. Here we measure the $P@N$ metric window by window and report the average $P@N$ over all windows. Following [7], we replace N with $|O|$ in the $P@N$ computation for each window, where $|O|$ corresponds to the total number of labeled (ground truth) outliers falling in this window. Only the top-$|O|$ points out of the top-N outlier list are used in the evaluation. Therefore, the $P@|O|$ for n consecutive stream windows is:

$$P@|O| = \frac{\sum_{i=1}^{n} \text{\# of True Outliers in top-}|O|_i}{\sum_{i=1}^{n} |O|_i}, \tag{15}$$

where $|O|_i$ denotes the number of the true outliers in the ith window.

To investigate the quality of the ranking in the Top-$|O|$ outlier list, we also measure the *average precision* (AP) [31]:

$$Average\,Precision(AP) = \frac{1}{|O|} \sum_{o \in O} P@rank(o). \tag{16}$$

Here P@rank(o) measures the $P@N$, where N is set as rank(o) representing the position at which a true outlier o appears. AP measures how well the true outliers are ranked among all data points.

8.2 Efficiency Evaluation

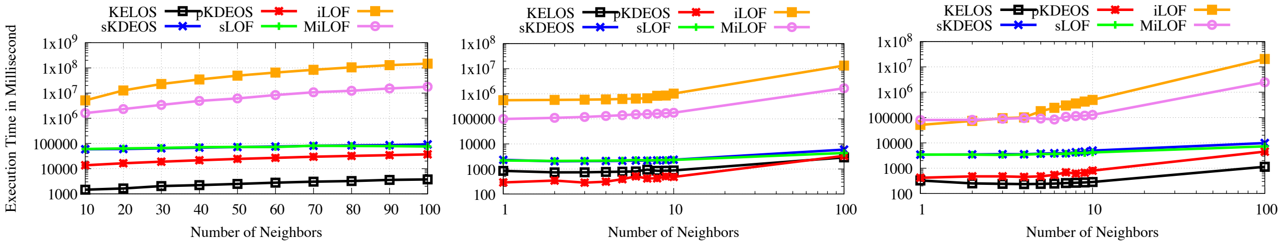
We evaluate the end-to-end execution time and memory consumption by varying the number of the neighbors k, the window size and the window overlap rate.

Number of Neighbors k. The k parameter defines the number of the neighbors to be considered in the computation of outlierness score for each point. We first report the execution time of all methods on real datasets with varied k from 10 to 100. The radius threshold θ of KELOS appropriate for HTTP, Yahoo! A1, and Yahoo! A2 are set as 0.095, 0.1 and 40 (See Sec.8.4 for parameter tuning). The window size of HTTP is set to 6,000 and window sizes of Yahoo! A1 and Yahoo! A2 are set as 1,415, and 1,412 based on the instruction of the data provider for the effectiveness of outlier detection. The sampling rates of pKDEOS is set as 10% which is a relatively high sampling rate ensuring that pKDEOS always has more than k kernel centers to use as k increases. For MiLOF, we configured it to keep 10% of the data in memory for LOF score approximation.

As shown in Fig. 9(a), KELOS is about 2-6 orders of magnitude faster than the alternatives. Among all alternative methods, iLOF and MiLOF are the slowest. To reduce the influence of the new arrivals they use a *point-by-point* processing strategy that computes the LOF score for each new point and update the LOF score of the affected data points immediately after a single insertion. It wastes significant CPU time on unnecessarily updating the LOF scores of some points that are modified again later due to the insertion of other new arrivals. sLOF and sKDEOS are 1-2 orders of magnitude faster than the previous two, as they compute the outlierness score only once for each data point in the entire window. pKDEOS is faster than sKDEOS and sLOF, because pKDEOS only utilizes the sampled points as kernel centers. Searching for the k nearest kernel centers from the sampled kernel center set is much faster than searching among all points in each window. However, pKDEOS is still at least 1 order of magnitude slower than KELOS on HTTP. This is because in order to satisfy the accuracy requirement, the number of the sampled kernel centers has to be large enough to represent the distribution of the data stream. While the aKDE approach of KELOS only uses the centroid of each cluster as abstract kernel center. Therefore, the number of the clusters tends to be much smaller than the number of the sampled kernel centers. Furthermore, KELOS effectively prunes most of the inliers without conducing the expensive density estimation, while in contrast, others have to compute the outlierness score for each and every data point.

As shown in Fig. 9(b), although pKDEOS is faster than KELOS on Yahoo! A1 due to the smaller population of the sampled kernel centers, KELOS outperforms pKDEOS in the effectiveness measurements (Tab. 1). On average, KELOS keeps slightly more kernel centers in the memory than pKDEOS for Yahoo! A2 (Fig. 12(c)). However, KELOS still outperforms pKDEOS on execution time because of our inlier pruning strategy.

Window Size. To evaluate how window size affects the efficiency of KELOS, we measure and compare the average window

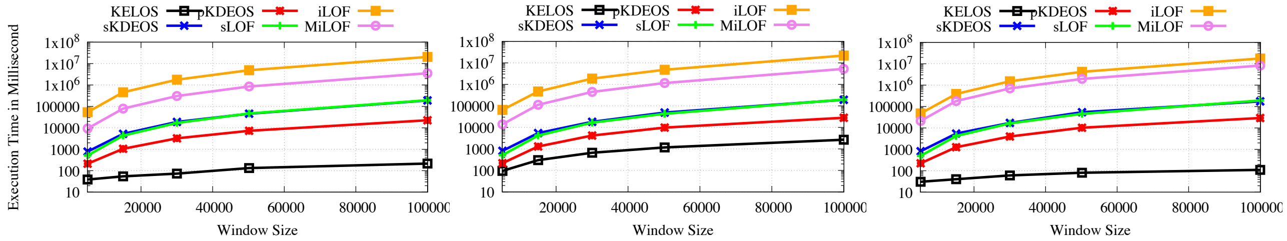


(a) HTTP

(b) Yahoo! A1

(c) Yahoo! A2

Figure 9: Execution time of varied number of neighbors k. Note the maximum k that each method can reach is different. For LOF-based methods, it depends on the total number of data points. For KDE-based methods, it depends on the number of the kernel centers available.



(a) One-Cluster Stream

(b) Three-Cluster Stream

(c) Six-Cluster Stream

(c) Six- Cluster Stream

Figure 11: Execution time on synthetic datasets of varied overlap rate.

processing time of each method by varying the window size of synthetic datasets from 5,000 to 100,000. For these experiments, we created three data streams with one, three and six Gaussian clusters with various parameter configurations (mean, variance and etc.) across the timeline and 10 outliers for each window. The parameters of different all the methods are configured such as they achieve the same accuracy ($P@|O| > 0.95$) with as little memory consumption as possible while k=10. As shown in Fig. 10, in general, the execution time increases with the increase of the window size (average data points within a single window). KELOS constantly outperforms all other baselines by 1-5 orders of magnitude.

Window Overlap Rate. We evaluate the efficiency of KELOS by varying synthetic streams' window overlap rate from 0% to 90%. The synthetic streams are created in the same fashion to the previous experiments. The parameters of different all the methods are configured such as they achieve the same accuracy ($P@|O| > 0.95$) with as little memory consumption as possible and k=10. Based on this controlled accuracy, we evaluate the average window processing time.

When the overlap rate increases, the execution time of all six approaches decrease as demonstrated in Fig. 11. This is because iLOF and MiLOF are designed to process the data incrementally. Although iLOF and MiLOF are not capable of handling data pruning, in these experiments, we simply assume that the overlapped data are already processed and we report the their processing times for the rest of the window. sKDEOS, pKDEOS and sLOF all leverage the skyband stream kNN search that incrementally computes the kNN for each point as window slides, while the clustering algorithm used by KELOS is incremental by nature as shown in Sec. 7. As shown in Fig. 11, KELOS is 2-5 orders of magnitude faster than iLOF, MiLOF, sKDEOS, sLOF and pKDEOS in all settings on all three streams. iLOF and MiLOF are the slowest. sLOF and sKDEOS are faster than the previous two but slower than pKDEOS. Although they all can save computation by avoiding some unnecessary reprocessing of the existing data, the reason of the performance difference is the same as we already explained in the previous experiments.

Memory Consumption. The memory consumption shown in Fig. 12 is evaluated by counting the number of the kernel centers and data points kept in the memory by each approach. sKDEOS, iLOF and sLOF (represented by sLOF in Fig. 12) utilizes all points as kernel centers or reference points, while pKDEOS and MiLOF (represented by pKDEOS in Fig. 12) dramatically reduces the number of the kernel centers by sampling and the number of the references by clustering. KELOS uses the smaller number of kernel centers as compared to sLOF which facilitate more accuracte density estimation. The number of the kernel centers is equivalent to the number of the clusters that tends to be small. sLOF and iLOF measures the local density at each point by computing the local reachability density (LRD). Since the LRD computation requires the access to all points falling in each window, it is equivalent to using all points as kernel centers similar to sKDEOS. On synthetic data stream, Similar to the memory consumption on the real HTTP dataset, KELOS uses the least number of kernel centers. pKDEOS and MiLOF uses fewer kernel centers or references than sKDEOS, iLOF and sLOF because of the sampling and clustering.

8.3 Effectiveness Evaluation

We report the accuracies of our KELOS, sKDEOS (≈ pKDEOS) and sLOF methods on the real data streams. Tab. 1 (with pKDEOS included) shows the peak $P@|O|$ and AP for each approach on each dataset. KELOS outperforms all other approaches in all cases. We are not reporting the results of iLOF and MiLOF, since they perform equally to sLOF in effectiveness. Similarly, for the KDE-based methods we only report the results on sKDEOS for various configurations.

Number of Neighbors k. The number of the neighbors k is the most influential factor that affects the detection accuracies of all methods. The parameter settings are the same to the efficiency evaluation when varying k.

Fig. 13& 14 demonstrate the trend of $P@|O|$ and AP as k varies. The line of KELOS stops at 800 in Fig. 13(a)&14(a), because KELOS uses cluster-based aKDE approach. The number of the kernel centers is restricted by the number of the clusters. Fig. 13(a) shows the results on the HTTP dataset. For our KELOS, as k increases, the $P@|O|$ increases until k reaches 80. It then starts decreasing after k is larger than 100. Overall sKDEOS and sLOF show the similar trend. Compared to KELOS they have to use a much larger k to get relative high accuracy. The trends on the Yahoo A1 and A2 datasets are different from that on the HTTP dataset as shown in Fig. 13(b)% 13(c). The $P@|O|$ continuously increases and gets stable after k reaches certain value. This confirms our observation that using as many as possible kernel centers in the density estimator does not always lead to more accurate density estimation. This justifies our decision of adopting the balloon kernel that only takes the close kernels into consideration when estimating the density at a point x.

The trends of AP are similar to the trends of $P@|O|$ on all datasets as shown in Fig. 14. Overall, KELOS is as accurate or more accurate than alternative approaches. Furthermore, compared to the alternatives, KELOS uses a smaller k to achieve high accuracy. This also contributes to the performance gain of KELOS in execution time.

8.4 Hyper Parameter Tuning

In KELOS, the radius threshold θ defines the maximum possible radius of the formed clusters, that is, the tightness of the clusters. Since the effectiveness of our aKDE approach (Sec. 5) and the pruning strategy (Sec. 5) rely on the tightness of the clusters, θ is important for the accuracy of KELOS. In this set of experiments, we vary θ from small to large on the large HTTP dataset that contains multiple data clusters. As shown in Fig. 15(a), when θ is at 0.1, the $P@|O|$ is at the peak. Then $P@|O|$ and AP of KELOS starts to decrease gradually as θ increases. Large θ results in a small number of clusters that have large radius. Potentially the centroid of a large radius cluster might not precisely represent all points in the cluster. This leads to inaccurate density estimation. Furthermore, a larger radius causes looser upper and lower KLOME bound. This makes the inlier pruning less effective. However, a smaller radius θ inevitably leads a large number of clusters. This increases the computation costs of both stream clustering and the cluster-based aKDE method as shown in Fig. 15(b). Therefore, KELOS will achieve the best performance when radius θ is set to the largest value that is still 'small' enough to generate tight data clusters.

Tuning Radius Threshold θ. Micro-clustering utilizes the radius threshold θ to make sure only the extremely similar points fall into the same cluster and produce tight clusters. The smaller the θ is, the tighter the formed clusters are. However, as shown in Fig. 15(a), although small θ achieves high accuracy in density estimation, it also slows down the overall speed of KELOS. Therefore, it is important to find an appropriate θ threshold that can balance the speed and the accuracy. Instead of trying to acquire an optimal θ value at the beginning by exploring some expensive preprocessing, in streaming context we recommend that the θ threshold could be dynamically adapted to the optimal value. More specifically, one can start by initializing the system using a relatively small θ value to ensure the accuracy of the results. Then the θ value can be gradually adjusted to larger values as the data stream evolves as long as the accuracy is still reasonably good based on the user feedback. As concept drift occurs when stream data evolves, the θ is adjusted again using the same principle.

9 RELATED WORK

Local Outlier Factor. Local outlier detection has been extensively studied in the literature since the introduction of the Local Outlier Factor (LOF) semantics [6]. A detailed survey of LOF and its variations can be found in [7]. The concept of local outlier, LOF in particular, has been applied in many applications [7]. However, LOF requires kNN search for every data point and needs multiple iterations over the entire dataset to compute these LOF values. For this reason, to support continuously evolving streaming data, iLOF was proposed [20] to quickly find the points whose LOF scores are influenced by new arrivals. This avoids re-computing the LOF score for each point as the window slides. However as the velocity of the stream increases, most of the points in a window will be influenced. Therefore this approach does not scale to high volume streaming data. In [21] an approximation approach MiLOF was designed to support LOF in streaming data that focuses on the memory efficiency. However, MiLOF only considers new incoming data. It does not offer any efficient strategy to handle the update caused by data expiration. Therefore, it is not efficient when handing windowed streams. in our experiments, iLOF and MiLOF are much slower than our skyband-based streaming LOF implementation sLOF.

Efficient Kernel Density Estimation. Kernel density estimation is considered as a quadratic process $O(nm)$ with n the total number of data points and m the number of kernel centers. Previous efforts have aimed to accelerate this process while still providing accurate estimation, such as utilizing sampling [26]. [14, 32] designed a method that incrementally maintains a small, fixed size of kernel centers to perform density estimation over data streams. However, to ensure the accuracy of density estimation over skewed datasets, the sample size has to be large. Therefore it cannot solve the efficiency problem of KDE in our context. [12] studied the density-based classification problem. It proposed a pruning method that correctly classifies the data without estimating the density for each point by utilizing a user-defined density threshold. However, this pruning method can not be applied to solve our problem, since a point with low density is not necessarily an outlier based on the local outlier semantics we target on.

Outlier Detection using KDE. For each point in the current window of a sliding window stream, [27] utilizes KDE to approximate the number of its neighbors within a certain range. This information is then utilized to support distance-based outlier detection and LOCI [19]. It directly applies off-the-shelf KDE method on each window. No optimization technique is proposed to speed up KDE in the streaming context. [16] is the first work that studied how to utilize KDE to detect local outliers in static datasets. This later was improved by [23] to be better aligned with LOF semantics. Each data point's density is estimated based upon the surrounding kernel centers only, therefore called local density. Instead of considering outliers only based on their density value, data points are measured based on the density in contrast to their neighbors. However, this work does not improve the efficiency of KDE. Nor does it consider streaming data. As confirmed in our experiment (Sec. 8.2), it is indeed orders of magnitude slower than our KELOS.

Other Streaming Outlier Detection Approaches. LEAP [9] and Macrobase [5] scale distance-based and statistical-based outlier detection respectively to data streams. They rely on the absolute density at each point to detect outliers, while we work with the local outlier method which determines whether a point is an outlier based on the density relative to its neighbors. It tends to be more effective than the absolute density-based methods [11]. Streaming HS-Trees [28] detects outliers by using a classification forest containing a set of randomly constructed trees. The points falling in the leafs that contain a small number of points are considered as outliers. Similar to [5, 9], this method also relies on absolute density of each point to detect outliers. RS-Hash [22] proposed an efficient outlier detection approach using sample-based hashing and ensemble. However, different from our local outlier mining problem, it focuses on subspace outlier detection, that is, detecting outliers hidden in different subspaces of a high dimensional dataset. Similar to iLOF [20] and MiLOF [21], DILOF [18] processes the data stream in a point-by-point fashion and incrementally detects outliers and sequential outliers from *landmark* windows. It does not handle data expiration which is a required operation in sliding windows scenario.

10 CONCLUSION

We present KELOS – the first solution for continuously monitoring top-N KDE-based local outliers over sliding window streams. First, we propose the KLOME semantics to continuously capture the *n* points that have the highest outlierness scores in the streaming data. Second, a continuous detection strategy is designed that efficiently supports the KLOME semantics by leveraging the key properties of KDE. Using real world datasets we demonstrate that KELOS is 2-6 orders of magnitude faster than the baselines, while being highly effective in detecting outliers from data streams.

ABSTRACT

The explosion in the amount of the RDF on the Web has lead to the need to explore, query and understand such data sources. The task is challenging due to the complex and heterogeneous structure of RDF graphs which, unlike relational databases, do not come with a structure-dictating schema. *Summarization* has been applied to RDF data to facilitate these tasks. Its purpose is to extract concise and meaningful information from RDF knowledge bases, representing their content as faithfully as possible. There is no single concept of RDF summary, and not a single but many approaches to build such summaries; the summarization goal, and the main computational tools employed for summarizing graphs, are the main factors behind this diversity.

This tutorial presents a structured analysis and comparison existing works in the area of RDF summarization; it is based upon a recent survey which we co-authored with colleagues [3]. We present the concepts at the core of each approach, outline their main technical aspects and implementation. We conclude by identifying the most pertinent summarization method for different usage scenarios, and discussing areas where future effort is needed.

1 INTRODUCTION

The explosion in the amount of the RDF on the Web has lead to the need to explore, query and understand such data sources. This need arises both for computer scientists and for scientists and practitioners in the many areas where Open Data is produced - ranging from agriculture to education, from cultural artefacts to criminality statistics. All users who need to tame, understand and analyze such complex RDF graphs are faced with several challenges.

Firstly, RDF graphs are often large compared with the human ability to understand and analyze them; even a “tiny” graph of e.g. 10.000 nodes is challenging for humans to comprehend. Secondly, unlike relational databases which come equipped with a prescriptive schema, RDF graphs lack regular structure or many times this structure exists but is unknown. Thirdly, size of the is challenging both for humans and for automated data processing tools. Fourthly, while RDF graphs may come equipped with ontologies, which specify the known relationships between the properties and classes present in the graph, the ontology itself is sometimes a source of complexity, especially if it is very large. In the presence of ontologies, graphs may contain implicit information, i.e. facts that hold in the graph despite not being physically present there. Reflecting the implicit facts of the ontology is in itself a challenge. Additionally specific parts of the ontology might not be used at all or very little in the specific Knowledge Base (KB).

Summarization has been applied to RDF data to facilitate these tasks. Its purpose is to extract concise and meaningful information from RDF knowledge bases, representing their content as faithfully as possible. There is no single concept of RDF summary, and not a single but many approaches to build such summaries.

Summarizing semantic graphs is a multifaceted problem with many dimensions, and thus many algorithms, methods and approaches have been developed to cope with it. As a result, there is now a confusion in the research community about the terminology in the area, further increased by the fact that certain terms are often used with different meanings in the relevant literature, denoting similar, but not identical research directions or concepts. We believe that this lack of terminology and classification hinders scientific development in this area.

Following up on a recent survey which we co-authored with colleagues [3], in this tutorial we present the main conceptual tools behind graph summarization, including some techniques developed prior to the advent of RDF, and show how all these techniques have been applied to the problems of summarizing semantic graphs. The goal of our tutorial is to acquaint the audience with the literature in this area, help them identify the tools and techniques most suited to the summarization problems they might have, and point out areas of interest for future work.

2 SCOPE

The tutorial aims at a broad range of researchers, students, IT professionals and practitioners, and developers. Anyone working with semantic graphs and RDF more specifically will benefit from this tutorial. Students and researchers will not only get a good introduction to the topic with a complete coverage of the state-of-the-art, but will also find a number of challenging research problems in these emerging technologies on which they may decide to focus their future research efforts. Practitioners will get a good overview of what the summarization algorithms, techniques and systems can offer nowadays and learn how they can use them to enhance their understanding of their available datasets. Developers of systems relying on semantic graphs will get helpful information that will help them improve further their products, enhancing query execution, data visualization and understanding.

Other tutorials [10, 15] considers the broad topic of summarizing large graphs, mostly using data mining tools, and with an approach tailored specifically to social networks; our tutorial focuses on the particularities of RDF graphs (and of their summarization).

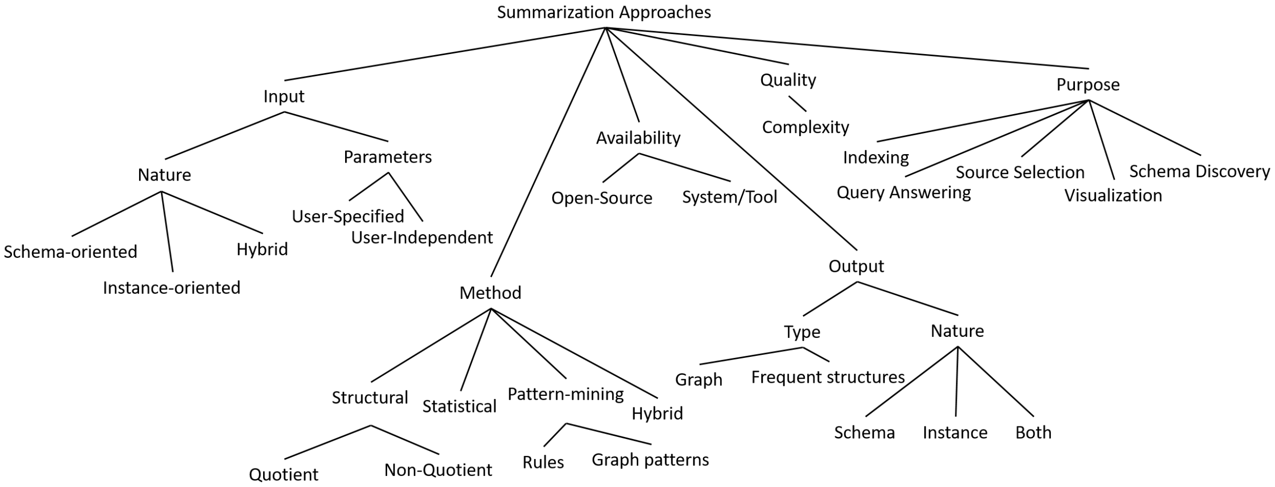

Figure 1: A taxonomy of the works in the area [3].

2.1 Tutorial goal

The goal of this tutorial is to introduce summarization notions and tools which are useful in order to concrete RDF data management applications. A broad set of techniques will be presented covering summarization of general RDF graphs, that contain or not ontological information, independent of their application domain.

3 OUTLINE

Our tutorial will be organized as follows.

3.1 Introduction and preliminaries

We will recall the basics of RDF graphs, RDFS and OWL ontologies, RDF queries (focusing in particular on conjunctive queries, the most frequently used in practice) and inference in RDF knowledge graphs in the presence of an ontology.

3.2 Applications

Next, we will present the main classes of application contexts which have justified the need for RDF summaries:

Indexing: The first and foremost application RDF summaries has been brought by the necessity of efficiently querying large and complex graphs. In this context, sets of nodes which are likely to be used together by queries are grouped together and their IDs are associated to a given summary node. Then, query processing proceeds in two stages: first, the summary nodes relevant to a given query are identified; then, from the summary node, an index lookup gives access directly to the respective data nodes.

Estimating the size of query results: To the same direction with indexing, summaries can be used to identify directly when no nodes are available for a specific query. More than this, summaries can also store statistical information on the available nodes, leading query optimizers to start query evaluation from the most selective conditions.

Source selection: Query evaluation across several graphs, in particular in a distributed setting where multiple graphs are each accessible behind its individual endpoint, can greatly benefit from the knowledge that one source (or one graph) does not have results matching a (sub)query. This is one facet of source selection: restricting query evaluation to avoid datasets on which it is guaranteed to have no answers. A variant consists of ordering the graphs to be explored (queried), so that in a finite time budget, the most interesting graphs are sure to be visited.

Graph visualization and schema discovery: Summarized information is easier to be visualized and comprehended. On the other hand when an ontology is not present, it can be extracted out of the available data, augmenting user understanding on the available information.

3.3 Classification & Dimensions

Then, we will present a classification of the available approaches according to the main algorithmic idea behind the summarization approach. We identify the following main categories; we also indicate a few of the relevant references (out of the 122 present in our survey [3]):

(1) **Structural methods** are those which summarize semantic graphs, based mostly on the graph structure, i.e. the paths and sub-graphs available in the RDF graph. Techniques in this category can be further categorized as quotient and non-quotient.
   - **Quotient** approaches are based on the idea of characterizing selected graph nodes as "equivalent" in a certain way, and then summarizing the graph by assigning a representative summary node to each class of equivalent graph nodes; further, each edge between two graph nodes leads to the corresponding edge being present between the two graph node's representatives. In a quotient summary, each property (edge label) from the input RDF graph is guaranteed present in the summary graph; more a quotient summary is guaranteed to be at most as large as the original graph. Different quotient summaries result from different notions of equivalence among the RDF graph nodes. Sample works in this area include [2, 4, 11, 22, 27], while [17] and [9] are important sources of inspiration from before the RDF age;
   - **Non-quotient** approaches are the remaining methods that are based mostly, on specific measures according to which the most important nodes are identified and then linked to formulate the presented summary. Pioneered by Dataguides [6, 20], the area features many recent works such as [21, 24, 29, 30]; [28] has an information retrieval approach, as it aims at extracting the most interesting triples to be shown to a user about a

subject; [32] summarizes ontologies found on the web, through the prism of the salience (interestingness) of their concepts.

(2) **Pattern mining methods** employee mining techniques to identify patterns appearing in the semantic graph. A pattern might be a set of instances having a certain set of properties, which are in exact or approximate terms representative of the graph or provide enough information on the graph using some cost function to determine that. We consider also as patterns the discovery of rules that can be used to reconstruct the graph and thus represent it adequately. Those patterns, together, compose the summary. Representative works in this area are, e.g., [8, 25, 33];
(3) **Statistical methods** on the other hand try to qualitatively summarize the contents of a graph counting occurrences, building histograms, measuring frequencies and other statistical measures out of the available semantic graph. This class comprises notably works such as [5, 7, 23, 31];
(4) Finally, several works combine techniques from several of the main areas listed above; these are **hybrid methods**, e.g., [1, 27] first and foremost aim at estimating the cardinality of query patterns, [26] summarizes RDF graphs and ontologies through the prism of statistics, while [19] aims at graph compression with bounded error, that is: a core (most regular) part of the graph is identified as comprising several copies of a same data pattern, and compressed into a single copy of this, whereas the rest is ignored from the summary and considered to be the summarization error (which the authors seek to minimize under certain constraints).

Further, we will characterize each of these proposal along a set of other informative dimensions:

(1) **Input:** An interesting dimension of analysis is the input required by each summarization method, as different approaches have usually different requirements for the dataset they get as input. RDF data graphs are usually accepted, RDF/S and/or OWL are considered for some of the works for specifying graph semantics whereas very few works consider DL models. Some works are based only on the ontology part whereas others consider only instances. Hybrid approaches are also available consuming both instances and the ontology for producing summaries. In addition, many works in the area require additional user input of fine tuning (e.g. summary size, weights, equivalence relations etc.) whereas some others are completely user independent.
(2) **Output:** Besides input, the available works might have also different output. The summary for example can be a graph or a selection of the most frequent structures such as nodes, paths, rules or queries. In addition we distinguish summaries that only output instances from those that output schema information as well.
(3) **Availability:** Several approaches are available by the authors as complete system/tool and some others provide only the corresponding algorithms/theory. Finally some systems are available online and can be readily tested.
(4) **Purpose:** As already explained in the applications of the summarization techniques, summaries can be build for indexing, source selection, visualisation, schema discovery or for facilitating query answering.
(5) **Quality:** Finally an important dimension of study, for each summarization algorithm is its completeness in terms of coverage, precision and recall of the result if an "ideal" summary is available as golden standard and its corresponding computational complexity.

Figure 1 presents the various dimensions that will be used in order to present the works available in each category.

Natural connections exist between the families of RDF summaries and the applications they are best suited for. Structural quotient summaries are most applicable to indexing and query answering through graph reduction; this holds especially for quotients built through equivalence relations such as bisimilarity (possibly bounded). Non-quotient summaries mostly target visualization, schema discovery and data understanding. Pattern mining summaries provide in many cases logical rules besides the summary graph as part of the final result, so could be possibly more useful in RDF graph compression scenarios. Summaries could also be really useful in data integration scenarios [14], where instead of generating mappings [16], [18] between data source schemas, summaries could be used to drive the definition of the mapping. Extending this to a scenario where the sources can also evolve [13], [12], summaries can play a key role in schema understanding and mapping redefinition.

3.4 Open issues and future research directions

RDF graph summaries can be useful in different application and research scenarios. Each scenario brings each own specific requirements and the possibility of having more than one items being suitable is present. One open issue in this respect is whether one could use the provided taxonomy to further automate the selection of the appropriate algorithms in the different use cases.

Identifying the *quality* of the RDF summary is also a difficult and not really widely addressed problem. The main problem that remains is how could one compare the summaries produced by the different algorithms and take into account the specificities of the problem at hand and provide an RDF summary with some guarantees. Given that even human experts do not agree on the quality of different summaries in many cases, this remains a challenging task.

Finally, one important problem that has been looked up very little is the *updates* of the RDF summaries produced, given the dynamic nature of most RDF datasets as well as their size. It is an open issue how one could update the summary without having to recompute the whole summary every time; and this problem has also a temporal dimension since one should answer not only how but also when this update is pertinent.

4 PRESENTERS

Haridimos Kondylakis is a scientific collaborator at the Institute of Computer Science, FORTH. His research interests span the following areas: Semantic Integration; Knowledge Evolution; Big Data Management; Data Series Indexing and Querying. He has extensive experience in participating in more than 16 European Projects and he also acts as a regular reviewer and a PC member for a number of premier journals and conferences. He has more than 110 publications in international conferences, books and journals including ACM SIGMOD, VLDB, VLDB Journal, JWS, KER, EDBT, ISWC, ESWC etc.

Dimitris Kotzinos is a Professor at the Department of Computer Science of the University of Cergy – Pontoise, member of the ETIS Lab and head of the MIDI team of the lab. His main research interests include data management algorithms, techniques and tools; development of methodologies, algorithms and tools for web-based information systems, portals and web services; and the understanding of the meaning (semantics) of interoperable data and services on the web.

Ioana Manolescu is a senior researcher, and the lead of the CEDAR team, joint between Inria Saclay and the LIX lab (UMR 7161) of Ecole polytechnique, in France. The CEDAR team research focuses on rich data analytics at cloud scale. She is a member of the PVLDB Endowment Board of Trustees, and a co-president of the ACM SIGMOD Jim Gray PhD dissertation committee. Recently, she has been a general chair of the IEEE ICDE 2018 conference, an associate editor for PVLDB 2017 and 2018, and the program chair of SSDBBM 2016. She has co-authored more than 130 articles in international journals and conferences, and contributed to several books. Her main research interests include data models and algorithms for computational fact-checking, performance optimizations for semistructured data and the Semantic Web, and distributed architectures for complex large data.

ABSTRACT

The last few years have seen the fast and ubiquitous diffusion of JSON as one of the most widely used formats for publishing and interchanging data, as it combines the flexibility of semistructured data models with well-known data structures like records and arrays. The user willing to effectively manage JSON data collections can rely on several schema languages, like JSON Schema, JSound, and Joi, or on the type abstractions offered by modern programming languages like Swift or TypeScript.

The main aim of this tutorial is to provide the audience with the basic notions for enjoying all the benefits that schemas and types can offer while processing and manipulating JSON data. This tutorial focuses on four main aspects of the relation between JSON and schemas: (1) we survey existing schema language proposals and discuss their prominent features; (2) we review how modern programming languages support JSON data as first-class citizens; (3) we analyze tools that can infer schemas from data, or that exploit schema information for improving data parsing and management; and (4) we discuss some open research challenges and opportunities related to JSON data.

1 INTRODUCTION

The last two decades have seen a dramatic change in the data processing landscape. While at the end of the last century data were usually very structured and managed inside relational DBMSs, nowadays they have very different characteristics: they are big, usually semistructured or even unstructured, without a rigid and predefined schema, and hosted and produced in data processing platforms that do not embrace the relational model. In this new scenario, where data come without a schema, and multiple data models coexist, JSON is affirming as a useful format for publishing and exchanging data, as it combines the flexibility of XML with well-known data structures like records and arrays. JSON is currently employed for publishing and sharing data in many application fields and for many different purposes: for instance, JSON is used as the result format for many web site APIs (e.g., Twitter, New York Times), as a common format for the remote interaction of modern web applications (e.g., Facebook's GraphQL is entirely based on JSON), as a common format for exchanging scientific data as well as public open data (e.g., the U.S. Government's open data platform: `https://www.data.gov`).

Given the wide diffusion of JSON and its use in scientific as well as mainstream applications, the need to directly manipulate JSON data inside applications rapidly emerged. To this aim, a schema language, specifically designed for JSON, has been introduced, but its adoption is not growing at a fast pace, since its specification is somewhat complex and many modern programming languages, like Swift and TypeScript, directly support JSON data through their own, simple type systems; furthermore, Walmart Labs endowed JavaScript, which is inherently untyped, with a powerful schema language for JSON objects by means of JavaScript function calls.

In this tutorial proposal, we will present and discuss existing schema and type languages for JSON data, and compare their features; we will also discuss several schema-related tools, with a particular focus on approaches for schema inference. The main aim of this tutorial is to provide the audience and developers with the basic notions for enjoying all the benefits that schemas and types can offer while processing, analyzing, and manipulating JSON data.

Outline. This *1.5-hour* tutorial is split into five main parts:

(1) **JSON primer (∼ 10 min.)**. In this very introductory part of the tutorial, we review the basic notions about JSON together with its JavaScript legacy, and present a few examples, coming from publicly available datasets, that we will use throughout the remaining parts of the tutorial.
(2) **Schema languages (∼ 20 min.)**. In this part of the tutorial we focus on existing schema languages for JSON data collections and discuss their most prominent features.
(3) **Types in Programming Languages (∼ 15 min.)**. In this part of the tutorial we review how modern programming languages support JSON data as first class citizens. In particular, we focus on programming and scripting languages for web and/or mobile applications, where JSON data interchange is a crucial task.
(4) **Schema Tools (∼ 30 min.)**. In this part of the tutorial we analyze tools that exploit schema information for improving JSON data processing. We focus on the problem of inferring a meaningful schema for schemaless JSON collections, as well as on the exploitation of schema information for improving data parsing and management.
(5) **Future Opportunities (∼ 10 min.)**. Finally, we outline open research problems as potential directions for new research in this area.

In what follows we describe at a very high level the technical content covered in each of the last four aforementioned parts.

2 SCHEMA LANGUAGES

In this part of the tutorial we will focus our attention on several schema languages for JSON data, with particular emphasis on JSON Schema [4] and Walmart Labs Joi [6].

JSON Schema emerged in the academic community and has been developed without a specific programming or scripting language in mind. JSON Schema allows the programmer to specify a schema for any kind of JSON values, and supports traditional type constructors, like union and concatenation, as well as very powerful constructors like negation types.

JSON Schema has already been studied. Indeed, in [21], motivated by the need of laying the formal foundations for the JSON Schema language [4], Pezoa et al. present the formal semantics of that language, as well as a theoretical study of its expressive power and validation problem. Along the lines of [21], Bourhis et al. [15] have recently laid the foundations for a logical characterization and formal study for JSON schema and query languages.

On the contrary, Joi has been developed by Walmart as a tool for (i) creating schemas for JSON objects and (ii) ensuring the validation of objects inside an untyped scripting language like JavaScript; furthermore, to the best of our knowledge, Joi has not been studied so far. Joi only allows the designer to describe the schema for JSON objects, but it still provides the ability to specify co-occurrence and mutual exclusion constraints on fields, as well as union and value-dependent types.

We will analyze the most prominent features of these languages, and compare their capabilities in a few scenarios. We will also briefly discuss JSound [5], an alternative, but quite restrictive, schema language, as well as a few other schema-related proposals, such that described in [24], where Wang et al. present a framework for efficiently managing a schema repository for JSON document stores. The proposed approach relies on a notion of JSON schema called *skeleton*. In a nutshell, a skeleton is a collection of trees describing structures that frequently appear in the objects of a JSON data collection. In particular, the skeleton may totally miss information about paths that can be traversed in some of the JSON objects.

3 TYPES IN PROGRAMMING LANGUAGES

Unlike XML, which found no space as a first class citizen in programming languages, with the obvious and notable exception of XQuery, JSON has been designed starting from the object language of an existing scripting language. Therefore, given its wide use in web and mainstream application development, JSON support has been introduced in several strongly typed programming and/or scripting languages.

To directly and naturally manage JSON data a programming language should incorporate the ability to express record types, sequence types, and union types. While record and sequence types can be easily found in many programming languages, union types are quite rare and usually confined to functional languages only.

In this part of the tutorial we will discuss the support for JSON objects inside the type systems of TypeScript [9] and Swift [8]. TypeScript is a typed extension of JavaScript, while Swift is an Apple-backed programming language that is rapidly becoming the language of choice for developing applications in the Apple ecosystem (iOS + macOS). These languages show similar features, but also very significant differences in the treatment of JSON objects.

We will also compare the features offered by these languages with those of the schema languages we presented in the second part of the tutorial.

4 SCHEMA TOOLS

In this part of the tutorial we will present several schema-related tools for JSON data. We will first discuss existing approaches for inferring a schema starting from a dataset and then move to parsing tools that are able to exploit dynamic type information to speed-up data parsing.

4.1 Schema Inference

Several schema inference approaches for JSON data collections have been proposed in the past. In [10–12] authors describe a distributed, parametric schema inference approach capable of inferring schemas at different levels of abstraction. In the context of Spark, the Spark Dataframe schema extraction [7] is a very interesting tool for the automated extraction of a schema from JSON datasets; this tool infers schemas in a distributed fashion, but, unlike the technique described in [10–12], its inference approach is quite imprecise, since the type language lacks union types, and the inference algorithm resorts to `Str` on strongly heterogeneous collections of data. Other systems, like Jaql [13], exploit schema information for inferring the output schema of a query, but still require an externally supplied schema for input data, and perform output schema inference only locally on a single machine.

There are also a few inference tools for data stored in NoSQL systems and RDBMSs. Indeed, in the context of NoSQL systems (e.g. MongoDB), recent efforts have been dedicated to the problem of implementing tools for JSON schema inference. A JavaScript library for JSON, called mongodb-schema, is presented in [22]. This tool analyzes JSON objects pulled from MongoDB, and processes them in a streaming fashion; it is able to return quite concise schemas, but it cannot infer information describing field correlation. Studio 3T [19] is a commercial front-end for MongoDB that offers a very simple schema inference and analysis feature, but it is not able to merge similar types, and the resulting schemas can have a huge size, which is comparable to that of the input data. In [23], a python-based tool is described, called Skinfer, which infers JSON Schemas from a collection of JSON objects. Skinfer exploits two different functions for inferring a schema from an object and for merging two schemas; schema merging is limited to record types only, and cannot be recursively applied to objects nested inside arrays. Couchbase, finally, is endowed with a schema discovery module which classifies the objects of a JSON collection based on both structural and semantic information [3]. This module is meant to facilitate query formulation and select relevant indexes for optimizing query workloads.

When moving to RDBMSs, in [16] Abadi and al. deal with the problem of automatically transforming denormalised, nested JSON data into normalised relational data that can be stored in a RDBMS; this is achieved by means of a schema generation algorithm that learns the *normalised, relational* schema from data. This approach ignores the original structure of the JSON input dataset and, instead, depends on patterns in the attribute data values (functional dependencies) to guide its schema generation.

4.2 Parsing

There are a few novel parsing tools for JSON data that take into account dynamic type information for improving the efficiency of the applications relying on them.

In a recent work [20], Li et al. present streaming techniques for efficiently parsing and importing JSON data for analytics tasks; these techniques are then used in a novel C++ JSON parser, called Mison, that exploits AVX instructions to speed up data parsing and discarding unused objects. To this end, it infers structural information of data on the fly in order to detect and prune parts of the data that are not needed by a given analytics task.

In [14], Bonetta and Brantner present Fad.js, a *speculative*, JIT-based JSON encoder and decoder designed for the Oracle Graal.js JavaScript runtime. It exploits data access patterns to optimize both encoding and decoding: indeed, Fad.js relies on the assumption that most applications never use all the fields of input objects, and, for instance, skips unneeded object fields during JSON object parsing.

5 FUTURE OPPORTUNITIES

We finally discuss several open challenges and opportunities related to JSON schemas, including the following ones.

Schema Inference and ML. While all schema inference approaches covered in the previous part of the tutorial are based on traditional techniques, a recent work by Gallinucci et al. [17] shows the potential benefits of ML approaches in schema inference; furthermore, ML-based inference techniques have already been used for non-JSON data, as shown by Halevy et al. in [18]. Hence, a promising research direction is to understand how these methods can be efficiently applied to large collections of data and whether they can overcome some limitations of previous approaches.

Schema-Based Data Translation. While JSON is very frequently used for exchanging and publishing data, it is hardly used as internal data format in Big Data management tools, that, instead, usually rely on formats like Avro [1] and Parquet [2]. When input datasets are heterogeneous, schemas can improve the efficiency and the effectiveness of data format conversion. Therefore, a major opportunity is to design schema-aware data translation algorithms that are driven by schema information and use it to improve the quality of the translation.

6 INTENDED AUDIENCE AND COVERAGE

Our goal is to present a coherent starting point for EDBT attendees who are interested in understanding the foundations and applications of schemas and types for JSON data processing. We will not assume any background in JSON schema languages, but will introduce them starting from the roots, giving broad coverage of many of the key ideas, making it appropriate for graduate students seeking new areas to study and researchers active in the field alike.

7 BIOGRAPHICAL SKETCHES

Mohamed-Amine Baazizi (Ph.D.) is an assistant professor at Sorbonne Université. He received his PhD from Université of Paris-Sud and completed his postdoctoral studies in Télécom Paristech. His research focuses on exploiting schema information for optimizing the processing of semi-structured data.

Dario Colazzo (Ph.D.) is Full Professor in Computer Science at LAMSADE - Université Paris-Dauphine. He received his PhD from Università di Pisa, and he completed his postdoctoral studies at Università di Venezia and Université Paris Sud. His main research activities focus on static analysis techniques for large scale data management.

Giorgio Ghelli (Ph.D.) is Full Professor in Computer Science, at Università di Pisa. He was Visiting Professor at École Normale Supérieure Paris, at Microsoft Research Center, Cambridge (UK), and at Microsoft Co. (Redmond, USA), member of the W3C XML Query Working Group, member of the board of the EAPLS. He worked on database programming languages and type systems for these languages, especially in the fields of object oriented and XML data models.

Carlo Sartiani (Ph.D.) is an assistant professor at Università della Basilicata. He received his PhD from Università di Pisa, and he completed his postdoctoral studies at Università di Pisa. He worked on database programming languages and data integration systems, and his current research activities focus on semistructured and big data.

Sayan Ranu
IIT Delhi
sayanranu@cse.iitd.ac.in

ABSTRACT

The steady growth of graph data from social networks has resulted in wide-spread research on the influence maximization (IM) problem. This results in extension of the state-of-the-art almost every year. With the recent *explosion* in the application of IM in solving *real-world* problems, it is no longer a theoretical exercise. Today, IM is used in a plethora of real-world scenarios, with *OnePlus*[1] series of mobile phones, *Hokey Pokey*[2] ice-creams, and *galleri5 influencer marketplace*[3] being the most prominent industrial use-cases. Given this scenario, navigating the *maze* of IM techniques to get an in-depth understanding of their utilities is of *prime* importance. In this tutorial, we address this *paramount* issue and solve the *dilemma* of "*Which IM technique to use and under What scenarios*"? "*What does it really mean to claim to be the state-of-the-art*"?

This tutorial builds upon our benchmarking study [1], and will provide a concise and intuitive overview of the most important IM techniques, which is usually lost in the technical literature. Specifically, we will unearth a series of *incorrect claims* made by prominent IM papers, disseminate the inherent *deficiencies* of existing approaches, and surface the *open challenges* in IM even after a decade of research.

1 MOTIVATION

Influence maximization (IM) has been one of the most actively studied areas of data management research over the past decade. With this, almost every year, a new IM technique has been published that claims to be the state-of-the-art. However, IM is no longer a theoretical problem. We rely on *Facebook* and *WhatsApp* to communicate with friends. *Twitter* is used to disseminate information such as traffic-news, emergency-services, etc. IM is used by companies to publicize their products or shape opinions (Ex: *OnePlus*, *galleri5*, and *HokeyPokey* [19]).

On the academic front, researchers are interested in classical IM [3, 7–10, 16–18, 21, 24, 25, 31] as well as more application-specific models such as IM under *competition* [22], *time and opinion-aware* IM [6, 12] etc. Undoubtedly, this extensive research has promoted prosperity of the family of IM techniques. However, it also raises several questions that are not adequately addressed. Given this widespread applicability, it is important to understand the following questions from a *neutral standpoint*.

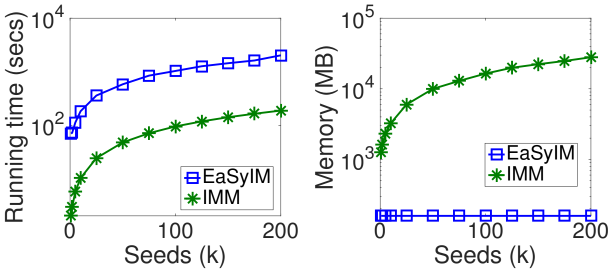

Figure 1: Comparing IMM ($\epsilon = 0.5$) with EaSyIM ($iter = 100$) under IC ($W(u,v) = 0.1$) on the YouTube dataset.

- *Which IM technique should one use given the resources in hand? How to choose the most appropriate IM technique in a given specific scenario?*
- *What does it mean to claim to be the state-of-the-art? More fundamentally, Is there really a single state-of-the-art technique as is often claimed?*
- *Are the claims made by the recent papers true?*
- *What are the unsolved challenges in the field?*

To highlight the ambiguity that plagues the current maze of IM techniques, we provide a concrete example[4] to motivate the need for answering the questions stated above.

What does it mean to be the state of the art? While many techniques claim to be the state of the art, in reality, they are often the state of the art in only one aspect of the IM problem. Consider Figs. 1a-1b, where EaSyIM [12] and IMM [30] scale better with respect to memory and running time respectively. Thus, neither technique can be termed as better than the other.

1.1 Relevance and Timeliness

• First, EDBT is an appropriate platform to present a tutorial on IM from a *neutral standpoint* since reproducibility tests and benchmarking have always been a key area of interest of the database community at large. Moreover, as shown in Fig. 2, of late database conferences have become the venue of choice for authors conducting research in the field of influence maximization, since ensuring scalability (while maintaining quality guarantees) has become central to the problems identified in this area.

• Second, to ensure a streamlined growth of the field, this tutorial, in addition to surveying existing IM techniques, serves as a *timely* and *relevant* avenue to *disseminate answers of the questions stated above to the data management community*. Overall, the tutorial will build upon our benchmarking study [1] and present our musings over almost a decade long literature (along with the recent advances) in the field of IM from top publication venues, and *unravel* many interesting and unknown avenues in the well-studied area of influence maximization.

[1] https://oneplusstore.in
[2] http://www.hokeypokey.in
[3] https://galleri5.com/aboutus

[4] A detailed analysis on more such examples may be found in [1].

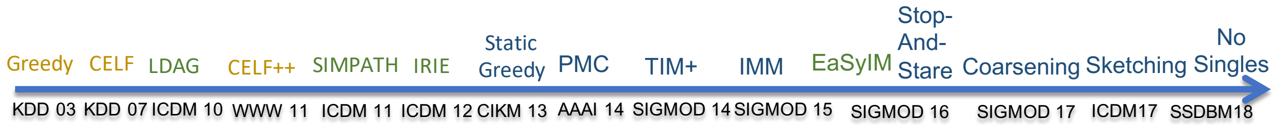

Figure 2: Timeline showcasing the Evolution of IM techniques.

- Lastly, as mentioned previously, IM is no longer a theoretical problem. It is regularly used by companies to publicize their products or shape opinions. *OnePlus*, *galleri5*, and *HokeyPokey* [19] for example rely completely on IM through social networks. To this end, the insights presented in this tutorial would definitely be advantageous to a broad audience at EDBT/ICDT ranging from theorists to researchers who are more interested in understanding and harnessing the practical power of IM in social networks.

2 INTENDED AUDIENCE, PREREQUISITE KNOWLEDGE AND LENGTH

The tutorial is aligned to the general area of data management and the web, thereby being relevant for a broad audience at EDBT: including students, academic researchers, and industrial experts specifically interested in benchmarking, data mining, social-network analysis, large-scale analytics, and performance tuning. No prior knowledge beyond basic probability and graph theory is expected. Familiarity with information-diffusion concepts would help, but not needed. The tutorial is self-contained and possesses introduction of most of the foundational concepts.

The key take away would be knowledge of the gaps including mis-claims and myths, leading to some of the never unraveled aspects of the IM problem, thereby enabling a more streamlined advancement in IM research. Since IM is a hot topic, we expect around 50 participants.

3 OUTLINE OF THE TUTORIAL

3.1 Introduction (20 minutes)

The first part of the tutorial will involve the formal definition of the IM problem along with an analysis of the fundamental information diffusion models: IC and LT [18]. The other aspect here would be to motivate the importance of IM, by citing real-world applications, in order to bridge the gap between theoretical models and real-world information diffusion.

Moving ahead, we will explain in detail the various challenges faced in designing effective solutions for the IM problem. We will analyze various properties of IM, namely – NP-hardness, submodularity etc., and also present the scenarios where exact estimation of influence is possible.

3.2 Summary of IM Algorithms (30 minutes)

First, we will present a categorized overview [1] of existing IM algorithms. This will enable the attendees to grasp the broad spectrum of IM techniques as portrayed in Table 1 in an intuitive and concise manner. Next, we will delve into a detailed description of each category.

Given that the IM problem is NP hard, Kempe et al. [18] leverage submodularity to propose a Greedy algorithm that provides the best approximation on the *quality* of obtained *spread*. Later, CELF [21] and CELF++ [15] were proposed to maintain the same quality of *spread* with an attempt to improve the efficiency by applying several optimizations over the Greedy algorithm.

Next, we will present the *heuristics* IMRank/IRIE [8, 17] and LDAG/SIMPATH [7, 16] that improve the *efficiency* and *scalability* aspect of IM, and perform well for the WC and LT models respectively. The caveat with these techniques is that they work well in practice, however lack any theoretical backing on the *quality* of the obtained *spread*. We will also introduce our techniques – *ASIM* [13] and *EaSyIM* [12], which are better both empirically and theoretically when compared to other heuristics.

Lastly, we will present a recent class of techniques that use *sampling* [9, 24, 25, 30, 31] to portray superior *efficiency* while retaining *quality* guarantees. These techniques either maintain reverse reachable (RR) sets of nodes or snapshots of cascades, and try to estimate influential nodes by sampling nodes from the original network. The caveat here is that most of these techniques are not scalable owing to their *exorbitantly* high memory footprint [1].

Table 1 summarizes the techniques discussed above, while stating their key highlights and the respective state-of-the-arts. This will enable the attendees to understand the representative techniques in the literature and the different aspects they address. It will also facilitate the attendees to appreciate as to why "*One Size Doesn't Fit All!*".

Finally, we will analyze why there does not exist any algorithm capable of simultaneously excelling in all the three fronts: (1) efficiency, (2) scalability, and (3) quality?

3.3 Myths, Mis-Claims and Insights (20 minutes)

In continuation to the overview of the techniques, here, we present our findings and provide recommendations to answer the question(s) posed by us in Section 1. We firmly establish that several *claims* from highly cited papers are *incorrect* (our experiments have been marked *SIGMOD Reproducible*), the evaluation procedure adopted by various techniques could produce misleading results, and expose a series of *myths* that could potentially alter the way we approach IM research. All the *insights* would be supported by *empirical* results, presented to the audience using a *python interface* to the publicly available implementations[5] of the discussed techniques.

3.4 Open Challenges and Future Directions (20 minutes)

The last part of the tutorial would focus towards *summarizing* the key insights discussed previously to eventually *shortlist* the best technique(s) and the corresponding scenarios in which they are the best. To this end, a decision-tree (Fig. 3b) will be presented as a tool to the audience. Next, we would delve into a detailed discussion on the open

[5] For details please visit our project page: https://sigdata.github.io/infmax-benchmark

Type	Theoretical Guarantee?	Highlights	State-of-the-Art
Greedy and Optimizations	Yes	Superior Quality and Scalability but low Efficiency	CELF/CELF++ [15, 21]
Heuristics	No	Superior Efficiency and Scalability at the cost of Quality	*EaSyIM*, IRIE, & LDAG/SIMPATH [7, 12, 16, 17]
Sampling Snapshots/RR sets	Yes	Superior Efficiency and Quality at the cost of Scalability	PMC, Stop-and-stare, Coarsening, Sketching, and NoSingles [23–27]

Table 1: The spectrum of IM techniques.

challenges in the field of information propagation, thereby providing a streamlined view of future research directions.

- The most important research direction is the development of a *scalable* and *efficient* algorithm with error *guarantees* (Fig. 3a), which still remains as the holy grail of influence maximization. While recent efforts by Popova et al. [27], Ohsaka et al. [26], and Nguyen et al. [23] are steps in this direction to improve scalability of the class of memory-intensive sampling algorithms [10, 24, 30, 31], more work is needed to achieve true scalability. To this end, there is a need for a generic framework inspired by classical data management systems which are shown to perform well for managing graph data [11], or the use of modern data management technologies that rely on distribution and parallelization to improve scalability and efficiency.
- Another compelling and novel research direction lies in validating the correctness/effectiveness of the classical information diffusion models proposed in [18] using real-world social media data capturing cascades from retweets or mentions as ground truth. The advantage of this exercise would be two fold: (1) Exploring the most unfathomed area in the field provides tremendous scope for advancement of the state-of-the-art, and (2) Curating a benchmark dataset for all the follow-up research. Such efforts would also attract further research on scalably learning influence probabilities from real-world interaction data extending on the works of [14] and [20].
- The challenges involved in scaling up influence maximization to massive networks under classical information diffusion models also cascade to the recent research activities around development of sophisticated diffusion models like opinion-aware [12], topic-aware [5] etc., which too are deprived of scalable algorithms. To this end, there is a need for devising a generic and unified framework for scaling up influence maximization under classical and various sophisticated real-world scenarios.

4 RELATED TUTORIALS

Multiple tutorials have been presented in the broad field of information propagation and IM at major data-centric venues [2, 4, 28, 29]. However, all these tutorials possess a common theme, i.e., each of them have provided an overview of models for information diffusion in networks and associated algorithms for influence analysis. While [2, 4, 29] were based on an algorithmic and data-mining perspective of the broad area of information diffusion, [28] focused on machine learning methods, specifically encircling the problems of network inference, influence estimation and control. In sum, the main focus of these tutorials was towards dissemination of the mathematical, technological, and algorithmic innovations to all-and-sundry, thereby enabling a step forward for sound analysis of research problems in the field of information propagation.

The proposed tutorial has the following key differentiations:

- First, the state-of-the-art has never been discussed from a neutral standpoint. More fundamentally, all the previous tutorials have given overviews of the existing literature, however, this exercise has not been from a perspective of a critic. We are the first to present some of the *highly controversial and ground-breaking discoveries*, thereby unraveling several *mis-claims and myths* in the existing IM research. This in-depth focus of our tutorial enables a more streamlined advancement in IM research with possible redefinition of the state-of-the-art.
- Second, IM is still a niche problem and provides many avenues to devise real world models and scalable algorithms capable of tackling competitive, time aware, opinion aware settings and many more. The knowledge gathered from this tutorial would facilitate more informed extensions to these settings.

5 TUTOR BIOGRAPHY AND EXPERTISE

Akhil Arora is a doctoral researcher at EPFL. His research interests include large scale data mining, databases, and machine learning. He is a recipient of the prestigious "EDIC Doctoral Fellowship" for the academic year 2018-19, and the "Most Reproducible Paper" award at SIGMOD 2018. He has published his research in prestigious data mining and database conferences, served as a reviewer, and co-organized workshops in these conferences. Further information available at https://www.cse.iitk.ac.in/~aarora.

Sainyam Galhotra is a graduate student at UMass Amherst. His research interests include graph analysis, data mining and integration. He is the recipient of the "Best Paper Award" at FSE 2017 and the "Most Reproducible Award" at SIGMOD 2018. He is the first recipient of the "Krithi Ramamritham Scholarship" at UMass for contribution to research in databases. He has published in top data mining, database and machine learning conferences. Further information available at https://people.cs.umass.edu/~sainyam.

Sayan Ranu is an assistant professor in the Computer Science department at IIT Delhi. His research interests include graph mining, spatio-temporal data analytics, and bioinformatics. He was a recipient of the Best Paper Award at WISE 2016 and the "Most Reproducible Paper" award at SIGMOD 2018. Sayan regularly serves in the program committees of conferences and journals including KDD, ICDE, WWW, ICDM, TKDE, VLDB Journal. Further information available at http://www.cse.iitd.ac.in/~sayan/.

5.1 Tutorials given by Authors

The authors possess adequate experience of delivering tutorials at reputed venues as indicated below:

- **Akhil Arora, Sainyam Galhotra, Sayan Ranu**, Shourya Roy: "Influence Maximization Revisited", COMAD 2018.
- **Sayan Ranu** and Ambuj Singh: "Indexing and mining topological patterns for drug discovery", in EDBT 2012.
- **Sayan Ranu** and Ambuj Singh: "Topological Indexing and Mining of Chemical Compounds", in BCB 2011.

5.2 Previous Edition of this Tutorial

An overview of the state-of-the-art IM techniques was presented at ACM CoDS-COMAD 2018. The current proposal for EDBT 2019 would include the following extensions:

- We will build upon our benchmarking framework to present detailed insights about the state-of-the-art IM algorithms in real-world scenarios. We will unravel several *myths and ambiguities that plague the current maze of IM techniques.*
- We will discuss in detail about the *open-challenges* that remain in the field of influence maximization and provide concrete pointers to important research questions in order to facilitate streamlined advancement of the field.

ABSTRACT

Contrast set mining identifies patterns that can best distinguish between two groups of data. While many machine learning models share the same goal, contrast set mining focuses on data understanding and interpretability. Most existing work in contrast set mining focuses on categorical data. In this work, we propose an algorithm that discovers contrast patterns on *mixed* data (datasets that contain both categorical and continuous attributes). Our algorithm is able to discover multivariate interactions using a supervised adaptive binning strategy. The binning strategy identifies meaningful bin boundaries in continuous attributes based on their relationships with other attributes. This in turn allows us to form better and more meaningful contrast patterns than traditional techniques that use global, pre-binning approaches. We propose various pruning strategies to reduce the search space, and show the utility of our algorithm on simulated data, several datasets from the UCI repository, as well as real manufacturing data.

1 INTRODUCTION

The work presented in this paper was motivated by a desire to reliably detect factors resulting in failure at final test during the semiconductor packaging and test process and is the outcome of a multi-year research grant funded by Intel, Corporation to develop a solution that can be applied to their manufacturing facilities. As the industry moves to more complex packages that involve complex process flows, the amount of data collected during the processing increases, and the signals being detected (as related to cause of test failures) become more diluted. At the same time, the cost of missing these signals increases, and hence there is a growing need to develop machine learning algorithms that can quickly detect the potential cause of part failures and deliver timely feedback to the engineers so that adjustments in the manufacturing line can be made to avoid generating scrap. Note that packaging can contribute up to 50% of the cost to manufacture a CPU, hence any scrap avoidance is highly desirable. As an example, during the baking stage of the manufacturing line, if the ovens are run at a higher temperature than usual, resulting in low yield, a timely notice could minimize potential loss. The behavior of manufacturing data is often predictable; however, at times there exist anomalies such as low yield for a batch. To find potential causes of this low yield, one could create a classification model comparing good chips and bad chips. Apart from a few models such as decision trees, most models are not interpretable to the user and hence non-actionable. Even though models like decision trees can be used to find explainable patterns, usually there is a single global model built for the whole dataset using a greedy strategy. To find all patterns, the user would need to build all possible trees which can take exponential time. Therefore, while decision trees are good for classification, they are not suitable if the goal is to detect patterns in the dataset. The matter becomes more complicated when we want to capture multivariate relationships between attributes (e.g. XOR data), which require more computational time.

The analysis of semiconductor manufacturing data is nontrivial because the numbers of attributes and instances are large, and the engineer needs considerable amount of time for analysis. Our intent is to learn the patterns ("contrast sets") that distinguish two groups, e.g. a normal group and an anomalous group, automatically, without external knowledge. We note that the main goal here is data understanding and exploration, rather than prediction.

Pattern mining algorithms are often used during the initial stages of the data mining process to understand relationships among features, or in a decision making stage. A major concern is displaying results that misconstrue relationships between attributes or giving incorrect insights to make decisions. For example, due to the large number of relationships between attributes to be considered, there is a high probability of discovering uninteresting or potentially spurious patterns. A large amount of existing work in pattern mining has focused on reducing the number of such uninteresting patterns, which is also one of the goals in this paper. Another concern relating to pattern mining is the time and space complexity. This can usually be reduced by either building a more compact representation of the data or pruning the search space. In this paper, we try to reduce the search space by pruning uninteresting regions.

Contrast set mining is a set of algorithms under the pattern mining paradigm to find patterns for which the supports differ significantly among groups. It is closely related to, and can be directly compared [21] to subgroup discovery and emerging pattern mining. There has been a lot of work in the area of contrast set mining [4, 14, 15, 26, 29]; however, there remain some issues that need to be addressed. First, in the manufacturing of semiconductors, many attributes of interest are continuous. Most of the existing work in contrast set mining, emerging patterns and subgroup discovery focus on improving the efficiency of the algorithms to find categorical contrasts, i.e. by reducing the search space and the number of database scans. Continuous attributes are typically handled by either computing some statistics (such as mean) that meaningfully differ among groups, or by using a binning technique as a preprocessing step and then treating the attribute as a categorical one. The latter can potentially provide more information since it identifies local patterns as ranges of values in the continuous attributes that can be actionable. Therefore, in this work we focus on binning-based approaches. A software suite Cortana has many state of the art subgroup discovery algorithms developed. It also has an implementation of an adaptive discretization method that we compare to in the experimental section. This approach, however, is a greedy approach and may miss (local) multivariate interactions between continuous features which we often find in semiconductor manufacturing data. As will be seen later, the patterns found using these algorithms seem to be redundant and cumbersome to interpret.

Binning or discretization is a fundamental and well-studied topic in data mining. Garcia et al. [10] published a detailed survey on discretization techniques, as well as a tool (KEEL) that contains implementations of 30 popular discretization algorithms. We applied these discretization algorithms extensively on various datasets, but we were not able to find an algorithm that satisfies all our requirements. Specifically, for our application (or applications containing continuous attributes in general), the discretizer has to be able to handle **multivariate data**, be **adaptive** (local bins with respect to a subset of attributes), and **dynamic** (tightly coupled algorithm with the end goal of finding the most meaningful contrast patterns). In addition, the algorithm needs to detect not only global correlations, but (local) multivariate interactions between features. Unfortunately, existing algorithms, including those implemented in Cortana, typically miss one or more of our requirements.

Another important aspect of the proposed algorithm is to show the user the most meaningful contrasts. The authors in [13, 27] have defined patterns that will most likely be interesting to a user. More specifically, a meaningful contrast is a pattern that is not redundant, is productive and independently productive. We define what each term means in the context of contrast pattern mining and extend it to cases where the patterns have only continuous, or have mixed features.

Our contributions are summarized as follows:

(1) We propose an algorithm, SDAD-CS (Supervised Dynamic and Adaptive Discretization for Contrast Sets), to find contrast patterns for datasets containing continuous (and categorical) attributes.
(2) Our binning technique is supervised, dynamic, and adaptive, and therefore finds better quality and meaningful bins as compared to the state of the art.
(3) The binning technique detects multivariate interactions and hence higher order contrasts can be detected.
(4) We introduce several pruning strategies to reduce the search space, which also results in finding more meaningful contrast patterns.
(5) We use statistical measures to find non-redundant, productive and independently productive contrast patterns.

2 RELATED WORK

A number of work on contrast set mining have been proposed [4, 14, 15, 26, 29]. In their pioneering work [4], the authors proposed an algorithm, STUCCO (Searching and Testing for Understandable Consistent COntrasts), that finds contrast sets in groups. STUCCO employs efficient search for contrast sets based on another rule mining algorithm, Max-Miner [5]. To assess the meaningfulness of the difference in support values across groups, the authors use a chi-square test on the null hypothesis that the support value is independent of group membership. In another work [26], the authors observe that existing commercial rule-finding system, Magnum Opus [25], can successfully perform the contrast-set mining task. The authors conclude that contrast-set mining is a special case of the more general rule discovery task. The techniques discussed above are only applicable to categorical data. A good survey on contrast sets, emerging patterns and subgroup discovery algorithms is provided in [21]. The authors also discuss how the interest measures (such as difference in support and WRACC) are compatible, i.e. the interest can be used interchangeably between communities.

Techniques derived from decision tree learning can be used; however, the authors in [16, 18, 23] explain some limitations of decision-tree-based method for our application. A number of work have been proposed to find subgroups in numerical domains. The authors in [20, 23] discretize numerical data into bins to find subgroups. The algorithm is implemented in an open source tool Cortana. Such techniques typically use an initial discretization method and then merge spaces based on an interest measure. We have compared against this approach in the experimental section. An interesting algorithm described in [11] also discretizes continuous attributes into bins for the problem of subgroup discovery. The algorithm uses optimistic estimates and horizontal pruning to prune the search space. This technique heavily relies on pruning based on the top-k subgroups, since the interest measure can be updated as soon as the algorithm reaches k subgroups. Finding all initial split points (exhaustive search in [11]) is expensive but if the initial partitions are not exhaustive, e.g. frequency or entropy based, the algorithm may miss interesting patterns that occur lower down the tree due to multivariate interactions. The current trend of recent algorithms tend to use sampling and user feedback to improve efficiency and quality of rules [6–8, 17]. This is an interesting direction; however, our goal is to develop an accurate and efficient discretizer in order to find contrast patterns. These algorithms can certainly be used in conjunction with our algorithm.

Quantitative association rule mining is well-studied and could potentially be used for contrast mining. Srikant proposed a discretization technique that partitions the range of the continuous attribute into *n* equal-frequency partitions, and assigns the partitions to consecutive integers [22]. If the supports for any consecutive partitions fall below the *minsup* threshold, they are merged. The problem, however, is setting the initial number of partitions *n* and handling multivariate interactions. If *n* is too small, it results in large partitions and potential information loss since elements in the same partition are indistinguishable. On the other hand, if *n* is too large, the algorithm becomes computationally expensive. In [2], the authors find extraordinary behavior by partitioning the antecedent of the rule into bins and finding the statistics of the consequent. The algorithm cannot handle multivariate interactions between continuous attributes. The algorithm described in [24] is a bottom-up merging algorithm. It merges contiguous parts of a feature based on the improvement of an interest measure. We also use a bottom-up approach to merge spaces; however, as will be shown later, our algorithm can handle multivariate interactions between continuous features and does not need initial small bins. MVD [3] proposed by Bay is able to detect multivariate interactions for continuous attributes. This algorithm is also a bottom-up approach which merges contiguous spaces if they are not statistically different.

3 PRELIMINARIES

Let *DB* be a dataset with *m* rows $R = \{r_1, r_2, \dots, r_m\}$ and *n* attributes $A = \{a_1, a_2, \dots, a_n\}$. An attribute can be either categorical or continuous. A categorical attribute can have multiple values, i.e.

for a categorical attribute a_i having l unique values, domain(a_i) = {v_{i1}, ...,v_{il}}. For continuous attributes, its values consist of real numbers i.e. domain(a_i) = $\mathbb{R}$. An item in DB is either a value in a categorical attribute, $a_i = v_{ix}$ where $v_{ix} \in$ domain(a_i), or range in a continuous attribute, $a_i \in [v_l, v_r]$ where $v_l \leq v_r$, $v_l \in \mathbb{R}$ and $v_l \in \mathbb{R}$. Using the above definitions, we note that items in a continuous attribute can have overlapping ranges. An *itemset c* is a combination of items in *DB*. Apart from having *n* attributes, *DB* has an extra attribute that contains the group information for each row (instance). Let $G = \{g_1, g_2, \dots, g_k\}$ be a set of groups. Each row belongs to exactly one group and multiple rows can be a part of a single group. If $|g_k|$ is the number of instances in group k and $count_k(c)$ is the number of rows that contain itemset c in group k then **support** $supp_k(c)$ is:

$$supp_k(c) = \frac{count_k(c)}{|g_k|} \tag{1}$$

Bay [4] formally defines contrast set mining as follows. An itemset is a contrast between 2 groups i and j if the support difference between the 2 groups is **large** and **significant**. The support difference is large if

$$supp_i(c) - supp_j(c) > \delta \tag{2}$$

and significant if

$$\chi^2_{ij}(c) < \alpha \tag{3}$$

where α and δ are user-defined parameters.

Contrasts should be non-redundant. In the context of frequent itemset mining, an itemset c is redundant if it contains a proper subset d that has the same support as i where i is an itemset of d [27]. An example given in [27] explains that any superset of itemset female, pregnant is unlikely to be interesting since female subsumes pregnant, i.e. these itemsets are functionally dependent.

An itemset c is said to be productive if for every partition d, where $d \subset c$, $supp(c) > supp(d) * supp(c \backslash d)$. Since the dataset is usually a sample of the population, statistical test such as fisher's exact test and chi-squared tests are performed on each partition of an itemset to check for significance of the product. Although this makes the algorithms computationally more expensive, it is an important step to determine productivity and finding meaningful patterns.

Another requirement is that a pattern should be independently productive. To be independently productive, an itemset should not be explained by any of its supersets apart from being productive and not redundant. Statistical tests are also performed at this step, usually as a postprocessing step.

An optimistic estimate (*oe*) of an itemset is the maximum possible value of an interest measure in any of the itemsets specializations[12]. If X' is the specialization of X and Int(X') is the calculated interest measure of X' then

$$Int(X') \leq oe(X) \tag{4}$$

optimistic estimates are used to prune the search space by calculating the upper bound of the children nodes of each explored node in the search tree.

Top-k pattern mining algorithms display the best 'k' patterns to the user based on some user defined interest measure. The advantage is two-fold. First, it removes the need for the user to enter a minimum threshold for the interest measure. For example, support-based pruning is the first stage of the Apriori algorithm [1] for association rule mining. Determining the best minimum support (*minsup*) is non-trivial, if *minsup* is too high or too low, it may find too few or too many patterns, respectively. The other advantage is that it helps prune the search space even if the interest measure is not monotonically decreasing based on optimistic estimates.

We use the following strategies to reduce the search space. An itemset is pruned if (1) it does not have support over δ in any group (*minimum deviation size* pruning); (2) its expected occurrence is less than 5, since statistical tests are not significant at that level; and (3) If the optimistic estimate of the χ squared value for the itemset's children is less than the current threshold. Also, to reduce the number of false positives, the value of α is adjusted according to Bonferroni's adjustment as explained in [4].

Figure 1: Search Tree for Mixed Data

To find combination of attributes (itemsets to be explored), any search algorithm such as breadth first search or depth first search can be used. Depth first search is not the preferred choice of search algorithm since it reduces the amount of pruning possible. More specifically, it may try to combine attributes which other algorithms may have found to be "non-combinable" early on. For example. if the support of a subset of an itemset is below the threshold, depth first search will not prune it. Breadth first search, on the other hand, can maximize pruning. However, the storage overhead at each level may be high. We use a search strategy [28] shown in Figure 1 since it can maximize pruning, and it requires less storage overhead than breadth first search. The figure shows how itemsets are combined, and the number on each node indicates the order in which it is explored. If an itemset contains only categorical attributes, calculating the support for each group is straightforward. When a combination containing at least one continuous attribute is encountered in the tree, our proposed algorithm, SDAD-CS, is called.

To explore contrast patterns for mixed (or exclusively continuous) itemsets, such as in nodes 4 to 12 in Figure 1, we propose SDAD-CS (Supervised Dynamic and Adaptive Discretization for Contrast Sets), a quantitative contrast-set mining algorithm. Given an itemset c containing 0 or more categorical items, and 1 or more continuous attributes $ca = \{a_1 \dots a_n\}$ where n > 0, SDAD-CS finds itemsets that are contrasts between the groups. The contrasts found should also have the interest measure (such as difference in support) greater than the current minimum. Each contrast pattern returned should contain items from all the attributes (categorical and continuous) specified by the calling function.

The core idea behind SDAD-CS is to first divide the space (range) of a continuous attribute in a top-down fashion, calculate the interest measures and determine whether to stop searching or to explore further. After that, it merges similar contiguous spaces in a bottom-up fashion and refines the space.

Let input group DB be all the rows and columns of the dataset containing the groups of interest. Let c and ca be the categorical itemset and continuous attributes to be explored, respectively. The pseudocode for SDAD-CS is shown in Algorithm 1. The α and δ are user input parameters (α is adjusted during execution). Though not shown specifically in the algorithm, α and δ are used each time there is a check for significance and largeness, respectively. The parent measure, which is initially set to 0, stores the parent's interest measure (such as difference in support). Min support is set to the current minimum support in the current list of top-k contrasts. If the list does not have k contrasts, min support is set to δ. Starting with the top-down part, $partition(ca)$ (Line 4 of the Algorithm) divides each continuous attribute at the median or mean (we use median) into spaces. For example, a continuous attribute with a range 0 to 100 with median 35 will be divided into [0-35] and (35-100]. Next, $find\_combs(p)$ (Line 5) finds combinations of spaces between continuous attributes. For example, if there are two continuous attributes, dividing each by its median creates four rectangles (spaces) on a scatter plot. Each space together with the categorical itemset creates a candidate itemset. If *cont* is the number of continuous attributes, then the number of spaces is 2^{cont}. These spaces define our initial bin boundaries.

The algorithm iterates over each space created. It checks if the space can be pruned (Line 7). This is performed by either checking a lookup table or by performing some calculation and saving the information in a lookup table, as will be described later. We use a hash map with the itemset as the key. More space-efficient data structures such as a hierarchical hash map can be used if space is an issue. Our pruning strategies are explained in detail in a later section; however, at this point it suffices to note that a space is pruned if it is found in the lookup table.

The next step is to calculate the support of the itemset in each group in the current space r (Line 10). SDAD-CS then calculates the interest measure – in our case the difference in support (and Surprising Factor) (Line 11). The algorithm then needs to make a decision whether to explore the current space further. This is determined by calculating the optimistic estimates for the child space. If the current database contains n groups, the optimistic estimate is calculated as follows.

Let r be the current space being explored, cca_r be the itemset found at space r and $count_k(cca_r)$ be the number of instances of group k in space r. If $|g_1|$, $|g_2|$ ... $|g_n|$ are the number of instances in group *1*, *2* ... *n* respectively, then,

$$supp_1(cca_r) = \frac{count_1(cca_r)}{|g_1|} \tag{5}$$

is the support of itemset cca in space r in group 1. Similar definition follows for the support of the same itemset in group n.

Let *level* be the current level in the recursive tree of SDAD-CS, $|ca|$ be the number of continuous attributes, then

$$max\_instances\_child = \frac{|DB|}{2^{level+1} * |ca|} \tag{6}$$

indicates the maximum number of instances in the child spaces created by a recursive call of SDAD-CS. This comes from the fact that the continuous space is split at the median and hence distributes the data points among all child spaces equally. It should be noted that the assumption is that the data is real-valued, and each reading is unique. Some care has to be taken if the number of unique values is far less than the number of data points.

The maximum support for itemset cca_r in group 1 in any of the child spaces is

$$max\_supp\_g1 = min(\frac{max\_instances\_child}{|g_1|}, supp_1(cca_r)) \tag{7}$$

The first part of equation 7 calculates the maximum support possible in a child space for group 1. We note here that the median is calculated based on all the given instances and the groups can be imbalanced. We see that dividing the space may not reduce the supports proportionally in all groups. If the number of possible instances in the child space is greater than the number of instances in group 1, then the first value inside the 'max' function is greater than 1. This is not possible and is taken care of in the second part of the equation. Also, support is monotonically decreasing as the space reduces, and hence if the support of the current space is less than the maximum **possible** support of the child space, the maximum support of the child space is the current support. A similar argument can be made for the other groups.

We can calculate minimum support by following Eq. 6-8:

$$other\_instances\_g1 = |DB| - count_1(cca_r) \tag{8}$$

$other\_instances\_g1$ is the number of instances of the other groups apart from g1 in the current space r.

Let

$$min\_instances\_g1 = max\_instances\_child - other\_instances\_g1 \tag{9}$$

which will be negative if the majority of elements are not g1.

$$min\_supp\_g1 = max(0, \frac{min\_instances\_g1}{|g1|}) \tag{10}$$

Finally, the optimistic estimate for the child space is given by

$$oe(cca_r) = max(\forall i \forall j, i \neq j, max\_supp\_gi - min\_supp\_gj) \tag{11}$$

i,j = 1..n

If the optimistic estimate calculated is greater than the minimum support, the child spaces are recursively explored (Lines 12-13). If a better contrast pattern is found in the child space, it is added to the current list of contrast patterns (Lines 14-15), else if the current contrast pattern is large and significant, then it is either added to the current list of contrasts D or D_{temp} (Lines 16-21). The current itemset is added to D if the interest measure is greater than its parents. However, if it is not, the algorithm waits until all the spaces are explored and adds it if at least the interest measure in one space is greater than that of its parent (Lines 22-23).

After finding contrast spaces, the algorithm merges similar and contiguous spaces to get more general and comprehensible contrasts in a bottom up fashion (Lines 26-30). To merge partitions, the spaces are sorted in increasing order of size. We observe that, SDAD-CS finds fewer and more meaningful itemsets since there is more opportunity of merging smaller itemsets. If we plot the continuous attributes on a scatter plot, the spaces created by two continuous attributes is a rectangle and the size is the area of the rectangle; by plotting 3 continuous attributes the space

Algorithm 1: Algorithm SDAD-CS

29                 Combine itemsets; update contrast set
30     Return D
```

is a cuboid and the size is the volume of the cuboid. In general, hyper-planes create hyper-cubes and the size is n-volume.

Lines 28-29 loop through the spaces and try to merge contiguous and similar ones. Again, similarity is tested using a chi square test with α_r and the resulting contrast is still large and significant. If the itemsets are merged, the support, *PR* (to be defined later), hyper volume and bin boundaries are updated accordingly. More specialized itemsets are deleted and the new itemset is inserted in the appropriate sorted place.

4.2 Interest Measures

The default interest measure we use in the quantitative analysis is the difference in support; however, we find that looking at the homogeneity of a space while searching can help us find interesting patterns. We define an interest measure, *purity ratio (PR)*, which describes how homogeneous the current region is with respect to the group. In general, any interest measure, such as entropy, can also be used here depending on the problem definition. Our data is highly imbalanced and working with just supports of the group eradicates this issue. For *purity ratio (PR)*, a value closer to 1 indicates that the current space contains mostly data from the same group. Suppose i and j are the groups we are contrasting, c is the itemset with discretized quantitative attributes, s_{ic} is the support of group i in the space of itemset c, we define *PR* as:

$$PR(c) = 1 - \frac{min(s_{ic}, s_{jc})}{max(s_{ic}, s_{jc})} \qquad (12)$$

One limitation with purity ratio is that it does not take the size of the itemset involved into consideration. For example, consider two itemsets: c_1 with supports of 0.02 and 0.04 in groups i and j respectively and c_2 with supports 0.30 and 0.60. Both have equal purity ratio. However, we notice that c_2 should be considered more interesting since it covers more instances. On the other hand, difference in support has another issue. Suppose we find two itemsets: c_1 with supports of 0.9 and 0.8 in groups i and j respectively and c_2 with supports 0.20 and 0.10, and we notice that both have similar support difference. However, c_2 (for our application) is more interesting, i.e. given the contrast c_2 the likelihood c_2 to be in group i is double that of j but there is almost a equal likelihood for c_1 to be from either of the groups. To overcome this, we define **SurPRising Measure**:

$$SurprisingMeasure(c) = PR(c) * Diff(c) \qquad (13)$$

By multiplying difference in support (Diff) in each group to purity (PR) it takes the size of the contrast into consideration while giving equal weights to both groups.

The optimistic estimate for Surprising Measure is the same as Equation 11, since in the best case, PR will always be 1 in any partition (PR = 1 if there is only one instance in a partition).

4.3 Pruning

For itemsets containing only categorical attributes, we use the same pruning methods as in [4], i.e. minimum deviation size, expected value and chi-square bounds. This can be directly applied to itemsets containing both continuous and categorical or only continuous items once the bins are formed. Apart from the above technique, we try to prune redundant contrasts. An itemset is redundant if the support of the itemset is equal to the support of one of its subsets. The rationale behind this can be explained using an example. Consider an itemset $\{female\ \&\ pregnant\}$. Female subsumes pregnant i.e. the support of $\{female\ \&\ pregnant\}$ is equal to support of $\{pregnant\}$. Any contrast that is a superset of $\{female\ \&\ pregnant\}$ is likely redundant.

If an itemset is redundant, the support difference will be the same as its ancestors. Not expanding this itemset will reduce the number of redundant contrasts and search space. We note that the itemset should be redundant in all groups. In many real world datasets, there might be missing values, or incorrectly entered values. In addition, highly correlated features also tend to have many redundant contrasts. Hence, we loosen the requirement of

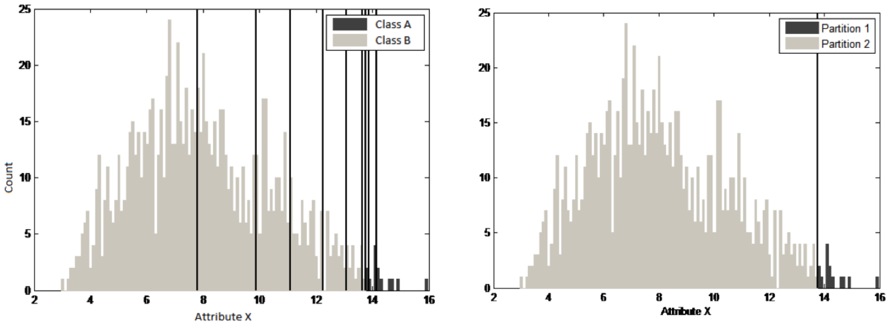

Figure 2: (Left) Vertical lines: all splits before merging. (Right) Final result after merging.

total subsumation and test whether the difference is statistically the same.

The datasets tested upon are samples of the population, and hence to make decisions for the population, statistical tests are needed. To check if two itemsets have statistically the same differences in support in the population, we use the central limit theorem. We choose this because we can assume that the difference in support for multiple samples of the population tend to follow a normal distribution. Extending the definition of central limit theorem to difference in support, it states that “Given no other samples, the best approximation of the mean of the difference in support for the population is the difference in support in the current sample."

Let α be the significance level, $|gx|$ and $|gy|$ be the sizes of groups x and y, respectively, $diff_{curr}$ be the current difference in the groups, $diff_{subset}$ be the difference of the subset, and $supp_x(c)$ and $supp_y(c)$ be the supports of itemset c in group x and y, respectively. For each subset, we calculate the bounds of the difference $diff_{bound}$. Let

$$a = \frac{supp_x(c) * (1 - supp_x(c))}{|gx|} \tag{14}$$

and,

$$b = \frac{supp_y(c) * (1 - supp_y(c))}{|gy|} \tag{15}$$

$$diff_{bound} = diff_{subset} \pm \alpha * \sqrt{a + b} \tag{16}$$

If $diff_{curr}$ is within the range of $diff_{bound}$, the difference support for the current itemset is statistically the same as its subset and hence may not be interesting and is pruned. Itemsets that are supersets of the current itemset will also not be meaningful.

Another case for redundancy for contrast patterns would be if there is a contrast found with support = 0 in a group but greater than δ in the other, then adding another item to the itemset may result in a redundant itemset. Extending this to itemsets containing continuous items, and looking at our definition of PR, we notice that when $PR = 1$ in a space, only one group is present in that space. Adding another item to the itemset would result in redundant contrasts. For example, consider a dataset containing attributes height and current country with groups toddler and adult. Consider we find a contrast height ∈]60,75] (inches) has support(adult)=0.8 and support(toddler)=0. Now adding current country to height may also result in a large and significant contrast, but it is clearly redundant between these groups.

A contrast pattern ’c’ is productive if for every subset ’a’ and ’c\a’,

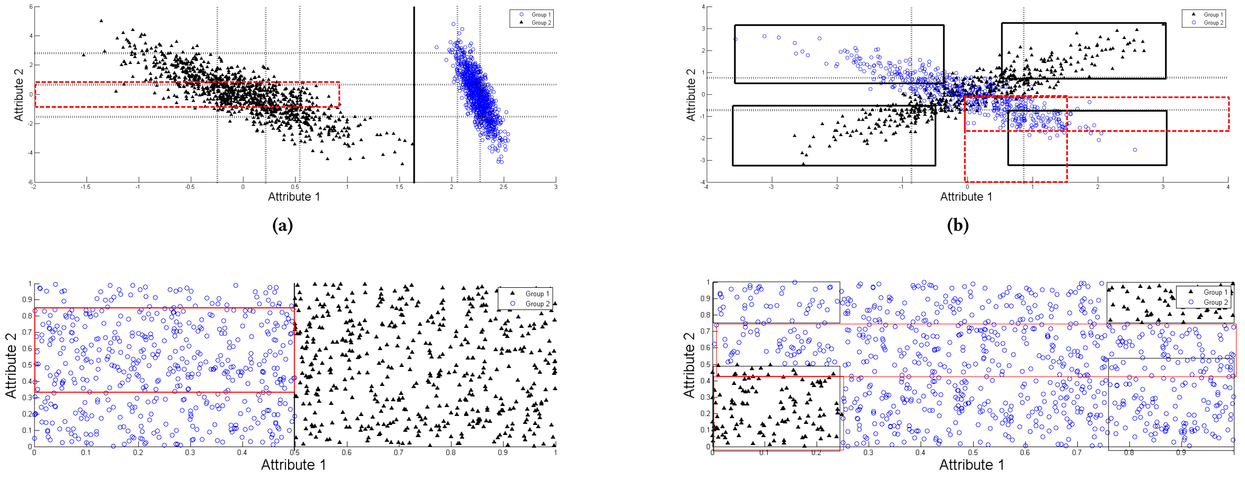
$$diff_c > supp_x(a) * supp_x(c \setminus a) - supp_y(a) * supp_y(c \setminus a) \tag{17}$$

if |g_x| > |g_y|.

If $diff_c$ is less than the product on the right-hand side of the equation for even one of the subsets, the contrast is clearly not productive. However, if it is greater, a statistical test is needed to confirm if it is indeed productive. We use chi-square test to check productivity. It should be noted that this formula is related to leverage in association rule mining which checks statistical dependence between variables.

At the end of the mining process, a check is performed to see if the contrasts are independently productive. Independently productive itemsets are meaningful, independent of their children or ancestor itemsets. For example, consider a dataset with two groups of days when a hurricane "develops" and "not develops," and a user wants to study the differences in the groups. There are a few necessary conditions for a hurricane to develop, e.g. temperature of water > 80 degrees Fahrenheit, depth of water > 200 feet and low wind shear. Considering these 3 features, the number of contrasts which will be found is 7. However, the only contrasts that the user might be interested in are the ones with all 3 conditions in it. Independently productive patterns provides the users with a compact set of patterns which are likely to be meaningful.

To check whether an itemset is independently productive, a check is performed on each superset of the itemset present in the final list. For example, consider itemset $\{A \,\&\, B\}$ and itemset $\{A\}$ in the list of contrasts found. Let r(A) be the indices of rows that item A is present, r(B) be the indices of rows that item B is present and r(A ∩ B) be the indices of rows that item A and item B are present. Now if itemset $\{A\}$ is independently productive then rows r(A) - r(A ∩ B) should also be a contrast, otherwise the contrast is found only because of itemset $\{B\}$. To check whether an itemset is a contrast, a chi-square test is performed to check significance difference in the groups. We note that an itemset may have multiple supersets and the check is performed only on supersets present in the final list. It is easy to see why this is the case by simple observation. If the superset is not a contrast, then it cannot be the case that the other features present in the superset caused the current itemset to be a contrast.



(a) (b) (c) (d)

Figure 3: (a) Simulated Dataset 1 (b) Simulated Dataset 2 (c) Simulated Dataset 3 (d) Simulated Dataset 4

4.4 Example

In Figure 2 we show an example of discretizing an itemset $c = \{X\}$, where X is a continuous attribute. Let G be the group attribute with value "A" and "B". The figures shows the histograms of X, and the different shades of gray denote the two groups "A" and "B". The darker shade denotes G = "A". Suppose 2% of all records belong in group "A", and the rest belong in group "B". X is first divided into two spaces at the median m, and SDAD-CS notices that PR in the left space is 1 since there are no instances of $\{X < m, Y = \text{"}A\text{"}\}$. This is a pure space and does not need to be split further. In the right space, however, the PR is $1 - (48/98)/(2/2) = 0.51$ and the optimistic estimate is $1 - 23/98 = 0.76$. The algorithm continues dividing the space and the new PR becomes $1 - (23/98)/(2/2) = 0.76$. All the partitions are shown in Figure 2(Left). Spaces are then merged from smallest to largest. The final partition after merging contiguous regions is in Figure 2(Right).

5 EXPERIMENTAL EVALUATION

SDAD-CS is compared with 3 other popular algorithms, MVD, Fayyad's entropy based method [9], and Subgroup Discovery interval binning [20] implemented in the Cortana software suite.

Experimental Setup: For all experiments, initial $\alpha = 0.05$ and $\delta = 0.1$. The search tree was stunted to have a maximum of 5 levels. For the simulated dataset, we use Surprising Factor as our interest measure since it results in the best contrasts qualitatively. For the quantitative analysis, we compare all the algorithms with SDAD-CS NP (No Pruning) . This was to level the playing field since many redundant and non-productive contrasts have a high interest measure and are pruned out by our algorithm. We use mean difference in support as the interest measure since the other algorithms are not developed to optimize Surprising Factor or Purity and hence would not be a fair comparison. These experiments however show the utility of our algorithm compared to the state of the art. We also discuss the scale and effect of non meaningful patterns found by not using our pruning methods.

We compare our algorithm to MVD [3] with initial $\alpha = 0.05$ and $\delta = 0.01$ of the size of the dataset. For MVD, the datasets were initially discretized to have 100 instances per small bin as in [3]. For Fayyad's discretizer, the Group attribute is treated as the Class. For subgroup discovery using Cortana, we use the WRACC measure (equivalent to finding support difference in groups [21]) with a minimum value of 0.01 with beam search and use the 'intervals' option for continuous attributes. The other settings for Cortana include keeping the target as nominal, search width 100, maximum time to infinity, maximum subgroups to k (100 in experiments), minimum coverage to 2 and maximum coverage to the entire dataset. Although Cortana is suite of algorithms, these settings seem to be the fairest comparison to our algorithm, and from here on we will refer to these settings as 'Cortana'. For Cortana we ran the algorithms twice, once for each subgroup, and then used all the subgroups found as the contrast set. The first part of this section qualitatively analyzes some of the contrasts found, and later we quantitatively compare the algorithms. Please visit https://zenodo.org/badge/latestdoi/8891484 to access the application version.

5.1 Simulated Dataset 1

As a litmus test, we first conduct experiments on 4 simulated datasets, to check the validity of the bins found. The first simulated data consist of 2 attributes as shown in Figure 3a. The bold line indicate the bins found by SDAD-CS and the dotted lines are the bins found by MVD.

The only split point SDAD-CS finds is with Attribute 1. Since $PR = 1$ for both contrasts we cannot do "better" by adding another attribute hence we prune these spaces i.e SDAD-CS will not find a contrast between Attribute 1 and Attribute 2. Although we see that there is some interaction (correlation) between the 2 attributes, which is detected by MVD, the goal here is to find a boundary that separates the groups and there is no interest in the underlying relationships in this case. MVD misses this splitting point. The entropy based method and Cortana finds the same contrast as SDAD-CS, however Cortana also finds a bin outlined by the red box which seems meaningless.

5.2 Simulated Dataset 2

This experiment shows the algorithm's ability to find meaningful contrast patterns in multivariate data. This dataset consists of two multivariate Gaussians in the shape of an "X" as shown in Figure 3b. Each Gaussian has a group attribute associated with it indicated by the markers.

The bin boundaries found by SDAD-CS are indicated by the rectangles in Figure 3b. We note that there is no rule found when we run SDAD-CS on each attribute individually. The contrasts found by MVD are similar to our algorithm. However, the entropy based method does not find any bins for this dataset. Cortana does not find the best bins which are shown by the red dotted boxes.

5.3 Simulated Dataset 3

In this experiment, we generated two variables uniformly distributed in the range 0 to 1. The only relationship in this dataset is that Attribute 1 in range 0 to 0.5 belongs to Group 2 and the rest Group 1. SDAD-CS finds contrasts at only level 1; however, Cortana finds meaningless contrasts at higher levels, shown in the red box. MVD finds similar contrasts as SDAD-CS.

5.4 Simulated Dataset 4

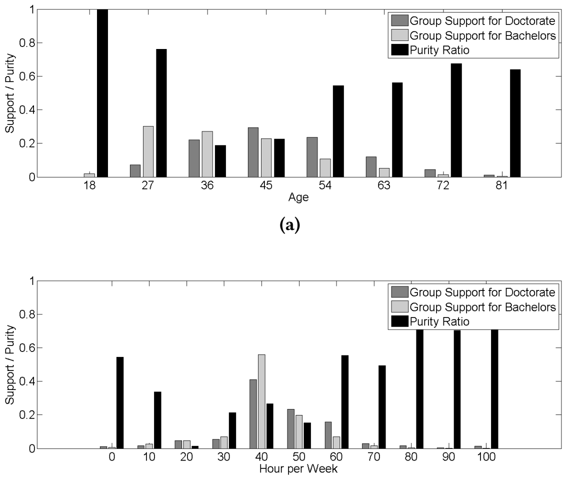
In Simulated dataset 4 we see interactions between attributes at level 2 of the search tree. We notice that during the search stage, there will be contrasts in the range 0 to 0.25 and 0.75 to 1 for Attribute 1 and 0 to 0.5 and 0.75 to 1 for Attribute 2. However, when the attributes are combined, the lower level contrasts are not independently productive and hence pruned by SDAD-CS. SDAD-CS finds a total of 6 contrasts. On the other hand, Cortana misses the top right contrasts and finds some meaningless regions shown in the middle of the figure.

5.5 Adult Dataset

5.5.1 Analyzing Bin Boundaries for Numeric Features. In this section, the differences in the contrasts found by the 5 algorithms on the Adult census dataset from the UCI Machine Learning repository [19] are shown. This experiment is a comparison between the 'Doctorate' and 'Bachelor' groups. We focus on Age and hours per week worked attributes since they highlight the differences between the algorithms.

Some of the quantitative contrasts found are shown in Table 1. Figure 4 shows the group support and the *PR* in each equi-frequency bin for Age and hours-per-week. The labels on the X-axis denote the bin boundary used and the Y-axis denotes the group support.

Looking at the contrasts found by SDAD-CS, we observe strong contrasts in the ranges 19–26 and 47–90 of the age attribute when we use PR as the interest measure to optimize. Looking at Figure 4a, we notice that, in the range 27–45, the supports for both groups are similar and hence it has a low *PR*. However, in the other ranges, there is clearly a dominant group. Similarly, in the range 50–100 for the hours-per-week attribute shown in Figure 4b, we see the majority belonging to the Doctorate group. The Bachelor group usually work less than 40 hours per week. The fifth contrast pattern discretizes {age, hours-per-week} which produces a better contrast (higher purity) than the contrasts found in the lower-order ones. This suggests that there is a multivariate relationship between these 2 attributes. We also notice the bin boundaries of {age, hours-per-week} change as compared to when they are discretized independently. This contrast shows that a global discretization may not work.



(a)

(b)

Figure 4: (a) Histogram comparing Age supports and purity ratio (b) Histogram comparing Hours per week supports and purity ratio

Cortana and SDAD-CS with support difference does not detect very good split points qualitatively. For example, in the range 19–26 in the age attribute we find only the group Bachelors. However, they find bigger bin boundaries. By looking at Figure 4a we notice the difference in supports and purity between ages 27 and 45 is small, however since the overall support in that space is much higher, the 2 algorithms find this as a large contrast. This is not surprising since the goal is to maximize the interest measure. A similar argument can be made for hours per week attribute. The contrasts found by Cortana when age and hours per week are combined are not *productive* according to the definition earlier. If we compare contrast 6 of Cortana and SDAD-CS with PR, Cortana finds a purer space. However, we also notice that in the range 19–26 of the age attribute, the support for the Doctorate group is close to 0, so *PR* is almost 1 for this contrast. Thus, we can prune this space for higher order combinations. An example of a contrast found without pruning this space is 19 ≤ Age ≤ 25 and 1 ≤ hours-per-week ≤ 40, which has support of 0 for the Doctorate group, and support of 0.10 for the Bachelors group. If this space is not pruned, SDAD would have found a purer contrast than Cortana, however, this clearly is a redundant space.

Fayyad's entropy discretizer and MVD detects level 1 interactions and finds strong contrasts, but fails to find any interaction between the attributes when combined. For the Doctorate group MVD forms a bin for Ages 48–59, which seems reasonable, however from 60–90 even though support difference is low, the purity (homogeneity) in favor of the Doctorate group is similar. Looking at the bar graph in Figure 4a, at around age 40, the support for both groups are similar, and as the age increases, we notice a higher support for the Doctorate group. MVD is not able to find the interaction between age and Hours worked

5.5.2 Analyzing top Patterns found. We now take a look at the top patterns found by Cortana (similar ones found by SDAD-CS without pruning). The setting for Cortana are as explained earlier; however, the depth of the tree was set as 2 for this discussion. The top 5 contrasts are shown in Table 3 (Cortana also displays contrasts such as $sex = Male\ and\ occupation = Prof\ specialty$

Table 1: Contrast Sets for Adult Dataset

S.No	Contrast Set	Supp (Doc.)	Supp (Bach.)
	Contrasts Using SDAD-CS with PR		
1	$18 < Age <= 26$	0	0.16
2	$47 < Age <= 90$	0.48	0.22
3	$1 < hour\_per\_week <= 40$	0.45	0.60
4	$50 < hour\_per\_week <= 99$	0.28	0.14
5	$49 < Age <= 69$ *and* $50 < hour\_per\_week <= 99$	0.13	0.03
6	$25 < Age <= 39$ *and* $1 < hour\_per\_week <= 39$	0.11	0.26
	Contrasts Using SDAD-CS with Support Difference		
1	$18 < Age <= 39$	0.26	0.57
2	$38 < Age <= 90$	0.76	0.46
3	$1 < hour\_per\_week <= 48$	0.55	0.73
4	$40 < hour\_per\_week <= 99$	0.55	0.40
	Contrasts Using Subgroup Discovery with Cortana		
1	$39 < Age <= 80.0$	0.74	0.43
2	$-inf < Age <= 39$	0.26	0.57
3	$6 < hour\_per\_week <= 49$	0.53	0.72
4	$49 < hour\_per\_week < inf$	0.45	0.28
5	$32 < Age <= 69$ *and* $49 < hour\_per\_week < inf$	0.41	0.19
6	$-inf < Age <= 43$ *and* $6 < hour\_per\_week <= 49$	0.20	0.50
	Contrasts Using Fayyad Entropy Binning		
1	$18 < Age <= 26$	0	0.16
2	$26 < Age <= 32$	0.08	0.19
3	$46 < Age <= 90$	0.24	0.51

Census Income	Below 50K/Above 50K	187141/12382	39/11
Ionosphere	g/b	225/126	34/34
covtype	Spruce-Fir/Lodgepole Pine	211840/283301	54/10

which is clearly the same as contrast number 4 in the table and is not considered here). We notice that the top 5 contrasts has one item in common $occupation = Prof\ specialty$. The question arises if all the contrast are meaningful.

Itemsets i, ii and iii in Table 3 are singular itemsets required for calculation of the expected support for the top 5 itemsets shown as a, b and c in table. Looking at Table 3, we see itemsets 1, 4 and 5 are not meaningful since the difference in support is not statistically different from the expected difference in support. Itemset 2 is clearly redundant and functionally dependent to itemset 3. Hence, of the top 5 contrasts found by Cortana, only contrast 3 would be displayed by SDAD-CS. It should be noted that these itemsets are seeds to higher order itemsets (with 3 and more items) which further exacerbates the problem. Later on we discuss the pervasiveness of this in all the datasets we encounter.

5.6 Quantitative Analysis

In this section, we compare the mean difference in support. We compare the algorithms based on difference of support since it is shown to be compatible with WRACC [21] (they are directly proportional). It should be noted that SDAD-CS finds significantly better contrasts with respect to Surprising Factor, however, it would not be a fair comparison since Cortana is not optimized for this interest measure.

Table 3: Top Contrast Sets for Adult Dataset with Cortana

S.No	Contrast Set	Supp (Doc.)	Supp (Bach.)
	Top 5 Contrasts found by Cortana		
1	$occupation = Prof\ specialty\ and\ 28 <= Age < 80$	0.74	0.21
2	$occupation = Prof\ specialty\ and\ 19302 <= fnlwgt < 606111$	0.76	0.28
3	$occupation = Profspecialty$	0.76	0.28
4	$occupation = Prof\ specialty\ and\ sex = Male$	0.61	0.17
5	$occupation = Prof\ specialty\ and\ class = > 50K$	0.55	0.11
	Required Itemsets with 1 item		
i	$28 <= Age < 80$	0.98	0.8
ii	$sex = Male$	0.81	0.69
iii	$class = > 50K$	0.73	0.41
	Expected Supports for itemsets		
a	$occupation = Prof\ specialty\ and\ 28 <= Age < 80$	0.75	0.22
b	$occupation = Prof\ specialty\ and\ sex = Male$	0.61	0.19
c	$occupation = Prof\ specialty\ and\ class = > 50K$	0.55	0.11

Each algorithm finds different number of contrasts. To have a meaningful comparison, we only compare the top k contrasts where k is decided by the algorithm that finds the least number of contrasts or 100, whichever is smaller. The itemsets are sorted on the interest measure which is used to compare the algorithms in the experiment i.e. the itemsets are sorted in decreasing order on difference. The datasets are from the UCI repository and are shown in Table 2.

The * and - in Table 4 indicate that the distributions are not significantly different from SDAD-CS according to the Wilcoxon Mann Whitney test, and that the experiment was not able to be completed, respectively. The results indicate that on average, SDAD-CS NP finds the best results followed by Cortana. However, many of the contrast found are redundant when analyzed qualitatively. For example, in the Shuttle dataset, SDAD-CS seems to find very bad contrasts compared to Cortana. Further analysis of the patterns show that $Attr\_1$ in (-inf, 54.0] has probabilities 0.91 and 0.01 in the 2 groups respectively and $Attr\_9$ in (-inf, 2.0] has probabilities 0.77 and 0. Cortana then finds another pattern $Attr\_1$ in (-inf, 54.0] and $Attr\_9$ in (-inf, 62.0] with probabilities 0.91 and 0.01 which is clearly not improving the pattern found in the previous level. However, these strong patterns contribute towards increasing the average interest measure. Comparing the results manually indicate the SDAD-CS finds all the non-redundant contrasts. Moreover, if we restrict the algorithms to find only patterns at the first level, SDAD-CS finds stronger patterns. Additional experiments were conducted to validate our algorithm on semiconductor manufacturing data and initial results indicate SDAD-CS found the most interesting patterns qualitatively.

We compare the time cost for MVD, SDAD-CS and SDAD-CS NP in Table 5. It should be noted that the time observed is only representative and may not be an accurate comparison. The implementation standards were kept similar, however, it is possible that the algorithms could be made faster by some implementation optimizations. In general SDAD-CS explores more spaces but that may not correlate to time taken. This may be because at each space, MVD is more computationally expensive. SDAD-CS with pruning is the fastest in general.

For each dataset we show the number of Redundant, Unproductive and Independently Productive Contrasts in the top 100 patterns without applying the filter. The results are shown in Table 6. As shown in the table the majority of the contrasts may not be interesting to the user.

6 CASE STUDY: ANALYSIS OF MANUFACTURING DATA

The previous section showed the ability of our algorithm to find better contrast patterns than other state of the art algorithms, however, through this section, we show the utility of contrast pattern mining in a real world scenario. We demonstrate that contrast patterns have the capability to find insightful information in a dataset from a high-volume semiconductor packaging factory. Note that the data has been encoded and normalized for intellectual property reasons. The patterns shown here can be easily interpreted by engineers which may not be possible with other machine learning paradigms. There are many examples where we can apply our algorithm in the semiconductor manufacturing domain, such as, analyzing the difference between machines or finding contrasts between a high yield and a low yield batch.

A large amount of information is collected on a per package level as material moves through the packaging and test process. The segment of processing in the manufacture of CPUs which is of interest to us, lies between the wafer test and final test operations. Wafer test is the test performed on an entire wafer before it gets singulated and packaged. Final test occurs after the packaging process, and is used to ensure the product is going to perform as designed under specified operating conditions. The data collected are tied to the part identifier and can consist of variables that have continuous, as well as, discrete values. One has parameters that correspond to contextual information related to, for example, the sequence of equipment that processed the part, including relevant subentities (e.g. test heads, pick and place heads, oven lanes, bond heads etc.), material information, along with parametric measurement information from sensors on process tools (such as temperatures and pressures), along with parametric measurements from test, as well as, and categorical data related to device performance. The data volumes are quite substantial when one looks at the data collected across the entire manufacturing flow and to show viability of the methods presented in this paper, a limited data set was normalized and used for testing. The intent of the activity is to use the methods to quickly identify manufacturing conditions that are resulting

in failures at final test to prevent generation of additional scrap material. Note that these failures are typically sporadic and the upstream signals often get diluted with increasing process complexity.

For this experiment we took a sample of the entire population and compared it with parts that failed a particular test. The data consists of 148 attributes including around 30 continuous attributes. A quick look at the contrasts indicate some information of the failing parts. These insights allow engineers to tweak or change things that are a probable cause of the failure for the test. In Table 7 we see categorical contrasts which suggest that most of the problems occur on a particular placement tool and pick head on a specific chip attach module (CAM) and most of the issues usually occur on the back row of the tray holding the parts. Both the location of the impacted parts in the trays and the specific placement tool point to a potential issue with the rear lane of the module. We also see in Table 7 that the time the impacted parts are spending above the solder liquidus temperature in the reflow oven is unusually higher. Another issue noted in 7 indicates that the average peak reflow temperature for the chips that failed the test seem to be higher as well. These results indicate an issue with the temperature control in the rear lane of the reflow oven on that specific module. With this information, feedback and changes along the manufacturing line can be made in a timely manner, including blocking any additional processing on that specific equipment/location until the issue has been addressed. Other algorithms however give a large number of contrasts and are sometimes hard to interpret and act upon.

In any practical scenario the scaling of the algorithm is very important. Apart from introducing some pruning mechanisms in the previous sections in a real world scenario the data usually does not fit in main memory. A usual way to handle this situation

Table 7: Contrast Sets for Manufacturing data

Contrast Set	Supp. Diff	Supp. (Population)	Supp. (Sample)
CAM entity-SCE	0.27	0.28	0.55

254.1609 <= CAM Peak temperature <= 256.8191	0.14	0.24	0.37

is by parallelizing the algorithm by using multiple machines (in a cluster). It should be noticed that SDAD-CS is run on combinations of features (itemsets) and can be run parallel of each other. Intermittent results can be used to prune the next stages. There are multiple strategies proposed in the literature of association rule mining (or search tree algorithms) to find candidate itemsets in parallel. A simple strategy is find contrast patterns at each level of the tree in parallel and then use those results to prune the next level of the tree. There is some loss of pruning of the search space across subtrees, but by using this strategy, we can treat each problem at the computing nodes as an independent problem, and use the pruning strategies discussed earlier within subtrees. The times taken to complete the experiments are 18, 106 and 225 minutes for samples containing 100000, 500000 and 1000000 instances respectively with 120 features.

7 CONCLUSION

In this paper we propose a method to find contrast sets in mixed data. Using a binning strategy that automatically determines the size and number of bins for the continuous attributes, we find meaningful contrasts even with the presence of multivariate interactions. Our algorithm is capable of finding meaningful contrasts which can potentially be more interesting to users by finding productive, independently productive and non-redundant patterns. We discuss strategies to reduce the search space. The experimental results show the utility of our algorithm in real datasets and how it finds better contrasts compared to existing techniques. The algorithm introduced in this work provides insights for analyzing data that fits in the main memory. Manufacturing data, as well as data in many application domains are very large. We discussed a way to scale up the algorithm in a parallel environment. This can be potentially used to provide more accurate and real time patterns to engineers.

ABSTRACT

Assessing the interestingness of data analysis actions has been the subject of extensive previous work, and a multitude of interestingness measures have been devised, each capturing a different facet of the broad concept. While such measures are a core component in many analysis platforms (e.g., for ranking association rules, recommending visualizations, and query formulation), choosing the most adequate measure for a specific analysis task or an application domain is known to be a difficult task.

In this work we focus on the choice of interestingness measures particularly for Interactive Data Analysis (IDA), where users examine datasets by performing sessions of analysis actions. Our goal is to determine the most suitable interestingness measure that adequately captures the user’s current interest *at each step of an interactive analysis session.*

We propose a novel solution that is based on the mining of IDA session logs. First, we perform an offline analysis of the logs, and identify unique characteristics of interestingness in IDA sessions. We then define a classification problem and build a predictive model that can select the best measure for a given a state of a user session. Our experimental evaluation, performed over real-life session logs, demonstrates the sensibility and adequacy of our approach.

1 INTRODUCTION

Assessing the potential *interestingness* of the output generated by a data analysis action has attracted considerable attention both in research and in the industry, and was proven highly useful for tasks such as association rules ranking [18], choosing data visualizations [31], data summaries [6], query formulation [27], etc.

Consequently, a multitude of interestingness measures has been suggested in previous work, each measure attempting to capture a different aspect of the broad “interestingness” concept. For example, *diversity measures* favor data patterns in which elements differ significantly from one another, *peculiarity measures* favor data patterns that display anomalous behavior. Other measures capture *conciseness*, *novelty*, and so on. Consequently, an important (and still open) question is *how can one choose which interestingness measure to employ?* To tackle this exact question, several comprehensive empirical evaluations have been conducted (e.g. [12, 17, 18, 22, 29]). These excellent surveys conclude that (1) there is no single measure that consistently outperforms the rest and (2) the adequacy of specific measures depends heavily on the task at hand and on the application domain.

Whereas most previous work examines the interestingness of specific, singular analysis actions, our work focuses on the interestingness notion within the entire process of Interactive Data Analysis (IDA). There is a growing understanding in the industry and research communities that users analyze datasets *interactively* by issuing a *sequence* of analysis actions of different types (e.g., OLAP, visualizations, mining). Notable and ubiquitous IDA tasks are data exploration, business intelligence (BI), and fraud detection. Typically in IDA, users interact with a dataset by executing a series of analysis actions, referred to as *session.* After issuing an action (e.g. group-and-aggregate, filter, plot, cluster), the user examines its results output (which we call *display*) then decides if and which action to issue next.

Our goal is to predict, at each step of a user’s analysis session, what is the most suitable interestingness measure that adequately captures the user’s current interest.

If successful, such a predictive model may be highly useful in several analysis “meta” tasks, such as facilitating an evaluation method for analysts’ effectiveness, improving existing (and future) analysis recommender systems (e.g. [16, 25, 31]) and enhancing systems for automatic data exploration e.g. ([9, 24]).

To our knowledge, our work is the first to consider dynamically changing interestingness in the context of IDA. Therefore, Our first intent is to demonstrate that interestingness in IDA has different characteristics than the ones assumed in previous work, posing both challenges and opportunities. We identified the following key characteristics, based on an in-depth analysis of real-life session logs:

1. There is not one measure that holistically captures “what is interesting” in IDA sessions. When using a single interestingness measure, even if it is the most prevalent one, our experimental evaluation shows that it is inadequate for more than *two thirds* of all our examined cases. Also, many valuable, interesting actions obtain high scores w.r.t. one measure, and low to medium scores by others, hence, different measures need to be employed in different cases.

2. Interestingness (and correspondingly, the measure used to capture it) changes dynamically even in the same user session. We empirically show that within a single user session the “most adequate” interestingness measure changes every 2.2 analysis actions on average.

3. Interestingness is *contextual*. Namely, the analysis context, comprising of previous actions in the same session and their result displays, is, to some extent, correlated with the interestingness preferences of the user (and the measures capturing them).

The following example illustrates the dynamically changing nature of the interestingness notion in a typical IDA scenario.

Example. Clarice is a cyber security analyst assigned to examine inbound network traffic data of a large organization, with the goal of searching for back-door communication channels. She loads the dataset to an IDA interface and performs a sequence of actions, as illustrated in Figure 1 (the sequence of actions is depicted on the upper part of the figure, and the bottom tables depict the actions’ results) First, she performs a *group-by* on the field “Protocol” in order to view the amount of traffic of each

Figure 1: An Example IDA Session

network protocol. She then returns to the previous display, and issues a *filter* action in order to examine HTTP packets transmitted after business hours (i.e.,between 7pm to 4am). Last, she performs another group-by action on the attribute 'Destination IP', in order to obtain a summary of the uncommon packets (transmitted after business hours) categorized by their destination IP address.

Since Clarice is an expert analyst, assume that all her actions yield interesting result displays. However, *each action is considered interesting according to different measures*: For instance, her first group-by action results in a display (as depicted in Figure 1) that summarizes all traffic according to the network protocol. If we use a *diversity*-based measure (such as Variance [15] or Simpson [15]) to assess the interestingness of this display, it would rank high - as the amount of packets greatly differs between the different protocols. However, if assessed by *peculiarity* based measures (e.g. [19, 28]), which consider displays showing anomalous/extreme patterns as more interesting, this display may obtain a low interestingness score.

In contrast, the results display of the second (filter) action contains rather unusual packets transmitted after business hours (e.g., having a very small length or issued from IP addresses that are uncommon in the dataset). Therefore, this display may be ranked as highly interesting by *peculiarity* measures. However, it may yield lower scores from *diversity* measures (since the attributes of the unusual HTTP packets are rather evenly distributed).

Last, her third (group-by) action results in a compact summary of the unusual HTTP packets, grouped by their destination IP address. This display is considered interesting according to *conciseness* based measures (e.g. [6]) that favor displays conveying a small, human-readable number of rows that summarize a large number of elements. Indeed, all unusual HTTP packets are outgoing merely two different destination addresses. However, this display obtains a low score from *diversity* and *peculiarity* based measures. ■

As illustrated in the example, **although the expert analyst makes actions resulting in interesting displays - each action is supported (i.e., given a high score) by a different interestingness measure, and obtains low to medium scores by others**.

However, attempting to predict the most adequate interestingness measure at each point in an IDA session poses immediate challenges and questions: (1) How can we derive the "ground truth"? Manual labeling may be possible yet time-consuming and costly. (2) Even the simple task of examining a single action and determining which measure finds it more interesting than others is quite difficult, since the different measures capture different facets of interestingness and have different value ranges and distributions.

To overcome these challenges we propose mining analysis session-logs, containing previous analysis actions performed by the same or other users. Given the current user's state in a session, we search the repository to find points in other sessions that are *similar* to the user's state. We analyze what were the relevant measures for these previous sessions and use them to predict the most adequate measure for the current user.

The key contributions of our work are as follows:

1. A simple yet generic data model for interestingness in an IDA environment. Our model is compatible with different types of interactive analysis platforms, from traditional SQL to OLAP and modern web-based interfaces (such as Splunk and Tableau). Our generic model supports a wide range of existing interestingness measures and can be easily extended to support user-defined measures as well.

2. A-posteriori, offline interestingness analysis. The session logs do not provide any information about what parts of the session were interesting and which measures adequately capture it. We therefore devise methods for deriving the most adequate measure at each point in a *past* session by analyzing the interestingness of the *next-action* performed within the same session. By using new techniques for computing *relative interestingness*, we can properly compare the scores of this action (given by different measures) and determine which one best captures its interestingness.

3. Online Interestingness Prediction. Using the results of the above offline analysis, we define a classification problem and build a predictive model that can select the most adequate measure for a current session-state, without knowing its continuation. This model can be used for a dynamic, context-aware selection of interestingness measures in an *ongoing* session, and

Class	Measure	Definition	Reference
Diversity	Variance	$\frac{\sum_{j=1}^{m}(p_j-\bar{q})^2}{m-1}$	[15]
Diversity	Simpson	$\sum_{j=1}^{m} {p_j}^2$	[15]

Conciseness	Log-Length	$1 - \frac{min(\log m, c)}{c}$	Following [26]

Table 1: A Partial List of Interestingness Measures

when combined with analysis assistance tools, can aid users in discovering interesting patterns in the data, compose meaningful visualizations, and so on.

4. Experimental evaluation. We evaluated our framework on real-life IDA session logs [1] acquired from over 50 experienced analysts in the domain of cyber security. Our empirical results show that our system can predict, with high accuracy, the correct measure to be used at each point in a user session.

The paper is organized as follows. In Section 2 we describe our data model for IDA interestingness and articulate the problem of interestingness measure prediction. Section 3 describes our framework, comprising the offline interestingness analysis an the online predictive model. Our experiments are detailed in Section 4. Last, we overview related work in Section 5, and conclude in Section 6.

2 BACKGROUND & PROBLEM DEFINITION

We first present a simple yet generic formal model for the IDA process, then describe the different notions of interestingness that we use. Last, we define the problem of *dynamic interestingness measure selection.*

2.1 IDA: Model and Definitions

An IDA session begins when a user loads a dataset, denoted $\mathcal{D}$, to an analysis UI (could be SQL, OLAP or a visualization-driven interface such as Tableau). Then, the user executes a series of *analysis actions* (e.g. SQL queries or visualization actions) $q_1, q_2, \ldots,$ examining the obtained results after each one. The results-set of action q_t, executed at step t is called a *display* (representing the results "screen") and denoted by d_t. The preliminary display is d_0, representing the dataset before any action was performed.

IDA session works intuitively like website navigation - at each point the user may invoke an action or backtrack to a previous display and take an alternative navigation path. We thus model an analysis session as an ordered labeled tree[1], denoted S. The nodes represent displays, and the edges outgoing from each node are labeled by the executed action and lead to the resulting display node.

We use S_t to denote the session after step t, namely the *state* in which the user examines the results display d_t, before deciding whether to execute a next action q_{t+1} or conclude the analysis.

Figure 1 illustrates an *analysis session tree* that corresponds to our running example, in which a user interacts with a dataset of network packets (ignore, for now, the dashed and gray parts). The directed edges represent actions q_1-q_3, and the nodes d_1-d_3 represent their corresponding results displays. The root node, d_0 represents the first display of the dataset before any action was invoked.

Last, we assume throughout this work that past analysis sessions are recorded in a *session log*. We denote by $\mathcal{R}$ a repository of such recorded sessions.[2]

2.2 Interestingness Notions for IDA

A typical interestingness measure, denoted i, takes as input an action q and its results display d, and returns a real number $i(q, d) \in \mathbb{R}$ indicating how interesting are the results (d) of the action q (higher score indicates a more interesting action).[3] For brevity, when d is clear from context, we omit it and simply refer to the *interestingness of action q* by $i(q)$.

While a multitude of different interestingness measures exist (See Section 5 for a discussion), w.l.o.g. we focus our attention in this work to eight common measures from the literature that correspond to four different facets of interestingness, following the categorization in [12] and [15].

The formal definitions of the considered measures (along with a corresponding reference) are provided in Table 1. Next, we intuitively describe each measure, then provide several examples.

Diversity. Diversity measures, e.g. *Simpson* and *Variance* [15] rank higher displays whose elements demonstrate notable differences in values. The definitions of the example measures that we use here are stated in Table 1. The notations are borrowed from [15], assuming an *aggregated* results display: m is the number of groups, v_j is an aggregated value for group j, $p_j = \frac{v_j}{\sum_{k=1}^{m} v_k}$ and $\bar{q} = \frac{1}{m}$. Example below.

Dispersion. In contrast to diversity, dispersion measures e.g. *Schutz* and *MacArthur* [15] favor displays consisting of relatively similar elements.[4]

[1] If the same display is generated twice (yet on different paths) it is represented by two different nodes

[2] Analysis sessions may either be recorded by the IDA platform, or, when it does not provide such a service, reconstructed from standard query logs by methods e.g. [32].

[3] Some measures consider more information, such as a reference display or a model of the user's prior belief. While our framework can be naturally extended to support such measures we omit them for the simplicity of presentation.

[4] In some cases the inverse score of a diversity measure can be used to evaluate dispersion, and vice versa.

Class	Measure (i)	Interestingness Scores				Relative Scores	
		$i(q_1)$	$i(q_3)$	$i(q_a)$	$i(q_b)$	$\bar{i}(q_3)$ (RB)	$\bar{i}(q_3)$ (N)
Diversity	Simpson	0.65	0.55	0.15	0.63	1	-0.07
Dispersion	Schutz	0.28	0.83	0.91	0.52	1	1.37
Peculiarity	Outlier Score Function	19.37	1.76	1.02	7.05	1	-0.74
Conciseness	Compaction Grain	51176	75454	39819	25706	2	2.2

Table 2: Interestingness Scores

Peculiarity. A display is peculiar if it presents or contains anomalous patterns. An example is a *Deviation*-based measure [31] that ranks a display higher if it demonstrates a difference from some reference display (e.g. the root display d_0); the p_j notation in the formal definition (Table 1) is the same as above, $\{p_j\}$ denotes the discrete distribution of p_j values, and $\{p'_j\}$ denotes the distribution of the aggregated values in the reference display. $\delta_{KL}(A|B)$ is the Kullback-Leibler divergence distance of the two distributions. Another peculiarity measure is the *Outlier Score Function* [19] (OSF) that focuses on the peculiarity of a single element (i.e, a single tuple, group, or cube cell) within the examined display. The final peculiarity score is simply the *maximum* of the elements' individual scores (See [19] for full details).

Conciseness. Such measures consider the *size* of the display, i.e. the number of elements it contains. Intuitively, displays that convey thousands of rows are difficult to interpret, therefore are considered less interesting. *Log-Length* scores a display proportionally to the log of its size, bounded by a constant c. *Compaction-Gain* (CG) compares the size of the particular display to the number of tuples in the original dataset (denoted O in the formula in Table 1).

In Section 5 we discuss other types of interestingness measures e.g. *surprisingness, actionability* and how they can also be incorporated in our framework.

As the reader can observe, each measure values different properties of the data and may rank a given display differently. The following example illustrates the interestingness evaluation according to the measure types presented above.

Example 2.1. Consider again the IDA session described in Figure 1, and the different interestingness measures described in Table 1. Let us assess the interestingness evaluation of actions q_1 (Group by 'Protocol') compared to q_3 (Group by 'Destination IP'). In Table 2, we report the interestingness scores of q_1 and q_3 according to four different measures, one from each interestingness type (we do not exemplify the calculation of each score, for that we refer the reader to the original papers as depicted in Table 1). Let us examine some of the scores:

1. Diversity, Dispersion: The results of q_1 are considered more interesting than of q_3 as $i(q_1) = 0.65$ and $i(q_3) = 0.55$ (See Table 1). This is due to the larger deviation in the groups' size in d_1 than what appears in d_3 which only contains two groups that are rather even in size. In terms of Dispersion, in which displays with less variations yield higher scores, q_3 is indeed more interesting than q_1 ($i(q_1) = 0.28$ and $i(q_3) = 0.83$)

2. Conciseness: In terms of the Compactness Grain measure, which considers the ratio between the number of tuples to the number of elements (e.g. groups) that covers them, we can see that $i(q_1) = 51,176$ while $i(q_3) = 75,454$. q_3 obtains a higher score than q_1 as its results-display d_3 covers a high number of packets in merely two groups (IP addresses), while d_1 covers all packets with a larger number of groups, one for each network protocol.

Interestingness Measure Prediction. Given a predefined set of interestingness measures $\mathcal{I}$, and a user session state S_t after t steps, our goal is to predict which measure in $\mathcal{I}$ adequately captures "what is interesting" at this point of the session. **Our main hypothesis in this work is that interestingness (and therefore the adequacy of measures) is *contextual*, hence correlated with previous actions taken by the user in the same session.** We illustrate this with our running example.

Example 2.2. Consider the Example Session in Figure 1, at state S_2, i.e. when the user examines Display d_2, before invoking the next action q_3. Our goal, as stated above, is to predict which measure from $\mathcal{I}$ (e.g., Diversity-based, Peculiarity, Conciseness, etc.) best captures the interestingness at this moment. While this seems like a challenging task, examining the previous actions in the session provides some intuition regarding which measure is preferable: In q_2 the user filters all packets to focus on *unusual HTTP traffic occurring after business hours.* As she examines a long list of anomalous elements, it is likely that she is interested in a more *concise* display that summarizes the data, rather than a display that demonstrates another peculiar pattern or one with high Dispersion.

Following this premise, we form a supervised multi-class classification problem that considers session-states as "samples" and assign them a "label" corresponding to interestingness measures in $\mathcal{I}$. In other words, we will assemble a training set containing labeled samples of the form $\langle S_t, i\rangle$ and build a predictive model $F(S_t) \approx i$ that best fits the training data.

To properly define this process, one needs to (1) develop means to determine "what is interesting" in a current state of an IDA session and which measure captures it best. (2) Once this is determined, develop a classification model for predicting what measure best captures the interestingness for the current session state.

We address the two issues in the following section, where we explicitly define the predictive task and model.

3 INTERESTINGNESS PREDICTION FRAMEWORK

We next describe our solution for interestingness measure prediction in IDA sessions. Before we describe our predictive model, we provide (Section 3.1) a set of techniques for *offline interestingness analysis*, in which we retrospectively derive what was the most suitable measure $i \in \mathcal{I}$ for a session state S_t, using the next action q_{t+1}. Then we describe in Section 3.2 how these techniques are used when constructing the training set and building the predictive model.

3.1 Offline Interestingness Analysis

Theoretically speaking, there are several possible ways to examine a session state S_t and determine what is the most suitable measure for it.

First, one can perform *manual labeling* by using expert analysts, familiar with interestingness measures, that can label a session state S_t with the most suitable measure as they see it. The problem with this approach is that it requires, first of all, a great manual effort that is not easily transfered to other contexts (e.g. IDA session logs performed on different datasets or for different purposes). Also, existing measures are often not intuitive even to expert analysts. A second approach could be prompting for user feedback at each session-state, gathering details about the user's intention, goals, and details regarding if and why the current display is interesting (w.r.t. each facet captured by the measures in $\mathcal{I}$). But this method, like the previous one, requires a considerable manual effort (this time by the users performing the sessions).

In contrast to these approaches, we devise means for deriving the adequate measure for a session state S_t solely by examining the continuation of the session. Assume for a moment that our repository only contains actions resulting in interesting displays. Then our key assumption is that for a session state S_t, **if the next action in the same session q_{t+1} is interesting *enough*** (we explain how this is determined in the sequel), **then we can use it to derive what is the measure that best captures the interestingness at S_t**.

A simplistic implementation of the above assumption is to simply choose, given a session state S_t, the measure $i \in \mathcal{I}$ that produces the highest score$i(q_{t+1})$. However, since the measures in $\mathcal{I}$ may produce scores of different value ranges and distributions, this method must be refined.

We therefore devise two interestingness *comparison methods* that are largely impartial to such biases. In each comparison method, we first compute, w.r.t. each measure i, the *relative interestingness score* of an action q denoted $\bar{i}(q)$, which is *comparable* to the relative scores $\overline{i'}(q)$ obtained by other interestingness measures $i' \in \mathcal{I}$. Once we have the unbiased, relative scores, we can simply choose a measure yielding the *maximal* relative interestingness as one that best captures the interestingness of an action q_{t+1}, hence is suitable for S_t. We call a measure *dominant* w.r.t. action q, denoted $i^{\star}(q)$, if it yields the maximal relative interestingness, i.e. $i^{\star}(q) = argmax_{i \in \mathcal{I}}(\bar{i}(q))$.

Last, we note that in real-life analysts are imperfect, hence IDA sessions may contain erroneous/redundant actions or simply uninteresting ones. We will show in the sequel how our analysis is used to eliminate such actions and minimize their negative effect.

We start by describing the Reference-Based Comparison method, which is comprehensive but expensive to compute. To overcome this, we then present an alternative method, the Normalized Comparison, which also reduces the score bias but requires a lower computational cost.

Reference-Based Comparison. Our first method for unbiased interestingness comparison, denoted Reference-Based comparison, examines the score of an action q as obtained by a particular measure and compares it to the scores achieved when employing *alternative actions*. Hence, instead of comparing individual scores of different measures for an action q, we first calculate how "high" each measure ranks q compared to a reference set of alternative action, denoted $R(q)$ (in Section 4 we explain how we generate $R(q)$ in our prototype implementation). Then we can simply derive that the measure i which ranks q the highest, is the one that best captures its interestingness (in case there is a tie, all measures that yield the highest relative interestingness are returned).

Algorithm 1 $ReferenceBasedComparison(\mathcal{I}, \langle q, p, d \rangle, R(q))$

```
1: for $q' \in R(q)$ do
2:     $d' \leftarrow$ The results of action q' on display $p$
3:     for $i \in \mathcal{I}$ do
4:         Compute the score $i(q', d')$
5: for $i \in \mathcal{I}$ do
6:     Compute the score $i(q, d)$
7:     $\bar{i}(q) \leftarrow |\{q' \in R(q) \mid i(q', d') \leq i(q, d)\}|$
8: return $argmax_{i \in \mathcal{I}}(\bar{i}(q))$
```

The Reference-Based comparison is depicted in Algorithm 1. It takes as input a set of measure $\mathcal{I}$, a tuple $\langle q, p, d \rangle$ which includes an action q together with its *parent* display p (i.e., the display on which q was employed), and its results display d, and last, a set of *alternative* actions, denoted $R(q)$. It then works as follows.

First, we execute each action in the reference set $R(q)$ (from the same parent display p of action q) then calculate its interestingness scores w.r.t. each measure in $\mathcal{I}$ (Lines 1-4). Next, we calculate the raw scores for q w.r.t. each measure $i \in \mathcal{I}$ (Line 6), then derive the *relative interestingness* score of q , denoted $\bar{i}(q)$, by counting the number of actions in $R(q)$ that obtained a lower interestingness score than q (Line 7). Last, we return the dominant measure(s) $i^{\star}(q)$ that produced the highest relative interestingness score (Line 8).

Example 3.1. We use the Reference-Based method to assess which is the dominant interestingness measure for action q_3 in our example session (Figure 1). While we can see from Table 2 that d_3 has high Conciseness score, it is also rather disperse. However is it more *disperse* than *concise*, or vice versa?

Let $R(q_3)$ be the set of alternative actions $\{q_a, q_b\}$ (The dashed edges and Grey displays in Figure 1). Their interestingness scores w.r.t. the different measures appear in Table 2. The relative interestingness scores for q_3 appears in the middle section of Table 2. For instance, in terms of Dispersion, since q_3 has a higher score than q_b yet a lower score than q_a its relative score is 1. However, in terms of Conciseness, since the score of q_3 is higher than both q_a and q_b, its relative interestingness (Conciseness) is 2. Indeed, Conciseness yield the highest relative score for q_3, hence is chosen as the dominant measure $i^{\star}(q_3)$ that best captures the interestingness of action q_3.

While this method completely eliminates the score biases of the different measures, note that it is rather expensive to compute (we demonstrate this in Section 4) as it requires to execute, at each comparison, all alternative actions in the reference set and compute their interestingness scores. Consequently, we devise a second, more efficient comparison method which significantly reduces the score biases using statistical analysis.

Normalized Comparison. The second interestingness comparison method, denoted *Normalized* Comparison, eliminates the score bias due to differences in the range and value distributions, by applying a two-staged normalization process to each measure: (1) to tackle the differences in the measures' value distributions we apply a Box-Cox [5] power transformation that makes the values resemble a normal-distribution. (2) To tackle the differences in the value ranges, we calculate the mean and standard deviation of each measure's (transformed) value distribution then employ z-score standardization [30] so that each computed value now represents the number of standard deviations the original value differs from the mean. The transformed and standardized score of each action q is defined to be its *relative interestingness score* $\bar{i}(q)$, and can now be compared to the relative scores produced by other measures in $\mathcal{I}$.

The Normalized Comparison, depicted in Algorithm 2, is divided into two parts.

First, Stage (1) of the normalization process is applied, in a preprocessing manner, to a sample of the score distribution of each measure. The function PreProcess (Lines 1-8) takes as input the set of measures $\mathcal{I}$ and a set QD of actions and their corresponding result displays, i.e. pairs of the form $\langle q, d \rangle$ (such a set can be extracted from the session repository $\mathcal{R}$). It then calculates the interestingness score w.r.t. each measure in $\mathcal{I}$ (Line 4) and transforms its value using the Box-Cox method (Line 5). Last, the mean and standard deviation of the transformed interestingness scores of each measure are returned (Line 8).

Once the preprocessing is done, the Normalized Comparison function (Lines 9-15) can be employed. It takes as input an action q with its results display d, a set $\mathcal{I}$ of interestingness measures and the mean and standard deviation of the transformed scores of each measure, and computes the dominant measure $i^{\star}(q)$ as follows: first, we calculate the interestingness scores $i(q, d)$ w.r.t. each measure in $\mathcal{I}$ and apply the Box-Cox transformation to it (Lines 11-12). Then the mean and standard deviation are updated (Note that Lines 11 to 13 can be skipped if theses values were already computed in the preprocessing phase), and the relative score is calculated by applying the z-score standardization (Line 14). Finally, we return the measure(s) that obtained the highest relative interestingness score $i^{\star}(q)$, as in the Reference-Based method.

Example 3.2. To illustrate the computation, we demonstrate how the Normalized method can be used to assess the measure $i^{\star}(q_3)$ which gives the highest relative score to action q_3 in our running example (depicted in Figure 1).

Assume we performed the preprocessing routine and calculated the scores of all other actions in the log, then performed the transformation and standardization described above. The normalized relative scores for action q_3 are depicted in the right-hand section of Table 2. Consistently with the previous example, the highest normalized score for q_3 is given by the *Conciseness* measure, as its score deviates more than 2.2 standard deviation from the mean conciseness scores.

Also, observe that similar scores of different measures can obtain significantly different results after the standardization process. For instance, the absolute scores of q_3 obtained by the *Dispersion* and *Peculiarity* measures are 0.74 and 0.71 (resp.), however their standardized scores are very different (2.39, -0.2 resp.)

In Section 4 we examine the correlation between the Reference-Based and the Normalized methods and compare their execution times. In what comes next, we describe how these methods are used to construct the training set and the predictive model.

3.2 Online Interestingness Prediction

We developed a predictive kNN-based model for selecting the most suitable measure at a particular session-state.

First we discuss what information is used to describe a session state S_t, then how the training set is constructed and the mechanism of the kNN-based classification model.

Algorithm 2 *NormalizedComparison*

```
1:  function PreProcess($\mathcal{I}$, $QD$)
2:      for $i \in \mathcal{I}$ do
3:          for $\langle q, d \rangle \in QD$ do
4:              Compute the score $i(q, d)$
5:              $\tilde{i}(q, d) \leftarrow$ BOX-COX($i(q, d)$)
6:      for $i \in \mathcal{I}$ do
7:          Calculate $\tilde{\mu}_i$ and $\tilde{\sigma}_i$, the mean and SD of all $\tilde{i}(q, d)$.
8:      Return $\tilde{\mu}_{\mathcal{I}}, \tilde{\sigma}_{\mathcal{I}}$, containing $\tilde{\mu}_i, \tilde{\sigma}_i \forall i \in \mathcal{I}$
9:  function NormalizedComparison($\mathcal{I}, \langle q, d \rangle, \tilde{\mu}_{\mathcal{I}}, \tilde{\sigma}_{\mathcal{I}}$)
10:     for $i \in \mathcal{I}$ do
11:         Compute $i(q, d)$
12:         $\tilde{i}(q, d) \leftarrow$ BOX-COX($i(q, d)$)
13:         Update $\tilde{\mu}_i$ and $\tilde{\sigma}_i$
14:         $\bar{i}(q) \leftarrow$ Z-SCORE($\tilde{i}(q, d), \tilde{\mu}_i, \tilde{\sigma}_i$)
15:     return $argmax_{i \in \mathcal{I}}(\bar{i}(q))$
```

Describing Session States. Recall that a session state S_t, is the subtree of S containing the first t actions and their result displays.

However, as older actions in the sessions may be of less importance to the classification model, we follow [25] and consider in our predictive model only the n most recent actions and displays, which we call the *n-context* of S_t, denoted c_t. More formally, c_t is defined as the minimal subtree of S that covers the most recent $min(n, 2t + 1)$ elements (i.e., displays and actions) up to step t (inclusive).

As an example, the 3-context at step $t = 2$ in our example session in Figure 1 includes Displays d_0 and d_2 and the action q_2.

In Section 4 we evaluate the predictive performance of the model when using n-contexts of various sizes.

Training Set Construction. Building a training set for a given session repository $\mathcal{R}$ and a set $\mathcal{I}$ of interestingness measures is performed as follows:

(1) Extracting n-contexts from the session repository. For each session state S_t in every session S in the repository we first compute its n-context. As we assume that the sessions in $\mathcal{R}$ are already represented as trees, deriving the n-context for a session state S_t can be done by a DFS-like traversal: Starting from display d_t, we process the nodes (i.e., displays) in reverse to the order of execution of their corresponding actions, considering only actions executed before step t until the size of the induced subtree (nodes+edges) reaches n, which is a configurable parameter in our framework.

For each session state S_t we keep a pair $\langle c_t, q_{t+1} \rangle$ comprising its corresponding n-context and the consecutive action q_{t+1} which will be used to derive its label (i.e., the suitable measure for that session state). For space efficiency, it is sufficient to store for each n-context only pointers to the original actions in the log rather than duplications. In Section 4 we explain how n-contexts are extracted and stored in our implementation.

(2) Assigning labels to n-contexts. For each pair $\langle c_t, q_{t+1} \rangle$, we use either one of the two comparison methods described above to find the dominant measure $i^{\star}(q_{t+1})$. This measure is assigned as a label to the n-context c_t, representing the most suitable measure for the corresponding session state S_t (recall that more than one measure may be qualified).

(3) Omitting globally "non-interesting" samples. Naturally, some of the actions in the session repository may be erroneous or simply non-interesting. Consequently, we want to eliminate from the training set samples whose consecutive action q_{t+1} is not interesting enough w.r.t. any of the measures in $\mathcal{I}$, hence can not be used for deriving the right measure. This is done by using a configurable threshold for the maximal relative interestingness score of q_{t+1}, denoted θ_I. If the relative interestingness obtained by the dominant measure $i^\star(q_{t+1})$ is lower than θ_I then we discard the sample $\langle c_t, q_{t+1}\rangle$ from the training set.

kNN-Based Classification. Once the training set containing labeled n-contexts is constructed, a classification model can be used, given n-context, to predict the *dominant* measure.

In principle, there are multiple techniques for performing supervised classification, however many of them requires a numeric vector representation for the samples (n-contexts in our case). However, we are not aware of such numeric representation of analysis sessions, yet numerous previous works [3, 11, 13, 25] define a notion of distance/similarity for analysis sessions (or a part thereof). For example the measure suggested in [25] uses tree edit distance to compare two session trees, together with two ground metrics that compare individual actions and displays. Alternatively, in [3] the authors suggest a measure based on local sequence alignment. We harness such a distance notion to form a simple kNN classifier: Given an n-context c_t, we search the training set for its k nearest-neighbors, then employ a majority-vote and return the most common label among the nearest neighbors. Last, it may be that some of the k nearest n-contexts may be too distant from c_t. To avoid the negative effect of such cases on the model's output, we use a distance threshold, denoted θ_δ, which is used to enforce a maximal distance (i.e., a minimal degree of similarity) between the kNN set and the given n-context. If the nearest neighbors retrieved are not similar enough, the model does not yield a prediction.

We intuitively explain this using our running example.

Example 3.3. Assume that our session repository $\mathcal{R}$ comprises only the example session depicted in Figure 1. We first extract n-contexts of e.g. size 3 from $\mathcal{R}$: For each $1 \leq t \leq 3$ we create the 3-context c_t: c_1 contains the single node d_0, c_2 contains d_0, q_1, d_1 and c_3 contains d_0, q_2, d_2. Recall from the previous examples that Compaction Gain measure (Conciseness) is the dominant measure for action q_3, therefore is used as a label for c_3.

Assume we are given another user's session on a different network log, however with the following last action q_u: "filter by protocol='SSL' & 10pm < Time<3am" (which is intuitively similar to q_2 in our example session in Figure 1). After extracting the n-context (containing q_u, its results, and its parent display) from the new session state, we predict what is the adequate measure using the kNN model: If using $k = 1$, then the most similar n-context in the repository is c_3, hence Compaction Gain will be return as prediction.

In Section 4 we explain how we evaluated the predictive model in various settings and compared its performance to several baseline approaches.

4 EXPERIMENTAL EVALUATION

We applied our offline interestingness analysis methods as well as the predictive model on an IDA session log containing real life analysis actions. We begin by describing the session log and our implementation choices, then describe our findings from the offline analysis. Last we evaluate the accuracy of our predictive model compared to other baselines, then test the effect on performance induced by the model's hyper parameters.

REACT-IDA: A repository of real-life IDA sessions. We used the only publicly available (to our knowledge) collection of recorded analysis sessions performed by real users on real-life datasets [1]. The sessions were collected as part of the experimental evaluation of an existing IDA recommender system [25], developed by some of the authors of this work (we discuss this system in more details in Section 5). The repository contains sessions performed by 56 network security analysts, recruited via dedicated forums, security firms, etc. The participating analysts were asked to explore 4 different network-logs datasets using REACT-UI [23], a dedicated, web-based analysis platform with an easy to use interface supporting data filtering, grouping and aggregation. Each dataset contains raw network logs that may reveal a distinct security event, e.g. malware communication hidden in network traffic, hacking activity inside a local network, an IP range/port scan, etc. After completing an analysis sessions, REACT-UI prompts the user to type a short summary of the findings. Sessions corresponding to summaries that successfully reveal the underlying security event are marked as *successful.* The repository contains a total of 454 sessions comprising 2460 distinct analysis actions, out of which 122 sessions (comprising 757 actions) are successful. The REACT-IDA session database in [1] also contains the original datasets used in the analysis, and the means for regenerating the actions and inspect their result displays, so that the each recorded session can be fully reconstructed.

4.1 Offline Analysis Evaluation

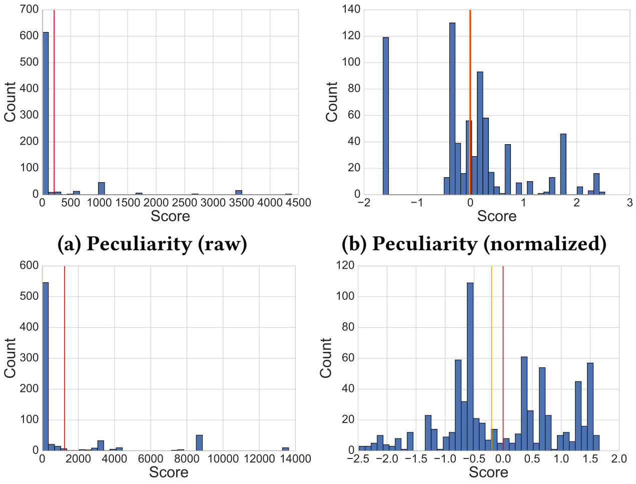
We next describe the application of our offline interestingness analysis methods on the REACT-IDA sessions database, accompanied by selected findings.

Computing interestingness scores. We re-executed the recorded actions in the REACT-IDA database and computed their interestingness scores w.r.t. all measures presented in table 1. Next, to form an unbiased set of measures $\mathcal{I}$, i.e., that does not contain dependent/highly correlated measures we computed the Pearson Correlation Coefficient for every pair of measures. While the average correlation score was 0.3 we saw that measures from *different types* (e.g. Dispersion, Peculiarity, Conciseness) have an average correlation of 0.071 compared to an average score of 0.543 obtained by measures of the *same type.* Consequently, we experimented with 16 different configuration of $\mathcal{I}$, containing one measure from each type. .

Applying offline comparisons. We applied both comparison methods to the REACT-IDA session database in order to calculate the dominant interestingness measure $i^\star(q)$ for each action q. As for the Reference-Based Comparison, recall that it compares the interestingness scores of an individual action to the interestingness scores of alternative actions. We constructed the reference action set as follows: For each action q with a parent display p we considered all actions in the databases from the same type (e.g. group-by, filter), omitting actions that when executed from display p result in displays comprising less than two rows.

As for the Normalized Comparison, we calculated the statistics over all actions (and their results) in the REACT-IDA database by applying the Box-Cox transformation and z-standardization to their raw interestingness values as described in Section 3.1. Each series of interestingness values (corresponding to a particular measure) was first shifted by a constant in order to eliminate negative scores (this is often required for power transformations). The configurable power parameter λ, which is used as the exponent for the values to be transformed, was determined using maximum-likelihood estimation, as is standard for such transformations.

As an example, Figure 2 depicts the scores histograms of the Outlier Score Function (Peculiarity) and the Compactness Grain (Conciseness) measures, before and after normalization. The red line in each figure represents the mean score, and the orange line represents the median. While the non-normalized scores are skewed towards zero, we can see that the normalized values distribute much more evenly, resembling a normal distribution.



(a) Peculiarity (raw) **(b) Peculiarity (normalized)**

(c) Conciseness (raw) **(d) Conciseness (normalized)**

Figure 2: Interestingness Scores Histograms

Understanding users' interestingness preferences. We studied the output of the interestingness comparison methods, namely the dominant measure w.r.t. each recorded action, in order to empirically validate our first two hypotheses presented in the introduction:

(1) Is there one measure/interestingness type that is sufficient to capture "what is interesting" in IDA? If indeed so, then it is sufficient to choose a-priori a single interestingness measure and apply it to all IDA tasks. To answer this question we counted how many actions in the REACT-IDA were labeled with the same dominant measure.

Figure 3 depicts the proportion of actions labeled with measures from the same interestingness type (averaged over all settings of $\mathcal{I}$), when using both the Reference-Based and the Normalized comparison methods.

We can see that in both comparison methods, the most common measure is dominant w.r.t. only 41% of the recorded actions, and the proportions of the rest of the measures types are rather evenly distributed. Due to ties, see that the sum of proportions is slightly larger than 1, i.e. where more than one interestingness measure was found dominant for the same action. Also, note that there are differences in some of the classes' size when a different comparison method is used (mainly in the Peculiarity and Conciseness classes). This is due to slight differences in the comparison base for each method: The Reference-Based method is affected by the parent display of the examined action (from which it was executed), whereas the Normalized is affected by the interestingness scores of other recorded actions, regardless of their parent displays and context.

The above result indicates that *there is no single interestingness measure that can be used for all actions in the repository.* However, as users' IDA sessions are performed on different datasets and for different purposes, one may still ask whether *one interestingness type is sufficient to capture interestingness within the same session?* If true, it may be sufficient to match a single interestingness measure with certain IDA tasks or datasets rather than dynamically choose a measure for each state in a user session. We therefore examined the relative interestingness scores of actions *of the same session.* We found that *on the course of a single session in the REACT-IDA repository, the dominant measure is changed every* 2.2 *steps* on average. This demonstrates that the interestingness preferences of the user, as well as the measures capturing them, are dynamically changing even within the same IDA session. In Section 4.2 we empirically validate our third hypothesis arguing that *interestingness is contextual* i.e., that one can successfully predict the right measure for a given session state S_t based on its corresponding n-context c_t.

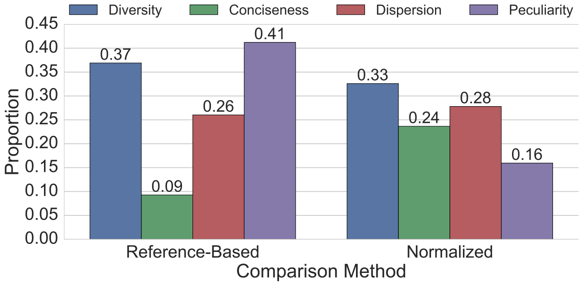


Figure 3: Interestingness Class Labeling Frequency

Correlation between the comparison methods. We studied how consistent is the output of the two comparison methods. First, we found that 68% of all recorded actions obtained exactly the same dominant measure as output, by both methods. We then performed a Chi-Square test for independence between the outputs of the comparison methods on all actions: The methods were found highly correlated with a negligible p-value $< 10^{-67}$. The latter result demonstrates the sensibility of our offline interestingness analysis, and that the methods may be used interchangeably.

Execution times. Applying the offline comparison methods includes three major parts:

(1) Calculating interestingness scores. Recall that the raw interestingness scores are precomputed for each measure in $\mathcal{I}$. While some measures are rather fast to compute (e.g. both Conciseness measures), others (such as the Outlier Score Function) are much more time consuming.

(2) Actions Execution. This part is relevant to the Reference-Based which compares the interestingness scores of a given action to a set of alternative actions. Thus, each such reference action needs to be executed on the same dataset (from the same parent display) by the IDA platform.

(3) Computing relative interestingness scores: Both methods calculate the relative interestingness score and return as output the dominant measure(s), yielding the highest relative interestingness.

We measured the running times required to apply the Reference-Based and the Normalized interestingness comparison methods, w.r.t. each of these computation parts. For the Normalized Comparison, running times include the corresponding segment in the preprocess routine for each action.

Table 3 depicts the average time required by the Reference-Based and the Normalized comparison methods in order to select

Component	Time (Seconds)	
	Reference Based	Normalized
Action Execution	2.218	–
Calc. Interstingness	4.84	0.106
Calc. Relative Scores	0.04	0.031
Total	**7.2**	**0.138**

Table 3: Offline Running Times

the dominant measure for a given action for each of the computation parts described above. First, observe that the Reference-Based requires an overall of 7.2 seconds compared to the Normalized which takes 0.138 seconds only. As for the computational parts, see that the Reference-Based requires a considerable amount of time for executing the alternative actions (Part 2) method (the average size of the reference actions set was 115) which is unneeded for the Normalized method. Consequently, the former requires computing all interestingness scores of the alternative actions, therefore its running time w.r.t. Part 1 is significantly longer than of the Normalized method. Part 3, in both methods is negligible.

4.2 Predictive Model Evaluation

We next describe our predictive kNN based model. We then explain how we evaluated its performance in comparison with several appropriate baselines.

Constructing the training set. **Extracting n-contexts.** We extracted *n*-contexts that belong to successful sessions from REACT-IDA repository using the DFS base method described in Section 3.2. We experimented with n-contexts of sizes 1 to 11 (we explain below how the default size was chosen). For each session state S_t, we stored the pair $\langle c_t, q_{t+1} \rangle$ comprising its context and the consecutive action.

Annotating n-contexts. We used the offline analysis results as described above, to label each pair $\langle c_t, q_{t+1} \rangle$ with its corresponding dominant interestingness measure $i^{\star}(q_{t+1})$. We then discarded all samples in which the maximal relative interestingness scores (obtained by $i^{\star}(q_{t+1})$) was smaller than the interestingness threshold θ_I (as described in Section 3.2).

In case that identical n-contexts obtained different labels[5] we unanimously labeled them by the most common label(s) associated with this n-context.

kNN Model implementation. As common for kNN based classification models, given a (non-labeled) n-context our model searches the training set for the top-k most similar labeled n-contexts, then selects the label by employing majority vote. To determine the similarity between n-contexts, we used the distance metric devised in [25] which was proven useful for IDA sessions. The metric is based on *tree edit-distance*, i.e. the minimum-cost sequence of *edit operations* (add, delete, and alter a node/edge) required to transform one n-context to the other. While a unit cost is given to delete/add operations, the cost of an *alter* operation (for a node/edge) is proportional to the similarity between the data displays and analysis actions. The latter is determined by two ground metrics for actions and displays: the first considers differences in the actions' syntax and the second measures the differences in the content of the compared displays.

As for the model's running times, we measured an average time of 6.04 milliseconds required to output a single prediction.

Parameter	Value Range	Default Configuration	
		Ref. Based	Norm.
n-Context Size (n)	$[1, 11]$	4	2
kNN Size (k)	$[1, 40]$	1	1
Dist. Thres. (θ_δ)	$[0, 0.5]$	0.2	0.1
Int. Thres. (θ_I)	$[0, 1]$ (RB) $[-2.5, 2.5]$ (N)	0.92	0.7

Table 4: Model Hyper-Parameters

We refrain from further discussing the computation costs and the scalability of the model and refer the reader to [25] for an in-depth performance evaluation of the nearest-neighbors search w.r.t. their distance metric.

Evaluation Methodology. We formed multiple test sets using the Leave-One-Out cross validation (LOOCV) method, i.e., in a single prediction task we take one sample (n-context) out of the training set to be used as a test set, then repeat the process for each and every sample.

We then used the following evaluation metrics: *(1) Accuracy*, which stands for the ratio between correctly predicted samples (true positives) and the number of all samples. Then, as is standard when evaluating multi-class classification models, we used the *(2) Macro-Averaged Precision* and *(3) Macro-Averaged Recall* measures, which takes the average of the precision (resp., recall) *w.r.t. each class* (i.e., each interestingness measure).[6] We also computed the *(4)Macro-Averaged F1* which is the harmonic mean of (2) and (3).

Last, since in some cases the kNN model does not output a prediction (recall from Section 3.2), we also measured the *(5) coverage rate*, namely the proportion of samples for which our model is able to produce a prediction.

Hyper-parameters tuning. Our model uses the following hyper-parameters: *(1) the size of n-contexts* used when constructing the training set to decide how many actions/displays are required to represent each session state S_t. *(2) The size of k*, i.e. the number of similar n-contexts used to perform a prediction. *(3) n-contexts distance threshold θ_δ*, representing the maximal distance allowed between each members of the kNN set and the given n-context. *(4) Interestingness Threshold θ_I*, i.e. the minimal relative interestingness score required for the sample to be considered as interesting and not to be discarded. Recall that relative interestingness is computed differently for each comparison method therefore this parameter has two sets of scales: For the Reference-Based method the threshold represents the minimal *percentile* rank of the actions in the reference set surpassed by the score of the given action (For example $\theta_I = 0.7$ means that we are interested in samples where the dominant measure ranks an action higher than at least 70% of the actions in the reference set). For the *Normalized* method, as the standardized scores largely falls between −2.5 and 2.5 standard deviations, θ_I represents the minimal number of standard deviations that the score should (positively) deviate from the mean.

To choose an optimal parameters configuration, we used a standard grid search consisting of more than $50K$ unique settings. Table 4 depicts the minimal, maximal and default value for each parameter, w.r.t. both interestingness comparison methods.

Since there is a tradeoff between the predictive performance and the coverage-rate (we explain this in the sequel), in order to choose an optimal configuration we calculated the skyline (also

[5] This can happen when users perform an identical subsequence of actions yet choose a different next action.

[6] In contrast, micro-averaged methods consider all true/false positives, regardless of the class.

	Reference-Based Comparison				Normalized Comparison			
	Accuracy	Macro-Precision	Macro-Recall	Macro-F1	Accuracy	Macro-Precision	Macro-Recall	Macro-F1
RANDOM	0.282	0.281	0.268	0.275	0.252	0.252	0.253	0.252
BestSM	0.397	0.397	0.250	0.306	0.329	0.329	0.250	0.284
I-SVM	0.632	0.636	0.482	0.549	0.655	0.674	0.617	0.643
I-kNN	**0.730**	**0.646**	**0.569**	**0.605**	**0.763**	**0.730**	**0.664**	**0.694**

Table 5: Interestingness Measure Prediction - Baseline Results

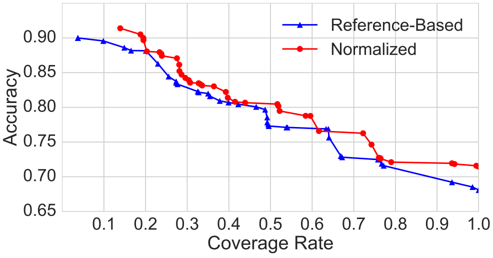

Figure 4: Configurations Skyline

called the Pareto frontier) for every comparison method. This resulted in a set of *dominant* configurations, w.r.t. the coverage and the accuracy/F1 score[7]. Figure 4 depicts the skyline plot for both comparison methods, between the coverage-rate (x-axis) and the accuracy (y-axis).

We chose default configurations from the skyline, as depicted in Table 4. Our default configurations yield accuracy scores of 0.730 and 0.763 (for the Reference-Based and Normalized methods, respectively), with coverage scores of 0.67 and 0.722 (resp.). In principle, any other configuration on the skyline can be chosen to ensure a different coverage-rate or predictive accuracy.

Baselines Comparison. We compared the performance of our predictive model, denoted *I-kNN*, with several other baselines.

(1) RANDOM, a naive baseline that selects a measure out of $\mathcal{I}$ uniformly at random. *(2) Best-SM*, this baseline chooses the *best single measure*, namely it always selects the one measure which is the most prevalent among the training set. This baseline corresponds to the common approach, taken in many analysis assistance tools (e.g. [10, 16, 31]), in which a single interestingness measure is chosen a-priori and used for all cases. Next, we experimented with two predictive models that are adequate to our setting in which the samples (namely, n-context) are compound objects rather than feature vectors: *(3) I-SVM*: a Support Vector Machine (SVM) model with a modified kernel [7] that can take an arbitrary distance matrix rather than using the Euclidean distance between vector-shaped samples. We used it with the dedicated distance metric for IDA sessions [25] described earlier in this section. We employed a standard grid search to tune the model's hyper parameters.

Table 5 lists the predictive evaluation scores for both the Reference-Based and Normalized comparison methods, averaged over all 16 measure combinations in $\mathcal{I}$.

First, we can see that the *Best-SM* baseline outperforms *RANDOM*, yet its accuracy is less than 40%. The latter reestablishes our first hypothesis that no single existing measure can adequately capture users' dynamic interestingness preferences, hence a-priori choosing a single interestingness measure in IDA may often lead to an erroneous outcome. Second, see that the *I-kNN* model outperforms the *I-SVM* demonstrating 14% higher accuracy and 10% higher F1 score. However, recall that in contrast to I-kNN (which uses the default configuration), the SVM base model obtains 100% coverage. Yet, as mentioned above, it is possible to choose a different configuration from the skyline (see Figure 4) to enforce full coverage. In such settings the improvement obtained by the kNN model over the SVM is less significant. Nevertheless, see that both predictive models *I-SVM* and *I-kNN* significantly outperforms *BEST-SM*, which corresponds to existing approaches to interestingness measures. This establishes our third hypothesis *that the right measure can be successfully predicted by examining the analysis n-context.*

In what comes next we examine the effect on the predictive performance (and coverage) of the model's hyper-parameters.

Hyper-parameters Effect. To study the effect of the model's hyper-parameters we repeated the predictive evaluation of the model while varying the values of each parameter and fixing the rest to their default values as depicted in Table 4.

In Figure 5 we present the Accuracy, Macro-F1 and the Coverage-Rate as a function of each of the system parameters (for both comparison method), where the other system parameters get their values from the default configuration (w.r.t. the comparison method used) in Table 4. We next examine the effect on the predictive performance and coverage when varying each of the model's parameters. Last, we present a summary of our findings.

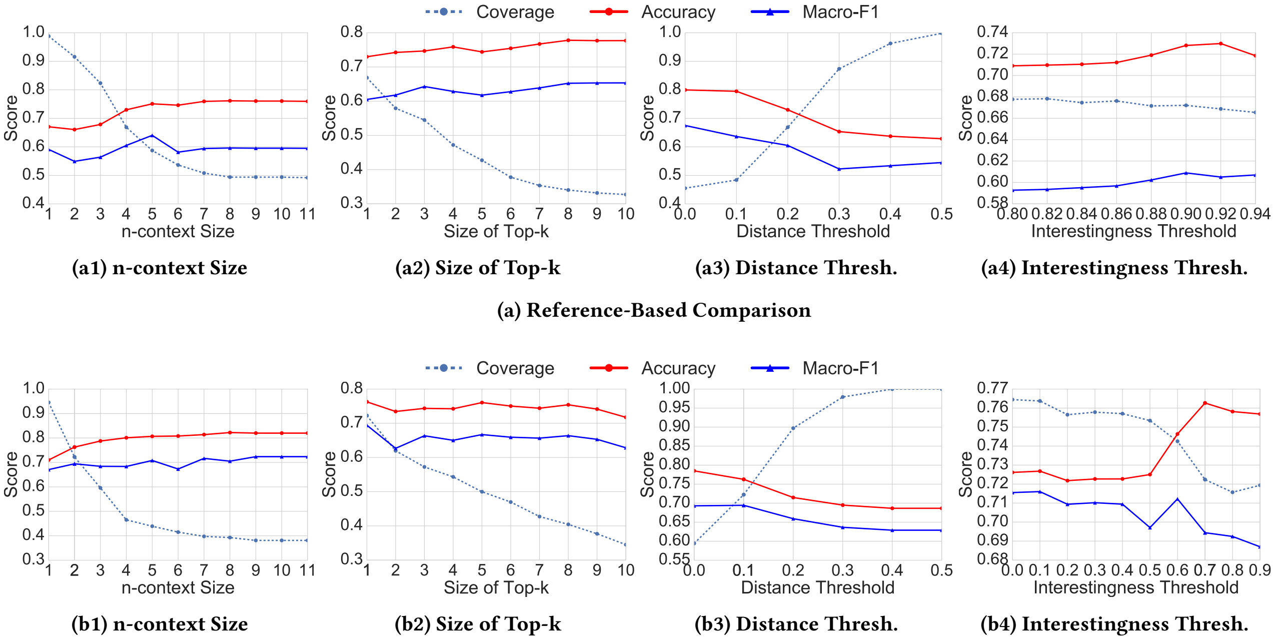
n-context Size. The n-context size, determined when preparing the training set, affects the amount of information the predictive models consider. Figure 5a1 and 5b1 depict the effect of n on the Accuracy, Macro-F1, and the Coverage-Rate of model for the Reference-Based and Normalized settings (resp.). As expected, increasing n (hence increasing the amount of information considered) positively affects the predictive performance. However, observe that the Coverage-Rate decreases. This is expected since when calculating the distance between larger, more compound, n-contexts the scores *increase* thus in more cases the k nearest-neighbors are not "similar enough" and the model does not output a prediction. When choosing n between 2-4, as in our default configurations, we obtained almost optimal predictive performance while retaining coverage of about 70% of the cases.

Size of k. The number of nearest neighbors considered by the model has a milder effect on performance, as can be seen in Figure 5a2 and 5b2 that demonstrate the effect of k on the Reference-Based and Normalized settings (resp.). In the Reference-Based method we can see a small, noticeable increase in performance, however it has a greater effect on the coverage of the model, since finding a larger set of nearest neighbors which are all similar enough to the given n-context is not always possible.

Distance Threshold θ_δ The distance threshold θ_δ is used by the model to enforce that the set of retrieved nearest neighbors are not too distant from the given n-context, hence avoiding erroneous predictions.

As expected, the lower (more tight) the distance threshold, the higher the predictive accuracy, as shown in Figures 5a3 and 5b3

[7] A configuration with x coverage and y accuracy is dominant if there is no other configuration with x' coverage and y' accuracy such that $x' \geq x \wedge y' > y$.



(a1) n-context Size **(a2) Size of Top-k** **(a3) Distance Thresh.** **(a4) Interestingness Thresh.**

(a) Reference-Based Comparison

(b1) n-context Size **(b2) Size of Top-k** **(b3) Distance Thresh.** **(b4) Interestingness Thresh.**

(b) Normalized Comparison

Figure 5: System Parameters Effect

displaying the effect of θ_δ when using the Reference-Based and the Normalized comparison methods. Naturally, the coverage decreases with θ_δ since there is not enough nearest neighbors with high similarity in many cases.

Interestingness Threshold θ_I. Recall that after we apply one of the offline comparison methods, we obtain the relative interestingness of each action. This allows us to filter out cases where the action executed by the user was not considered as interesting w.r.t. any of the measures in $\mathcal{I}$. For both comparison methods this indeed increases the predictive performance, as can be seen in Figures 5a4 and 5b4

Summary of Findings. We conclude this part by pointing out the trade-off between the predictive performance of the model and its coverage. When increasing the size of n-context and the kNN set size we increase the amount of information considered by the model, since a larger set of more comprehensive n-contexts are used as the basis for prediction. This naturally increases the model's predictive performance yet decreases the coverage since there are fewer cases where we can find, e.g., a large number of nearest neighbors highly similar to the given n-context.

A similar effect occurs when increasing the interestingness and similarity thresholds θ_I and θ_δ, which are used to ensure that the model uses only "high-quality" samples. Increasing theses thresholds improves the predictive performance yet decreases the Coverage-Rate, since there are fewer cases where such high-quality samples are relevant.

5 RELATED WORK

There is extensive literature that considers the interestingness of analysis actions on one hand, and interactive data analysis on the other.

Evaluating and comparing interestingness measures. As mentioned in the introduction to this work, interestingness measures are widely used in the field of data analysis, employed in tools e.g. for ranking and sorting association rules [17, 29], data patterns [4], generating useful visualizations [31], exploring OLAP data cubes [16] and many others.

Since dozens of measures were devised in the literature, each capturing different facets of the broad concept, several surveys and comparative studies have been performed to evaluate their usefulness [12, 14, 17, 18, 22, 29]: In these works the authors empirically evaluate many of the measures on real and synthetic datasets, and provide guidelines for choosing the right one for a given task and application domain. For example, [17] presents an empirical evaluation of more than 30 interestingness measures, applied for ranking buying patterns of customers. In [29], the authors examine 21 measures for association rules, concluding that neither one is consistently better than the others. [14] focuses on measures for data summary, empirically showing that the score distributions tend to be highly skewed.

While these notable studies contribute to the understanding of the usefulness of measures for different analysis tasks and scenarios, *they do not address the case of IDA - in which the interestingness criteria may dynamically change as the analysis session progresses.* To our knowledge, our work is the first to experimentally demonstrate this phenomenon and to provide a dynamic interestingness assessment (and selection of the appropriate measure), at each step of an ongoing analysis session.

Subjective facets of interestingness. For brevity, we considered in this work only *objective* facets of interestingness, such as Diversity, Peculiarity and Conciseness. However, several works suggest measures that capture *subjective* facets of interestingness [8, 20], i.e. that use prior information about the user and provide a more personalized interestingness assessment. For example, in [20] the authors devise measures for capturing interestingness facets such as *surprisingness* and *actionability* by considering user prior beliefs encoded as a set of classification rules (e.g. "has_job → loan_approved").

Incorporating such measures in our framework is possible yet requires the model to consider user information in addition to the n-contexts. This is an exciting direction for future research.

Learning Interestingness. Some works also suggest learning-based solutions for interestingness assessment. In [9] the authors present a system for guided data exploration based on active-learning. The system presents users with an initial set of tuples and asks then to annotate each tuple as interesting or not. Harvesting this feedback, the system can improve and personalize the tuples presented to the users. In [21], they present a visualization ranking system which is based on supervised binary classification of visualization into "interesting" or "non-interesting", based on students' annotations as ground truth.

In contrast to our work, these works tackle specific analysis tasks (i.e. filter/select queries and visualizations) hence can not be trivially generalized to the context of IDA which consists of sequences of actions of multiple types, and where (as we had shown in the experiments), interestingness, even for the same action on the same dataset, may vary through the process.

Second, both [9] and [21] require, and rely on users' feedback, which as explained in the introduction has limitations in our context. Different from these works, our solution provides a general-purpose system suitable for various types of analysis actions, and does not relay on particular user annotations. However, harnessing user feedback and learning-to-rank models in our system could be a promising direction for future work.

Mining IDA session-logs for action/query recommendation. Previous work [2, 11, 13, 25] suggests that mining IDA session logs can be used for predicting/recommending the next action in a session. These works utilize a collaborative-filtering approach, intuitively arguing that "if users are posing similar sequences of queries, they are likely interested in the same subpart of the dataset". However, in our previous work [25] we argue that in real life IDA scenarios analysts often examine different datasets from different purposes, hence recommending previous actions from the log to new users is generally impractical. To overcome this, the system described in [25] provides users with high-level "suggestions" that aggregate meaningful action-fragments mined from previous actions in the log. Combining our solution with [25] is an interesting direction for future work, where our solution can assist the system in [25] to better sort the output suggestions and further materialize them to concrete, executable actions.

6 CONCLUSION

This work examines interestingness measures in the context of interactive data analysis (IDA). We show that interestingness in IDA has unique characteristics: it dynamically changes even within a single session, and can not be holistically captured by just one measure. Using a real-life session log we demonstrated these characteristics and evaluated our interestingness predictive model, showing it can successfully select an appropriate interestingness measure for each step in an IDA session. Our model and framework may be employed in existing analysis recommender systems, allowing them to better fit the recommended next actions (e.g., visualizations, queries) to the current interestingness preferences of the user.

As for future work, we previously mentioned several ideas such as using our system to evaluate the effectiveness of analysis sessions. Also, incorporating user feedback and learning-to-rank models in our system is an exciting idea for future research.

ABSTRACT

An increasing amount of marketing intelligence data is becoming available today. This includes data that describes information technology (IT) inventories, i.e. IT products purchased by companies. It is advantageous for hardware and software service providers to analyze this data and build recommender systems to propose new products for client companies. Real-time recommendations are usually done based on matrix factorization methods or association rules. In this work we study the applicability of generative models to the recommendation problem. We focus on models that are able to reveal latent connections between companies and deployed IT products and build discriminative features of the IT structure of a company. Additionally generative models of company-product data are of interest for service providers for efficient company comparison, application of similar marketing strategies towards the groups of similar companies. In this work, we first formalize the notion of a company and its IT install base. Then, we estimate various generative models that are able to reveal hidden structures in data. These are mainly topic and language modeling techniques emerging in natural language processing to the task of company-product modeling and sequential models that are widely used for product recommendations. More precisely, the analysis is done using (a) Latent Dirichlet Allocation (LDA) with the products in a company are treated as a set, (b) *n*-gram models or sequential association rules and (c) Recurrent Neural Networks (RNN), when the time of product appearance is taken into account. The techniques are used for a corpus consisting of 860k companies. The results of the study demonstrate that simpler generative models with lower number of parameters, such as LDA, fit company-product data better and are more beneficial for company IT install base modeling both in terms of goodness of fit of the model and recommendation quality.

1 INTRODUCTION

Information technology (IT) install base[1] data is provided by specialized companies that carefully maintain its quality in terms of confidence of IT products' presence and accuracy of timestamps of their appearance. This kind of data has already been exploited for industrial applications and proved to be extremely useful to get market insights in several contexts such as, for example, new market development or white space determination. Data usually refers to companies. For a specific company, different types of information are provided, for example, insights about the internal structure, what the company buys, etc. IT install base data is a specific type of marketing intelligence data that provides, for a set of companies, knowledge about the type of IT equipment they own and how this equipment is distributed across their physical locations.

Install base information is particularly useful when addressing white spaces. If a provider of hardware services tries to acquire new customers, install base information will illuminate the insights about the business potential for a particular product domain. More interestingly, when combined with data about established customers, install base information can be used to identify companies that are similar to existing clients and therefore have a high potential of becoming new customers by acquiring certain sets of products.

In this paper, we concentrate on the problem of modeling company-product relations in order to (1) identify similar companies and (2) build product recommendations. Besides the computational complexity of the similarity search problem due to the large number of companies and product types, another challenge is that a naïve comparison of the individual product types owned by companies turns out to be biased towards product types that are common to a large number of companies. Therefore, after reviewing the related work, we focus on two approaches that consider the hierarchical similarity of objects (companies) based on contextual proximity of their features (product types). This happens to be an assumption in the field of Natural Language Processing (NLP). In our case, the similarity on the lower level is defined via the co-occurrence of the product types in a company. Higher levels correspond to hidden structures in the install base and the representation of a company itself.

To get the best model representations of products and then of companies, we estimate and evaluate various types of generative models. We choose the best model in terms of goodness of fit and predictive power. This model is used to extract product and company representations which are then applied for similarity search queries and marketing recommendations. In particular, we compare the performance achieved by these two modeling techniques: Latent Dirichlet Allocation (LDA) and Recurrent Neural Networks (RNN). The products belonging to a company compose a multilevel structured representation of the IT install base. Such

[1] Install base refers to the IT inventory of a company.

products are used as the basis of company similarity evaluation. The LDA and RNN techniques are beneficial for the IT install base modeling as they are able to reveal hidden hierarchies. RNN is preferred over other neural network architectures as it is able to take into account time-correlations of product time series. Besides, both techniques are among the best performers in the corresponding domains. LDA produces interpretable parameters, while the embeddings obtained by RNN modeling lack the interpretability. Uninterpretable parameters is a significant drawback for business applications, which can be tolerated if these models would perform much better.

The main contributions of this work are the following:

(1) We formalize the problem of modeling the IT install base of companies for various types of input data, such that the state-of-the-art unsupervised techniques from NLP domain can be applied. First, we formalize company-product data treating products in a company as a set and use corresponding non-sequential models for this case. Second, we treat the product data as sequences according to the time of their appearance. The models are then compared using their data fitting quality.

(2) The applicability of topic modeling via LDA and language modeling via RNN is assessed for our data. We demonstrate that LDA with 2, 3 and 4 latent topics fits the data best and, additionally, provides the most discriminative company features for the task of company clustering.

(3) We assess the practical applicability of the LDA and RNN models to an industrial product recommender and compare them with sequential association-rule and matrix factorization approaches.

(4) After solving various data integration challenges, we apply the output of the best performing model, enriched with internal company-product data, to a recommendation tool that searches for similar companies and makes recommendations.

2 PRELIMINARIES AND PROBLEM FORMALIZATION

The goal of this paper is to develop a recommendation system that also allows companies to be compared based on their install base. This comparison will be used to generate sets of similar companies and will allow possible business developments to be identified in real time. As the system in development is to be used by offering managers, the interpretability of the results is a crucial requirement to be able to justify the outcome. In consequence, models with interpretable parameters bring an advantage in our settings.

As a source of marketing intelligence data, we use information provided by HG Data Company, Inc. [12]. HG Data Company is building and maintaining a comprehensive database with competitive intelligence about deployed technologies. Essentially, for each company assessed, this database provides the following information: the type of IT products available at each site of the company without specifying the quantities and product model details, some indication about the confidence of the information provided, and dates of the first as well as the most recent successful confirmation of product presence.

Product descriptions are organized in a hierarchical fashion. This hierarchy contains four levels. At the top, we find the *vendors*. For each vendor, there is a list of *category parents* giving a high-level grouping of the product types, for example, “Data Center Solution” or “Hardware (Basic)”. Each *category parent* contains a list of *categories*, which are finer-grain groups. Examples of categories are “Printers” or “Midrange Computers”. Finally, each category contains the *product types* available for the vendor considered.

Our aim is to develop a sales recommendation application. Given a customer, potential customers with similar IT install base are provided as input to our solution, which then combines this information with internal data. To align the product description between our proprietary data and the result of the company similarity evaluation, we have focused on the category layer. Unfortunately, the product types do not contain a certain product details, thus, do not allow us to link the products with the lowest level of product descriptions in our proprietary data.Therefore for each company we consider the product categories[2] associated with the company, independently of the vendor. In our version of the HG Data Company database, there are 91 distinct categories. Out of those categories, we decided, because of the nature of our application, to restrict our study to hardware and low-level hardware management software categories, thus, using 38 distinct categories.

To link data from the HG Data Company database to our internal data, we solved integration and cleaning issues. In the HG Data Company database, companies are identified by their D-U-N-S® numbers. This number is a unique 9-digit identifier, assigned by Dun & Bradstreet, Inc. [8] to each business location. Therefore, each company entity, such as branches, subsidiaries and headquarters, has an individual D-U-N-S® number, and the set of all D-U-N-S® numbers associated with a company is organized hierarchically.

After we had chosen the product categories or company attributes and aggregated the subsidiaries of a company, we created our corpus for model training which is a binary company-product matrix. As we do not have information about product quantities, we consider only binary values in the company-product matrix, where 1 means that the product belongs to the install base of the company and 0 means that it does not.

More formally, let us consider a set of N companies represented in the HG Data Company database $C = \{c_0, \ldots, c_{N-1}\}$. Each company c_i has a given set of products A_i in its install base belonging to k categories, which can also be called attributes. This set of attributes is included in the set of all possible attributes $A = \{a_0, \ldots, a_{M-1}\}$ containing M elements[3]. That is

$$\forall c_i \in C \; ; \quad c_i \longmapsto A_i = \{a_{i_0}, \ldots, a_{i_{k-1}}\} \subset A. \tag{1}$$

The attributes might be sorted by the time of their appearance in the IT install base of a company and treated as data series. We denote the sorted version of A_i as A_i^S. The information about the attributes or products from A_i can be re-written using vectors $\mathscr{A}_i$ instead of sets of products:

$$\forall c_i \in C \; ; \quad c_i \longmapsto \mathscr{A}_i \; , \quad \dim(\mathscr{A}_i) = M \; , \tag{2}$$

$$\mathscr{A}_i = \left[\mathbb{1}_{a_0 \in A_i}, \ldots, \mathbb{1}_{a_{M-1} \in A_i} \right] . \tag{3}$$

A naïve approach to compare companies is to calculate the distance between their initial attributes $\mathscr{A}$ or A^S. In Section 3, we discuss why such an approach leads to results that are not sufficiently meaningful. The initial attribute space does not represent companies in a discriminative manner because the distance

[2] In the remainder of the paper we use the terms products and product categories interchangeably, meaning product categories.

[3] In our application $M = 38$.

between companies is affected too strongly by the most popular attributes. To overcome this problem, we introduce a new space of company features that better represents the IT install base:

$$\forall c_i \in C\;;\;\; c_i \longmapsto \mathscr{B}_i \in \mathbb{R}^L\;,\;\; L < M. \tag{4}$$

Considering the new company features $\mathscr{B}$, it is possible to express the distance between two companies as a classical distance between two vectors:

$$\forall c_i\;,\;\; c_j \in C\;;\;\; dist(c_i, c_j) = d(\mathscr{B}_i, \mathscr{B}_j), \tag{5}$$

where $d(.,.)$ is any vector distance, e.g., euclidean or cosine distance.

One of the goals of this paper is to automatically discover the most representative features of a company $\mathscr{B}$, based on initial company attributes A^S or attribute vectors $\mathscr{A}$. The features should be representative in terms of goodness of fit of the generative model of company-product data and in terms of quality of similarity clusters of companies. The methods of feature learning for companies are discussed in Section 4. Learned company and product features are, then, used for product recommendations.

3 RELATED WORK

In this section, we consider the applicability of existing methods for building discriminative company representations, namely, the feature vectors $\mathscr{B}_i$ for each company c_i. $\mathscr{B}_i$ are built using product vectors of a company, A_i, or a sequence of products per company, A_i^S. This representations should capture the hidden structures in the company-product data.

3.1 Co-Clustering

Co-clustering or bi-clustering is a technique used for building two-dimensional groups of objects that are represented by a matrix. The matrix is clustered along the rows and the columns. The principle of co-clustering was first introduced by Hartigan in 1972 [10]. Since then, several algorithms have been proposed mainly aimed at product recommendations.

The PaCo algorithm [27] and the OCuLaR algorithm for co-clustering with overlapping [11] are most closely related to our problem. The main issue with these approaches is that they are built on initial company representations $\mathscr{A}_i$, which may be not the best features to distinguish IT install bases of companies. When we applied the PaCo algorithm as well as spectral co-clustering to a small sample of around 500 companies that belong to a healthcare industry, we could not generate meaningful co-clusters. The only co-cluster generated contained overall popular products. Our first attempt of using LDA for this small subset of companies and products [18] provided us with much better results and inspired us to continue our search of company features in this direction. We believe that modified product features could improve the quality of co-clusters. As we also show in Section 5, raw initial company-product representations $\mathscr{A}_i$ neither describe the generative model of our data well nor perform well for the task of company clustering. In addition, given the large number of companies to analyze (on the order of a million), co-clustering results are difficult to interpret because the intuitive visual way to consume co-cluster results is not possible in this case.

3.2 Pattern mining

Another possibility is to explore product install base modeling using the approaches of the frequent pattern search from the time series domain. One family of such approaches is Association Rule mining [2], which is partially time agnostic. It was demonstrated in [6], [7] that taking into account the sequential nature of data is beneficial for time series tasks, such as similarity matching and nearest neighbor search. This inspired another line of techniques that are based on estimating Markov Chain models via real-time algorithms for ‘conditional heavy hitters‘ discovery [20], [17]. However, the mined patterns are not able to represent the hidden structures of the IT install base of companies, though we use them to compare more advanced methods with.

3.3 Applicability of NLP Concepts

In the past decade, much attention in the literature was given to modeling techniques related to NLP. In this subsection, we discuss their applicability to the problem of modeling install bases of companies. One of the key tasks in NLP is language modeling. The goal is to learn representations for hierarchies of concepts, starting from words, phrases, and sentences, which are then organized into more sophisticated concepts, such as documents and topics. In recent years, a lot of research has been devoted to the advancement and improvement of topic modeling and language processing methods, including, among others, LDA and Deep Neural Network (DNN) approaches. We assume that the generative model of our company install bases is similar to the NLP models. The product-company world consists of the following layers: a layer of companies, a layer of product categories and a hierarchy of latent structures inside the install base. Given this assumption, these company layers can be mapped to NLP concepts for application in the LDA and DNN methods. Considering NLP terminology, we associate companies with documents and products with words. All companies that we consider in our analysis form the corpus of company documents. We further assume that products or product embeddings can be grouped into latent topics, which then construct specific and discriminative features $\mathscr{B}_i$ for each company c_i, $0 = 1, 2, ..., N - 1$.

3.4 Deep Neural Networks and Product Embeddings

Currently DNNs are the core of the-state-of-the-art techniques for the tasks related to NLP. Mikolov *et al.* [16] [15] use a simplified architecture of neural networks that allows them to use very large training datasets and to build accurate word embeddings in Euclidean space of high dimensionality very efficiently. The word embeddings can afterwards be used directly without any transformation or aggregation as features for clustering. They also can be aggregated to represent a document as a vector in a smaller space using, for example, the Fisher Kernel Framework (probabilistic modeling of the corpus of documents using a mixture of Gaussians [14]) similarly as described in the work [5].

The larger the training set (hundreds of millions) and the larger the dimensionality of the word embedding, the better is the representation, although after a certain point the improvement is no longer significant. This is partially due to the large size of the vocabulary that typically needs to be learned, namely, 600K. As in our case the number of products is much smaller, there is a chance that we will learn good embeddings from tens of thousands of companies.

State-of-the-art performance on language modeling task is achieved by RNN family of models and specifically by RNN with Long Short-Term Memory (LSTM) units with the dropout regularization method [29]. This technique applies a distinct view on the information flow, using information not about independent instances but taking into account the sequential nature of data. Therefore, recurrent networks are sensitive to the past inputs and can adapt to them. Other RNN realization, such as Gated Recurrent Unit (GRU) [4] which is a simpler version of LSTMs, has recently gathered popularity, but study [9] empirically demonstrates the the performance of GRUs and other RNN architectures can be better for some datasets, but do not outperform LSTM in general. We will apply LSTM architecture to our company-product modeling using a time series input, A_i, and analyze its performance both in terms of goodness of fit and as a recommender of future IT products of companies.

In work [19], we have demonstrated that LSTMs are applicable to the task of modeling company-product time series. We used RNNs with Long Short-Term Memory (LSTM) units with the dropout regularization method [29]. Prior to applying RNNs in our work [19] we demonstrated that company-product time series are of clear sequential nature. This was done using statistical hypothesis testing and was based on the fact that the frequency of the i.i.d. time series observations has binomial distribution. In this work, we compare accuracy of the RNN modeling, where product time series are taken into account, with the performance of LDA, where products in a company are treated independently, without their timestamps. We also assess both methods for the recommendation task, comparing their results with the association rule-based recommender.

3.5 Latent Dirichlet Allocation

Blei *et al.* [3] introduce LDA, which is a generative probabilistic model for collections of discrete data, such as corpora of documents (or company-product vectors in our case) that is also used for collaborative filtering. Each item, such as a document or a company, is modeled as a finite mixture of an underlying set of topics or hidden groups. The topic probabilities for an item provide an explicit representation of a document. In parallel, word embeddings are also trained. The embeddings represent relatedness of words in the space of document topics.

The number of latent topics is a user-defined parameter. It can be chosen using measures of the goodness of fit of the LDA model, such as, a total log-loss for a testing set of documents or as the average perplexity of how well each single word is modeled. In our case of company-product modeling, LDA learns both product embeddings and company representations $\mathscr{B}_i$ in the vector space that is the size of the number of latent topics. The main advantage of LDA over RNN and other topic modeling techniques such as Latent Semantic Indexing [13] is that LDA-learned features are easy to interpret. This fact is important for adopting those techniques in marketing environment.

4 MODELING APPROACH

In the current setting, we can model and learn the semantic information about companies in terms of their IT install base, which is based on the fact that similar products and, then, similar companies should be close in the L-dimensional space, where $L < M$. In this case, the recommendations are extracted using the notion of similarity between the companies. Recommendations are based on the similarity calculated given the dataset from HG Data Company. The gaps in possible product offerings are extracted from our internal databases for similar companies. The strength of the recommendation is in this case measured via the strength of the company similarity.

We compare two types of unsupervised models: non-sequential modeling (LDA-based), when products are considered independently ($\mathscr{A}$ company features are used as input), and sequential modeling (LSTM-based), when we take into account the order of product appearance in the HG Data Company database via A^S input. Both modeling techniques capture the hidden structures in the company-product data and produce features (representations) for products and companies. We assess the quality of the following company-product representations:

(1) Naïve representation: binary or Term Frequency-Inverse Document Frequency (TF-IDF) [22] vector of products. In our case, TF-IDF can be also reformulated as product frequency-inverse company frequency.
(2) RNN-based representation: embedding (vector) that shows the position of a company in an L-dimensional vector space. The position depends on the contextual similarity of products of a company.
(3) LDA-based representation: vector of real numbers that shows the probability that a company belongs to an LDA topic.

The modeling methods are evaluated using the measures of goodness of fit of a model, and, additionally, the representations are evaluated for the company clustering task. When the proper representation is chosen, we can find the top-k similar companies based on HG Data Company data. The models are also evaluated for the recommendation task.

4.1 Model adaptation and parameter estimation

We train LDA both on initial binary company-product representations[4] and TF-IDF representations. The type of data representation is considered as one of the parameters for LDA training. Although LDA intrinsically models data to give more weight to the most representative features, we verify whether the model improves if TF-IDF representation is given as an input. Another crucial parameter of LDA modeling is the number of latent topics; this number is chosen using goodness of fit measures.

For RNN, we used various architectures as modeling parameters. More details about LSTM modeling can be found in [19]. We select the parameters of LDA and LSTM by minimizing the perplexity level of a model. The average perplexity per product is calculated on a test set using $\mathscr{A}_i$ or A_i^S company representation, with the total number of products being n. Perplexity[5] shows how well the probability distribution defined by a model (for example, LDA or LSTM) predicts testing data and is calculated as follows:

$$Perplexity = \exp^{-\frac{1}{n}\sum_{i=1}^{n}\ln P(a_i)},$$

where $P(\cdot)$ is the probability distribution induced by a model. The lower the perplexity, the better the model. The best features of a company $\mathscr{B}$ are computed using the models with the lowest perplexity. Instead of the original binary vectors $\mathscr{A}$ or binary sets of products A^S, a company is represented via the vector of latent LDA topics or company embeddings trained on RNN.

[4] Initial binary representation can also be called 'Bag Of Words' (BOW) representation in terms of NLP theory.

[5] We use the terms perplexity and average perplexity per product interchangeably.

4.2 Validation of Company Representations using Clustering

To see how extracted features perform in comparison with initial binary features, or initial TF-IDF features, we assess the quality of learned representations for a clustering task.

As measure of clustering quality, we use silhouette scores[6]. The silhouette score is calculated as the ratio of intraclass and interclass distances. The higher the score, the better the clusters are separated from one another. We choose an appropriate model depending on the silhouette score value for the desired number of clusters. We expect that the model with the highest silhouette scores is also the best according to the perplexity results, as both validation measures favor the most descriptive and representative features.

4.3 Recommendation Capabilities of Generative Models

In addition to the perplexity evaluation, we also check the recommendation capabilities of LDA, LSTMs and n-gram based models. For the marketing recommendation scenario, it is essential to provide an outlook over a relatively long period of time; typically the span of interest r ranges from 6 to 24 months. To evaluate this capability, we assess the model recommender for a sliding window W_r that covers r months. This time window slides with a granularity of two month in order to accumulate significant changes in the install base of a company. At each iteration, the recommender provides a series of observations *i.e.* the probability of a given product appearing within a particular window W_r. In order to access the statistically significant accuracy, we gather the accuracy information for a number of sliding windows. The cardinality of the set of accuracy observations is equal to the number of sliding windows and is denoted as l. All the previous information that happened before the start of a sliding window is used for model training.

To obtain a recommendation for a particular product, we assess the conditional probability of seeing that product appearing given the time series of products that a company acquired so far. The probability is obtained as the output of a model. If for a product p_i the probability of the generative model M, $Pr(p_i|M, p_{i-1}, p_{i-2}, ...)$ exceeds a threshold ϕ we assume that the product p_i should be recommended to a given company. Products $p_{i-1}, p_{i-2}, ...$ represent previous products acquired by that company. As the optimal probability threshold ϕ is not known in advance we treat it as a parameter of the validation of the model recommender. For each ϕ and for each company time series we estimate the average precision and recall measures for the company time series and all the sliding windows l. Recall shows how many of the true products that company buys in the future are retrieved by the recommender. Precision represents the ratio of the retrieved products that are in the true future product set.

5 EXPERIMENTAL EVALUATION

The experiments are done for 860k aggregated companies and 38 product categories[7]. Company aggregation is performed using domestic D-U-N-S® numbers, that is, all company sites in one country are aggregated. Products are consequently aggregated into a set containing all products available in all sites of a company. The companies belong to 83 industries, such as “Health Services”, “Agricultural Services”, etc., which are encoded with the SIC2 codes.[8]

First, we estimate the perplexity of initial company representations $\mathscr{A}$. This is equivalent to the perplexity of the unigram ‘bag of words’ model. The perplexity is equal to 19.5. The perplexities of bi- and tri-gram models are also reported in [19]. Their value is not lower than 15.5, which will be the evaluation baseline.

LSTM. For LSTM, we used A^S company representations, where products are sorted according to the date of their first appearance in a company. LSTM is applicable for sequential data. The sequential nature of our data was checked in work [19], where we demonstrated that 69% of the bigrams and 43% of the trigrams have frequencies that are statistically significantly higher than in the case of independent identically distributed products. This demonstrates that the time dependencies among the products are indeed strong. The hypothesis testing was based on the binomial distribution of frequencies of n-grams.

We used 12 different architectures of LSTM model by varying the number of hidden layers ($N_{layers} = \{1, 2, 3\}$) and the number of nodes in the layers ($N_{nodes} = \{10, 100, 200, 300\}$). We used 70% of the initial corpus for training, 10% for parameter validation and 20% for model testing. We used the LSTM model implementation of the ‘tensorflow’ package [1]. Training was done for 14 epochs over the training data. The resulting perplexity values for each RNN architecture are given in Figure 1.

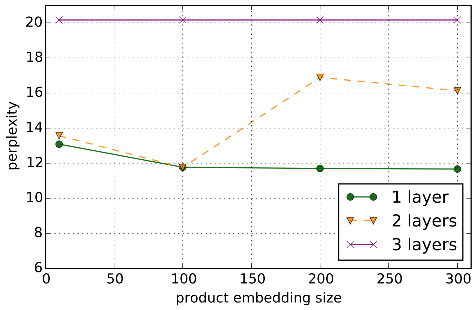

Figure 1: LSTM average perplexity per product for test data.

As can be seen from the results, the lowest (best) perplexity achieved by LSTM model is 11.6 for the test set, which corresponds to 1 hidden layer and 200 nodes per layer. The number of nodes per layer corresponds to the product embedding size. LSTM also learned meaningful representations of IT products, that are illustrated and discussed in [19].

LDA. In the case of LDA, we need to set the number of latent topics. Altough LDA takes into account the representativeness of words (products in our case), we consider both raw binary representations and TF-IDF representations as input for the model. The division of the corpus into training and test datasets is done in the same way as for RNN modeling. The LDA implementation used is from the *gensim* package [23]. The perplexity curves of LDA for both inputs are shown in Figure 2.

[6] For the experiments, we use the silhouette score implementation available in Python programming language (Python Software Foundation, https://www.python.org) package *sklearn*[21]

[7] The full list of product categories is available at: http://www.hgdata.com/Technologies-We-Track.

[8] Standard Industrial Classification (SIC) is a taxonomy established by the US Government to classify industries. The full list of SIC encoded industries is available at: http://siccode.com/.

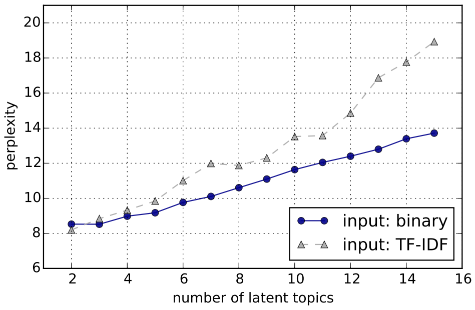

Figure 2: Average perplexity plots measured on test data for LDA models.

It appears that the perplexity of raw binary inputs is better than that of TF-IDF pre-processed input. The leads to the conclusion that LDA indeed is able to assign higher weights to the most representative products and that therefore, no additional pre-processing is needed. Moreover, lower numbers of hidden topics, namely. 2, 3 and 4 lead to lower perplexity values, which vary from 8.5 to 8.9.

The minimum achieved perplexities for each method with the ranking placing the best methods first are shown in Table 1.

Table 1: Minimum perplexities achieved by each method varying the parameter settings.

	Method Name	Min. Perplexity
1	LDA	8.5
2	LSTM	11.6
3	*N*-grams	15.5
4	Unigram 'bag of words'	19.5

Lessons learned. We conclude that, for our company-product data, LDA models perform better than LSTM models. Note that LDA models do not take into account the time component of the company-product space, whereas RNN is built over time ordered sequences of products. We assume that more sequential training data might be needed to build more accurate LSTM models as they have more parameters than LDA models. Indeed, the number of parameters to estimate in LDA models is equal to $n_t + n_t * M$ [3], where n_t is the number of latent topics in the LDA model and M is the vocabulary size of products. In the case of four latent topics, we have 156 parameters to estimate. The number of parameters to estimate for LSTM is dominated by $n_c * (4 * n_c + n_o)$ factor [24], where n_c is the total number of memory cells and n_o is the number of output units. In the case of one the best performing LSTM settings in our deployment with 100, the number of parameters is lower bounded by $100(4 * 100 + 100) = 50000$.

Another hypothesis is that the distribution and properties of hidden structures in company-product data correspond better to LDA modeling assumptions. The fact that LSTM with only one hidden layer fits the data the best out of other LSTM architectures supports this hypothesis.

5.1 Recommendation accuracy

To assess the recommendation accuracy we follow the methodology described in Section 4.3. The time span of the product time series in our deployment range from 1990 till the end of January, 2016. We use a trained model (LDA, LSTM or *n*-gram based) to predict products within a sliding window W_r of 12 month starting from January,1 2013, thus, $r = 12$. The window slides by two month. This way we obtain 13 accuracy observations. The first recommendation window starts on January 1, 2013 and finishes by January 1, 2014 and the last recommendation window starts on January 1, 2015 and finished on January 1, 2016.

The precision and the recall of the LDA3 is compared to the LSTM-based recommender and *n*-gram recommender based on exact Conditional Heavy Hitters [17], that is another data series technique capable of capturing time correlations in the data and predicting future states of the system. The exact Conditional Heavy Hitters are also exact time-dependent association rules. Based on the experiments to validate temporal correlations in product time series described earlier, the depth of the context for Conditional Heavy Hitters (CHH) is chosen to be 2. Thus, we study the dependencies on the previous products up to the second order.

The plot with the average Precision and Recall values, for different values ϕ of conditional probabilities that are used as a recommendation threshold is shown in Figure 3.

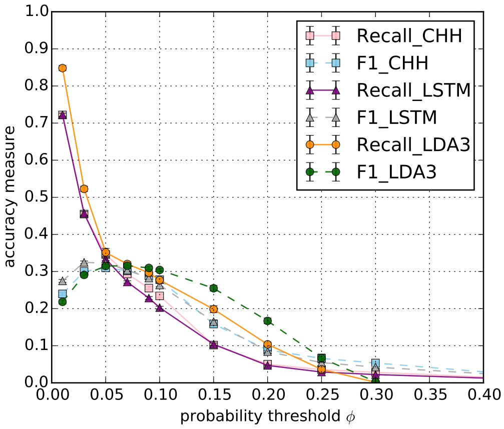

Figure 3: Recall and F1-score with the corresponding confidence intervals for the recommenders based on LDA, LSTMs and Conditional Heavy Hitters (CHHs).

The average numbers of retrieved and correctly retrieved products by each method with the confidence intervals are shown in Figure 4.

We can infer (Figure 4) that ϕ should be smaller or equal to 0.2, as for higher values the numbers of products retrieved by the methods are too low. The accuracy results demonstrate that the recall of a recommender based on LDA model is consistently higher than the recall of LSTM and CHH-based recommenders for the appropriate values of ϕ. The F1-score is also higher for large range of ϕ. For the values of $\phi \geq 0.25$ the recall values are not statistically significantly different as their confidence intervals intersect. Also we note that beyond the probability threshold $\phi = 0.5$ LDA and CHH did not produce any recommendations, thus, precision values are not defined for this points and recall values are equal to zero.

The plots on Figures 3 and 4 demonstrate also that the recall LSTM and CHH is similar as they retrieve similar number of true future products of a company, but CHH-based recommender

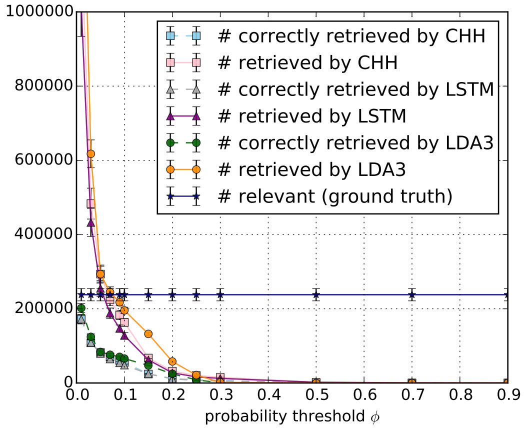

Figure 4: The average number of retrieved, correctly retrieved and relevant products for LDA, LSTM and CHH with the confidence intervals.

tends to produce more false positives, i.e. it recommends more products that should have not been recommended. This causes significant differences in precision.

The task of product recommendations is very hard as it is quite difficult to capture all the underlying processes that influence the choice of future models. This is witnessed by the fact that so far, the best models we tried are only able to reach the values of precision and recall around 0.25 - 0.43 for $\phi \in [0.05, 0.15]$. This means that they are able to capture a true generative model to some extend. The random generator that produced a product recommendation with a uniform probability = $1/38 \approx 0.026$ retrieved all the products for the thresholds ϕ <= 0.026 and on average close to zero of the correct products for higher thresholds. The differences between the accuracy measures for LDA and LSTM, LDA and CHH-based methods are statistically significant for most of ϕ values as the corresponding 95% confidence intervals do not intersect. We have also assessed the accuracies LDA-based recommender with two and four latent topics, their performance has been very similar to the results of LDA with the three latent topics which has been described above. As a future work we will study the influence of the sliding window size on the recommendation accuracy.

5.2 Comparison with Matrix Factorization

We also compared the hidden layer methods with one of the best-performing matrix factorization techniques, Bayesian Probabilistic Matrix Factorization (BPMF), which was introduced in work [25] and implemented in [28]. As the system requires rankings as an input, we use a ranking transformation of the training and test data described in the previous section. This means that if a company has product x, its ranking is equal to 1, otherwise, its ranking is equal to 0.

The BPMF recommendation results that we obtained for the product recommendations in our deployment were similar to the initial results for co-clustering that we reported in Section 3.1. In the majority of the cases, recommendations produced by BPMF for a given company include all possible products. The distribution of the BPMF recommendation scores can be seen in Figure 5. This is due to the fact that BPMF, and matrix factorization methods in general, was developed for sparse and imbalanced datasets. The data in our deployment is relatively dense, and cannot be reasonably approximated by a low-rank matrix, which is the basis of BPMF.

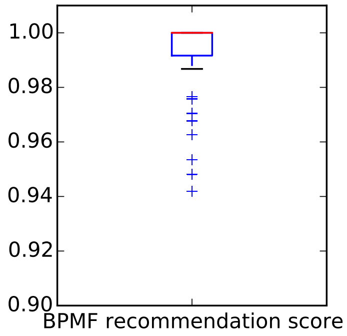

Figure 5: Boxplot of BPMF recommendation score values.

The precision, recall and F1-score values depending on varying BPMF recommendation score values (in the interval [0.9, 1.0]) are shown in Figure 6.

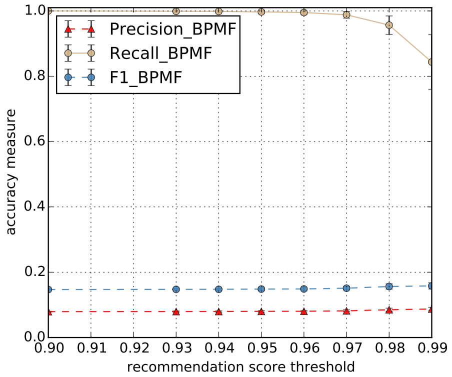

Figure 6: Accuracy values of Bayesian Probabilistic Matrix Factorization method.

All the scores for the thresholds of recommendation score that are lower than 0.94 are the same as for the values 0.91, 0.93 and 0.94. This means that almost for all of the threshold values the full set of available products is recommended regardless the previous products purchased by a company. Thus, BPFM does not produce meaningful recommendation results and does not provide us with effective features for company-product modeling. In contrast, additional feature search for products, as done in LDA and LSTM, leads to high-quality recommendations.

5.3 Company clustering.

As LDA is the best-performing model based on the analysis of perplexity and recommendation accuracy, we will now study the suitability of LDA-learned features for clustering. For this purpose, we build silhouette curves for the features obtained with the best-performing LDA configurations, that is, with the number of topics equal to 2, 3 and 4. We then compare these results with silhouette curves that are built on i) raw binary company-product representations, ii) raw TF-IDF company representations and iii)

LDA representations with TF-IDF input for 2 and 4 hidden topics. The results are shown in Figure 7.

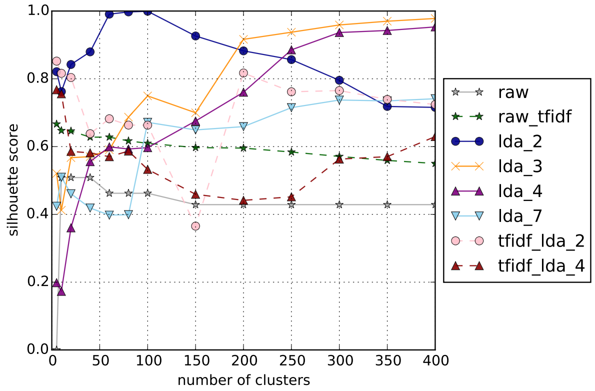

Figure 7: Silhouette curves.

Note that the higher silhouette score, the better the clusters of companies are separated. A higher score means that the distances between companies within one cluster is much lower than the distances between companies in different clusters. In Figure 7, we can see that the initial binary representations of companies are not very discriminative (blue line with stars) as the silhouette score is the lowest for almost all number of clusters. Clustering on the initial representation with TF-IDF transformation performs better then clustering on the initial binary representation, as the silhouette curve is higher and around 0.6 for a varying number of clusters. Clustering on LDA-generated representations with TF-IDF input (tfidf_lda_2 and tfidf_lda_4) performs better than clustering on raw TF-IDF, especially, when two latent topics are used. Company representation associated with the best silhouette curves are generated by LDA with raw binary inputs for the number of latent topics equal to 2, 3 and 4. This result is in accordance with the perplexity outcomes. This means that LDA with these numbers of latent topics represents the install base of the companies the best.

We notice that silhouette scores for lower numbers of clusters from 5 to 200 are higher for LDA representations with lower numbers of topics, i.e., 2 topics, whereas higher numbers of topics (3 or 4) discriminate larger numbers of clusters better.

The t-SNE [26] 2D projections for the product embeddings based on LDA3 and LDA4 are shown in Figures 8, 9. The original names of the product categories are shortened for better visualization, e.g., 'SW' and 'OS' stand for software and operating systems.

It appears that the main products that construct a topic produce clusters of products. It is also interesting to see that most of the hardware products are close to each other for both the LDA3 and the LDA4 representation. These are 'server_HW', 'storage_HW', 'HW_other'. Similarly, software products tend to appear together, for example, 'commerce', 'media', 'collaboration' 'product_lifecycle', 'electronics PCs SW' and 'retail'. Thus also the semantic proximity of the products is captured by LDA models.

Lessons learned. The good quality of company clusters and the meaningful representation of products discussed above mean that the LDA method is able to automatically infer representative features both for companies and products in our deployment.

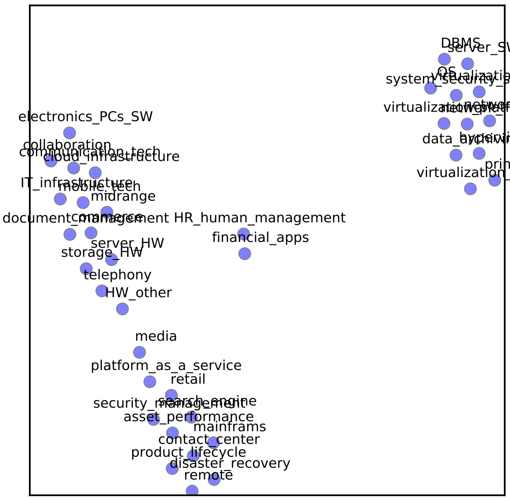

Figure 8: LDA3 product embeddings.

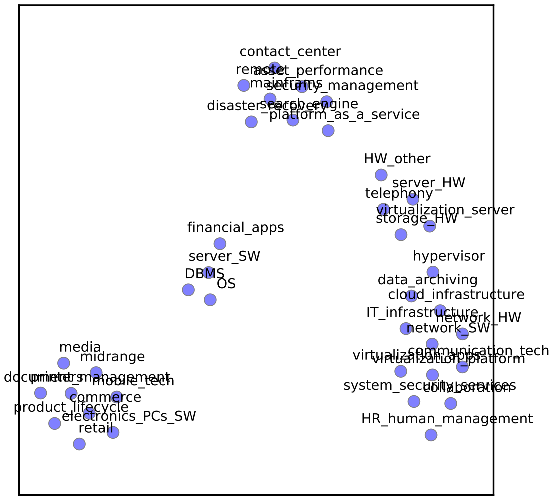

Figure 9: LDA4 product embeddings.

6 SALES APPLICATION

We have deployed LDA-based company representations in our recommendation tool. The company similarity search is based on LDA company representations with the HG Data Company dataset as input. Recommendations are built using our internal datasets. The tool searches for top-*k* similar companies that are calculated using their LDA representations based on HG input. As LDA training is not done in a streaming fashion, it is done offline and can be retrained on demand or when the concept shift is taken place. In addition to the global similarity search, the tool also provides the user with filtering capabilities based on industry, location, number of employees and revenue.

This tool is currently used for an internal recommendation system.

7 CONCLUSION AND DISCUSSIONS

In this work, we assessed several data modeling techniques for product-company modeling, company similarity matching and recommendation. Companies have been considered to be similar based on the closeness of the structure of their IT install base. Assuming intrinsic hierarchies between products, companies and possibly latent install base structures, we have compared several techniques from the NLP domain capable of learning this kind of hidden hierarchical structures. These are unsupervised modeling techniques, namely, Latent Dirichlet Allocation and Recurrent Neural Networks. Having evaluated different model architectures, we demonstrated that LDA with 2, 3 and 4 latent topics fits our data best. We applied the company features learned by LDA to determine the top-k similar companies, assessed the recommendation capabilities of the methods and deployed the best performers in a recommendation tool.

The results show that though there is clear sequential nature in the data, still the techniques that does not take time into account perform the best. The reason of this may be due to the higher number of parameters to learn in sequential techniques and the fact that our corpus is not enough to train all the parameters.

As future work, we will gather additional internal data about the IT structure of companies with proper timestamps and assess other deep neural network architectures starting from lower levels of product descriptions. We believe that, because of their hierarchical nature, deep neural networks should be able to discover hidden structures in IT install bases of companies if sufficient training data is provided.

8 ACKNOWLEDGMENTS

We would like to thank Viktor Kuropiatnyk for helping us make sense of D-U-N-S® data; Michel Speiser and Daniel Bauer for their algorithm of company name matching, which we used for record linkage. Katsiaryna Mirylenka also thanks Daniil Mirylenka for the fruitful discussions during the idea crystallization process.

ABSTRACT

Point of Interest (POI) data constitutes the cornerstone in many modern applications. From navigation to social networks, tourism, and logistics, we use POI data to search, communicate, decide and plan our actions. POIs are semantically diverse and spatio-temporally evolving entities, having geographical, temporal, and thematic relations. Currently, integrating POI datasets to increase their coverage, timeliness, accuracy and value is a resource-intensive and mostly manual process, with no specialized software available to address the specific challenges of this task. In this paper, we present an integrated toolkit for transforming, linking, fusing and enriching POI data, and extracting additional value from them. In particular, we demonstrate how Linked Data technologies can address the limitations, gaps and challenges of the current landscape in Big POI data integration. We have built a prototype application that enables users to define, manage and execute scalable POI data integration workflows built on top of state-of-the-art software for geospatial Linked Data. This application abstracts and hides away the underlying complexity, automates quality-assured integration, scales efficiently for world-scale integration tasks, and lowers the entry barrier for end-users. Validated against real-world POI datasets in several application domains, our system has shown great potential to address the requirements and needs of cross-sector, cross-border and cross-lingual integration of Big POI data.

1 INTRODUCTION

Our daily lives evolve around locations. From navigation applications, to social networks, tourism, and logistics, we use information about locations to search, communicate, decide, and plan our actions. Selecting a location for a given activity has a varying complexity and significance, ranging from simple, everyday routines (e.g., where to have dinner), to more complex planning (e.g., where to open a shop), and to life-changing decisions (e.g., where to live, work or invest). Locations that exhibit a certain interest or serve a given purpose are commonly referred to as *Points of Interest* (POIs), covering anything from shops, restaurants or museums to ATMs or bus stops. POIs are complex entities that are characterized by their *geospatial shape* (points, lines, polygons) along with various *thematic attributes* indicating their name, type, functionality, services, etc., as well as their *relations* to each other (e.g., containment, part-of) with respect to spatial, temporal, and thematic contexts.

Creation, update, and provision of POI datasets is a multi-billion, cross-domain, and cross-border industry. Advances in the timely and accurate provision of POIs result into significant direct and indirect gains throughout our Digital Economy[1]. The value and impact of POIs is reflected in the complex, expensive and labor-intensive effort required for their production and maintenance, which inherently involves stakeholders and users throughout their value chain. Initial production involves field-work, constant monitoring for their evolution and accuracy, integration of user-feedback mechanisms for reporting errors, quality assurance of new data, and roll-out across a plethora of services and products. The greater the *size*, *timeliness*, *richness*, and *accuracy* of POI data, the better the product's *value*. Inversely, incomplete or inaccurate information has a profound effect on all types of end-users and applications.

The *value chain* of POI data has rapidly changed in the last few years. The advent of *open* data, *crowdsourcing*, and *social media* provides new data sources of even greater volume, heterogeneity, diversity, veracity, and timeliness. Such Big POI Data assets are harnessed by both startups and established commercial vendors alike to enrich their products, while also giving rise to new business models founded on domain-specific collection and provision of POIs (e.g., Foursquare[2], Yelp[3]). Enrichment, curation, and update of POI data is increasingly becoming collaborative, with stakeholders and end-users actively involved in all steps of the value chain. This intensifies the challenges relating to their quality-assured integration, enhancement, and sharing.

POI data is by nature *semantically diverse* and *spatiotemporally evolving*, representing different entities and associations depending on their geographical, temporal, and thematic context. Due to its use in various domains and contexts, POI information is typically fragmented across diverse, heterogeneous sources. These are common issues in Big Data integration [7], but combining and assembling POI information is further hindered in practice by the lack of common identifiers and data sharing formats. Even the way we typically identify and share information about POIs is inherently *ambiguous*. Addresses, coordinates, and place names are equally used throughout applications as pseudo-identifiers; but practice shows that they fail to effectively disambiguate POIs. Integrating POI data using current approaches remains labor-intensive and does not scale, thus limiting data coverage. The industry makes typically two compromises to reduce the complexity to feasible levels: focus on a specific domain (e.g. fuel stations), and/or restrict the spatial-, temporal-, and feature-space of data. In both cases, this leads to loss of information and thus lost value.

To tackle these challenges of Big POI data integration in the context of the SLIPO project[4], we transfer knowledge and apply state-of-the-art techniques and tools from the domains of Linked Data, Big Data and GIS. We argue that *Linked Data* technologies [2] are ideally suited to handle the inherent geospatial, thematic, and semantic ambiguities of POIs, without resorting to general-purpose entity matching platforms [16]. Recent advances in spatially-aware Linked Data technologies[5] address the scalability challenges of integrating, enriching, and querying semantically diverse geospatial Big Data assets and can effectively maximize the value extracted from open, crowdsourced and proprietary data sources.

The scope and ambition of our work in terms of complexity and coverage is inherently defined by current practices and needs in the industry. Indicatively, HERE Places API[6] offers information about 55 million POIs with names and categories in 237 countries; Google Places API[7] advertises over 150 million POIs globally; from OpenStreetMap, we have extracted more than 18.5 million POIs regarding specific categories[8]. Hence, we are targeting data integration concerning millions of POIs. We provide a complete suite of integrated software and services for POI data integration, supporting all stages of the POI data lifecycle (transformation, linking, fusion, enrichment). Our prototype application employs mature, scalable, open-source software specialized in geospatial linked data integration. We have tested its operation against several use cases for POIs in different application domains (geomarketing, tourism, navigation) with very encouraging results concerning execution cost and accuracy. Our experience shows that stakeholders can orchestrate those tools in coordinated, iterative *workflows* to progressively increase both the size and the quality of the integrated POI data.

The remainder of this paper is organized as follows. Section 2 presents the main challenges concerning Big POI data integration. Section 3 outlines the POI data integration lifecycle applied in SLIPO. Section 4 describes the SLIPO data model for representing information about POIs throughout the executed workflows. In Section 5, we explain the specific processes involved in the POI data integration process. Section 6 outlines the provided functionalities for extracting value-added analytics from the integrated POI datasets. Section 7 presents the current status of our prototype application. In Section 8, we report our experience from POI data integration scenarios in two real-world use cases. Finally, Section 9 summarizes the paper and discusses future work.

2 CHALLENGES IN POI DATA INTEGRATION

POIs are complex entities, described and associated with multifaceted and multi-modal information. They also exhibit complex (spatial, temporal, thematic) relationships, and they often have a long and complex lifespan. Any effective and systematic approach towards POI data integration needs to rely on robust, flexible and semantically-rich modeling of POI profiles and handling of POI identifiers, especially for applications dealing with cross-sector, cross-border, and cross-lingual content.

Consider a simple example regarding an imaginary POI. Suppose that the "Acropole Palace Hotel" was registered in 2015 at the local *Yellow Pages* directory and was assigned an identifier, along with some basic information (name, address, telephone, fax), as illustrated at the upper side in Figure 1. Later on, its address was geocoded and the resulting location coordinates were also included in the record to be used in a mobile city guide. At some point in time, this hotel was acquired by another company, which renovated and rebranded it to "Xenia Hotel", and also opened a restaurant at the roofgarden. This hotel is since listed in a *hotel reservation application* under a new identifier and with updated, multi-lingual information, which also features its current offers and services, as well as customer ratings (shown at the bottom side of Figure 1). Such changes need to be detected and included in the mobile city guide application, by matching and integrating new POI representations with old ones to avoid duplicates and to update obsolete information. In this example, such a matching (denoted with an `owl:sameAs` link) can be based on the phone number and the address of this POI (properties marked with red color in Figure 1). The challenge arises from the inherent *heterogeneity* in POI data characteristics. As shown in this example, this involves diverse attribute schemata, varying formats in values (e.g., in phone numbers) or different representations of the same information (e.g., address represented in a structured or unstructured format), which need to be resolved to determine whether these two records actually refer to the same POI.

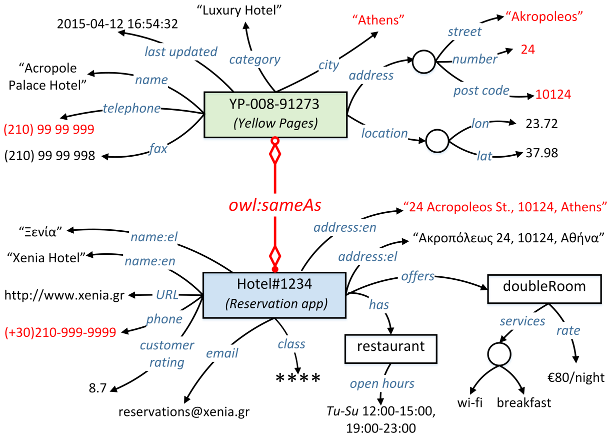

Figure 1: Matching different representations of the same POI coming from two data sources.

This example is only indicative of how different companies in different sectors and application domains collect, use, and extend information about the same POI. It also points out the importance of *volatile* data in the POI profile, e.g., its facilities, prices, events, etc. Moreover, it brings up several cases of *ambiguity* that arise and lead to data integration challenges that stakeholders have to face throughout this process. Next, we outline these challenging issues in POI data integration:

- *Lack of standardization.* Even though POI data is ubiquitous, there are no de jure standards yet for POI models, formats and identifiers. This is due to licensing and commercial competition, different hardware and software characteristics, and diverse requirements among mobile and web applications. Thus, POI datasets provided by different vendors are often not compatible with each other and require excessive effort and domain knowledge to be integrated and reused. At the most basic level, there are no (globally) *unique identifiers* assigned to POIs, making it difficult to identify duplicates among datasets and to link together different pieces of information for the same POI.

[4] Acronym for **S***calable* **L***inking and* **I***ntegration of big* **PO***I data*, http://slipo.eu/

[6] https://developer.here.com/products/geocoding-and-search
[7] https://cloud.google.com/maps-platform/places/
[8] http://slipo.eu/?p=1397

- *Inherent ambiguity of POIs.* POIs are entities having a twofold nature, *geospatial* and *semantic*; moreover, their characteristics and associated information *evolves over time*. This results in multiple sources of ambiguity when dealing with POI data. In the spatial dimension, coordinates given for the same POI in different sources typically differ, while the spatial extent of a POI is often ignored, and its location is abstracted and approximated by a single point. Even if the shape is retained, it may have varying levels of accuracy. Hence, when encountering multiple POIs in different sources with slightly different coordinates or shapes, it is challenging to determine whether these refer to the same or different real-world entities. Similar issues arise when using POI names. The same POI may appear with slight naming variations in different sources, while different POIs may in fact have the same or similar names. Furthermore, different sources employ different classification or tagging schemes to categorize POIs and describe their type. This ambiguity is amplified when the temporal dimension is introduced, e.g., for determining whether two different representations refer to the same POI that evolved over time (as in Figure 1) or to two distinct POIs.
- *Long update cycles.* Due to the effort needed for maintaining and curating POI datasets, the contained information often remains relatively static. Further, it typically focuses on certain, mostly factual aspects of a POI, such as its title and a set of categories or tags. When and how this information is updated depends on the way it is collected and the available resources. Hence, for most providers, POI data is updated in yearly cycles. Moreover, if and when it is refreshed, typically the dataset will just be updated to the latest version, as it is not straightforward to apply a systematic and principled approach for recording and representing the *evolution* that has occurred, or more generally to track and record events that are related to that entity. Hence, even though such information may actually exist, there is often no historical profile of a POI that evolves over time and keeps track of associated events.
- *Fragmented POI profiles.* Based on how and for what purpose a POI dataset has been created, its contents typically cover only certain aspects of the POIs. For example, a navigation service and a city guide may have different priorities when deciding which POIs to include and what kind of information about them to collect. Although a wealth of information may exist for a POI, different parts and pieces may be found in different (types of) sources. Still, more complete POI profiles would allow more sophisticated and accurate analyses.
- *POIs treated independently and out of context.* POI datasets are typically treated as collections of individual entities. Each POI is modeled, stored and analyzed independently, without considering or establishing connections and links to other POIs. The reason is that *relationships* between POIs are more difficult to model, represent and analyze. However, this significantly limits the type of analyses that can be carried out over sets of POIs and creates gaps with the actual needs of users.

In SLIPO, our approach places particular emphasis on these issues related to POI models, identifiers, and resolving the aforementioned cases of ambiguity, as explained next.

3 THE POI DATA INTEGRATION LIFECYCLE

In this Section, we provide an overview of the POI data integration lifecycle supported in SLIPO. The underlying idea of our proposed system is to address the POI data integration challenges in the Linked Data domain [2]. Thanks to a simple, standardized, yet flexible model (*Resource Description Framework*[9]), Linked Data technologies can handle the inherent geospatial, thematic, and semantic ambiguities of POIs. Existing POI data assets need first to be transformed into RDF, so that individual POI profiles can be interlinked, fused, and enriched. This takes place in successive steps that progressively increase the size and/or the quality of POI data throughout a virtuous cycle, implementing an iterative workflow (Figure 2). Next, we outline the purpose of each stage, the processes that take place, and their output.

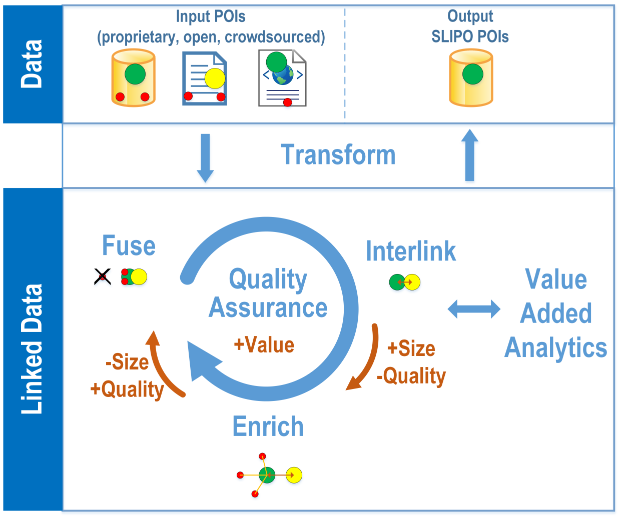

Figure 2: The POI data integration lifecycle.

The lifecycle begins with a *transformation* stage. This assumes as input POI data collected from heterogeneous and diverse data sources (proprietary, open, crowdsourced), having different attribute schemata and formats. The spatial, temporal, and thematic attributes in the input data are transformed into RDF triples conforming to a common, vendor-agnostic, well-defined, yet agile and extendable *POI ontology*. Hence, schema mappings from attributes of the original schemata to the classes and properties of this ontology are applied. After transformation, the resulting RDF triples can be stored in files or in an RDF store.

Subsequent stages are applied in the Linked Data domain against the previously transformed RDF data comprising an iterative, step-wise *workflow* that first increases the *size*, and then the *quality* of POIs. This forms a *virtuous cycle* that begins by expanding POI coverage, completeness, and richness, delivering data of greater size. Then, it focuses on increasing the quality of the POI data, fusing these intermediate results and enforcing appropriate quality assurance algorithms. This inherently reduces the size of data in absolute numbers, but increases their value. This process can be repeated in the same manner, iteratively increasing the size and then refining to increase quality, as many times as required. For example, an expert user can introduce additional data sources, apply different rules, focus on other types of metadata, etc. Such an iterative workflow involves the following stages:

- *Interlinking.* This is applied among transformed RDF datasets to link together individual RDF representations of the same real-world POI. It exploits structural properties, textual similarities, spatial proximity, etc., based on various user-specified

[9] https://www.w3.org/RDF/

metrics and thresholds. This deduplication process creates owl:sameAs links between matching POI entities, thus tackling the lack of common identifiers between POI entities across data sources, and enabling their management at later stages of the integration process.

- *Enrichment.* This step identifies and retrieves additional information from external sources that relates to the processed POIs, and creates extra properties for these POIs, increasing the richness and completeness of the data. It also discovers semantic relations between POI entities and other resources (e.g. areas, events, time), such as partOf relations (e.g., a school yard is part of a school etc.) or occursAt relations (e.g., events at a certain venue). Essentially, this phase enhances and contextualizes POI profiles with information extracted and assembled from other relevant sources, leading to a multi-faceted and more comprehensive view of POIs. For instance, it can enrich a POI profile with extra information concerning opening hours, price ranges, event timelines, etc.
- *Fusion.* This stage consolidates linked POIs and their properties. From two linked POI entities, it produces a unified and consolidated representation that is more complete, concise and accurate than the individual initial linked entities. For matching properties (e.g., similar names, nearby geometries) between a pair of linked entities, potentially different fusion actions can be applied. Fusion actions may include selection of properties from one of the entities, merging of properties from both entities, selection of those properties that satisfy a specific criterion (e.g., more complex, more timely), etc. Eventually, this leads to significant increase in completeness, coverage, timeliness and quality of POI data.
- *Value Added Analytics.* The POI data lifecycle includes an additional step, offering large-scale aggregation analytics in various dimensions, clustering, association rule mining, and predictive analytics. We can perform large-scale spatial, temporal, and thematic aggregation or extract *associations* between POIs and other entities. Results can be modelled as integrated sets or sequences of POIs. For instance, such a set can represent a thematic area of interest not explicitly defined in the original data, but implicitly discovered; this encapsulates a set of POIs that are spatially co-located and related thematically for direct exploitation in several use cases (e.g., geomarketing).

Quality assurance is performed throughout all steps of the lifecycle and ensures that each phase produces correct and accurate results, taking into account dataset-specific and use-case-specific quality indicators and rules, including also manual validation and authoring. Several indicators can be used, most of them already adopted by industrial vendors that manage and exploit POIs: size, timeliness, coverage, accuracy, etc.

Eventually, at the end of the POI data integration lifecycle, another transformation is also required. This involves the *reverse transformation* of the integrated POI data back to conventional formats (i.e., de facto POI formats), enabling their use in existing products, systems and services.

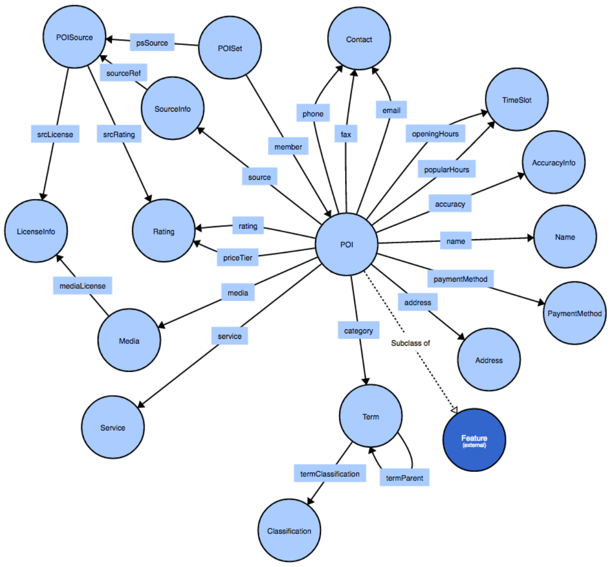

Figure 3: Main classes and properties in the POI ontology.

4 POI DATA MODEL

We have developed a comprehensive ontology for POI data to model and represent multi-faceted and enriched POI profiles and thus leverage Linked Data techniques and tools for POI data integration. This model accommodates and extends existing POI formats, providing a uniform and semantically rich model for assembling and managing POI data from heterogeneous sources, since a widely accepted, de facto model is missing. To design this ontology, we have taken into consideration POI data representations employed by several well-known and widely used POI data sources. These included both open data sources, like OpenStreetMap and Wikimapia[10], as well as proprietary data schemata like Foursquare or Google Places. We also studied the structure of POI data assets based on samples obtained by commercial vendors in several countries (Austria, Germany, Greece). Finally, we investigated other efforts, especially an ongoing work on POI modelling by W3C and OGC Working Groups[11], as well as models for representing places proposed by collaborative projects[12].

The main challenge in POI data modelling arises from the high degree of heterogeneity across sources, given that these have different scope, goals and purposes. Thus, they model POIs from different perspectives and with varying levels of detail. Among the main issues we addressed with our POI data model are:

- *Names*: Accommodate the presence of different types of names (e.g., official vs. commonly used ones), alternate or historical names, acronyms, multi-lingual names, etc., as well as phonetic transcriptions or transliterations useful for internationalized POI information.
- *Addresses*: Represent addresses both in structured formats (separate components for country, city, street, house number, etc.) and flat formats (concatenated strings), with potentially missing information in either case.
- *Geometry*: Allow both for point geometries (longitude and latitude coordinates) and more complex geometries (lines, polygons), potentially in different coordinate reference systems.
- *Classification*: Support both hierarchical categorizations (i.e., categories, subcategories, etc.) and free tags.
- *Source* of POI data (e.g., a commercial vendor) may be specified using its title, homepage, description, license, logo, etc.
- *Media*: Support for auxiliary assets such as photos, videos or audio associated with a POI.

[10] http://wikimapia.org/api/
[11] http://www.opengeospatial.org/projects/groups/poiswg
[12] https://schema.org/Place

- *Contact information*: Include various elements, such as phone, email, fax, Web page, social media accounts, etc., with different structures and formats.
- *Amenities*: Include extra information on a variety of attributes such as offered services, opening and/or popular hours, ratings, payment methods, etc.

Figure 3 illustrates a graph with the main classes and object properties of our OWL ontology[13] as used internally in the POI data integration lifecycle. POI is the main class for representing POI features and is modelled as subclass of a spatial Feature in GeoSPARQL [24], thus directly inheriting properties regarding geospatial location. It supports multiple geometric representations, and the type of each geometry (e.g., centroid, navigation point, map pin, boundary) may be specified as well. Extra attributes for specialized use cases not covered by the ontology can be represented in the form of key/value pairs.

Overall, this ontology adheres to well-established standards (RDF, GeoSPARQL) and is geared towards processing efficiency. In addition, it can be extended and enhanced with domain-specific POI profiles, which include additional properties and relationships. We are currently working on modelling the provenance of POIs and their metadata, their evolution across time leading to different versions, as well as changes occurring to their contents and representation (e.g., extra attributes).

5 POI DATA INTEGRATION STEPS

SLIPO offers a complete and integrated suite of software tools that support all steps of the POI data integration lifecycle. All tools are available as open source software and are the state of the art in geospatial linked data integration. Specifically, the suite includes: (a) TripleGeo, for POI data and metadata *transformation* into RDF; (b) Limes, for *interlinking* of POIs; (c) Fagi, for the *fusion* of linked POI data into unified, concise and complete descriptions; and (d) Deer, for *enrichment* of POIs with implicit metadata, third party datasets and thematic, temporal and spatial metadata. Next, we describe them in more detail.

5.1 Transformation

Transformation is the entry point for POI datasets, converting them from their original format to RDF, thus enabling their subsequent processing in the Linked Data domain. We have extended our open-source *Extract-Transform-Load* (ETL) software TripleGeo [25] to enable scalable and efficient transformation of POI datasets from a variety of de facto geospatial formats into RDF triples. In TripleGeo[14], we employ adaptable, configurable, and reusable mappings from existing attribute schemata into our POI ontology (Section 4). We also support classification hierarchies for assigning categories to POIs. Moreover, TripleGeo can handle all common geometry data types and established coordinate reference systems. Its main features include:

- *Native support for a multitude of geospatial data formats.* Currently, TripleGeo supports 9 common file formats (e.g., ESRI shapefiles, GML, KML, CSV, JSON), and JDBC-based access to 8 geospatially-enabled DBMSs (e.g., Oracle Spatial, PostGIS).
- *Improved geospatial support* not only of primitive geometry types (points, linestrings, polygons), but also more complex geometries (MultiPolygons, Geometry Collections), as well as on-the-fly reprojection to another coordinate reference system.
- *User-defined mappings* specify rules that dictate how to generate RDF triples from original thematic attributes in the input POI data according to a given ontology. Such mappings allow transformation of all available attributes per POI entity and can be specified in the generic RDF Mapping Language RML [5, 6]. We also provide an alternative, simplified mapping facility specifically tailored to our ontology, offering much faster transformation even for very large volumes of POI data.
- *Classification schemes.* POI data providers employ diverse classification or tagging schemes to categorize POIs and describe their type. TripleGeo accepts specification of (possibly hierarchical) classification schemes for POIs, produces RDF triples that fully describe this information along with especially assigned URIs, and introduces extra links between a POI and its respective category under this scheme.
- *Customized URIs.* We construct HTTP Universal Resource Identifiers for POIs based on automatically generated Universally Unique Identifiers (UUIDs). This follows recommended patterns and best practices for creating persistent, unique, vendor and technology independent URIs. Thus, POI data owners have enough flexibility and control over creating and managing their own POI identifiers, while still adhering to a uniform format.
- *Reverse transformation* from RDF to all common geographical file formats. POI data that have been interlinked, fused, and enriched in previous executions of the POI data integration lifecycle can become accessible and exploitable by existing software (e.g., DBMS, GIS) or services (e.g., web mapping, route planning) commonly utilized in the industry.
- *Comprehensive configuration.* Users can control various parameters of the transformation process at different levels of complexity based on their technical background and expertise.
- *Compliance to standards.* The produced RDF geometries are fully compliant with the OGC GeoSPARQL standard for RDF spatial entities [24]. Transformation of INSPIRE-aligned data and metadata [10] is also supported [26], thus abiding by the EU Directive for interoperable Spatial Data Infrastructures.
- *Scalability.* Our experiments with various data sources show that TripleGeo is currently orders of magnitude faster compared to its original release [25], as well as faster than GeoTriples [17]. It can efficiently transform millions of POIs even without any sophisticated data partitioning schemes. Indicatively, it can transform all 7.4 million POIs extracted from OpenStreetMap for Europe into RDF triples in less than 3 minutes, effectively generating more than 715,000 triples/sec.

Using TripleGeo, we have launched a free download service[15] that offers global POI data extracted from OpenStreetMap and transformed into RDF format, retaining all original tags and also creating resolvable, machine-readable URIs per POI.

We are currently working on extending TripleGeo towards *semi-automatic workflows* to assist and guide users in creating attribute mappings for new datasets. We have built a utility that employs Machine Learning to learn new mappings from a corpus of previously specified ones, available from the various use cases of POI datasets we have handled so far. This utility also analyzes the contents of each attribute in a new POI dataset, based on its data type (string, numeric, etc.), formatting (e.g., phone numbers, postal codes), as well as the presence of special characters. Users can then verify or modify the automatically suggested mappings through a graphical interface before applying them for transforming their POI data into RDF.

5.2 Interlinking

The aim of interlinking POI datasets is to develop scalable approaches for integrating massive heterogeneous, and incomplete POI data at a world-scale. Limes[16] is integrated in SLIPO and incorporates many algorithms for performing efficient interlinking among POI resources. In the context of SLIPO, Limes receives as input two RDF POI datasets conforming to the SLIPO ontology. Thus, Limes's input POI data are first transformed by TripleGeo, into the proper RDF format and schema. Further, apart from the two input POI datasets, Limes requires as input a configuration file containing the Limes configuration parameters. Limes's output consists in a single file, which contains the links between corresponding POI entities from both input POI datasets. The output of Limes is essential for running other SLIPO tools in a POI data integration cycle (Figure 2).

Limes v1.0.0 is the first version of Limes that has been developed in the context of the SLIPO project and focuses on POI-specific interlinking. One of the major goals was to abstract as much complexity as possible from the end users. So, in order to keep user interaction at a minimum and requiring no knowledge of Linked Data technologies and concepts, we aimed at adapting and fine-tuning Limes's functionality specifically for POI data, as well as at automating the interlinking process as much as possible. To this end, we emphasized on the development of the backend of the platform, aiming to enrich and specialize the core interlinking functionality of the framework. Next, we outline the new features and functionality of Limes:

- *POI-specific point-set distances.* New point-set distances based on the vector representations of the POI resources (e.g. *Hausdorff, mean, surjection* and *sumOfMin*). Altogether, we implemented a set of 10 point-set distance functions based on our survey published on [30].
- *Topological relation discovery* based on the vector representations of the POI resources (e.g. a POI resource contains, crosses or touches another POI resource). For instance, find all parking locations within shopping malls. Therefore, we develop Radon [8, 29], an efficient algorithm for rapid discovery of topological relations among POI resources with 2D geometries.
- *Temporal relation discovery* based on timestamps associated with the POI resources (e.g., one POI takes place after, before or during another POI). For example, a specific area is used as a parking location only during a football match. To tackle this problem, we proposed Aegle [13], a novel approach for efficient computation of links between POIs' temporal representations according to *Allen*'s interval algebra.
- *Combining the new techniques with the ones already in Limes.* In Limes v.1.0.0 we integrated the novel algorithms for the 10 POI-point-set distances as well as Radon and Aegle into the Limes core. In particular, a new mapper is implemented for each of the new relation types. Such mappers are combined with the already existing mappers for efficient link discovery of the new types of relation specific for POI resources.
- *Novel machine learning approaches for POI interlinking.* In most cases, finding a good metric expression[17] (i.e. one that achieves high F-Measure in interlinking POI entities) is not a trivial task. Therefore, in Limes we implemented Wombat, a novel machine learning approach for auto-generation of mappings among POI resources. Wombat is inspired by the concept of generalisation in quasi-ordered spaces [28]. Wombat minimizes the Limes configuration task by providing unsupervised, supervised and active learning versions.
- *Integration with the SLIPO Workbench.* Limes v.1.0.0 realizes two deployment modes: (a) standalone, as an individual software that accepts as input linked POI datasets and provides as output a mapping file containing the links between the input POI datasets; (b) deployment within the SLIPO Workbench, where Limes serves as an integral component of the SLIPO Toolkit and is loosely integrated by the SLIPO Workbench with the other software components into forming POI integration workflows.
- *Scalability.* In addition to the original Limes parallelization algorithm [31] and optimized planners [12, 22], in Limes v1.0.0 we evaluated the scalability of our novel POI-specific approaches. Our evaluation proves that Radon [8, 29] is able to outperform state-of-the-art approaches up to 3 orders of magnitude while maintaining a precision and a recall of one. Also, our evaluations of the runtime of Aegle [13] show that Aegle outperforms the state of the art by up to 4 orders of magnitude while maintaining a precision and a recall of one. Recently, we have implemented a simple, yet efficient in our setting, distributed execution scheme, which functions independently of core interlinking in Limes. Specifically, we have two implementations based on Spark and Flink frameworks. Currently, we run an intensive evaluation for both frameworks to find the pros and cons of each. Finally, we studied the effect of geometry simplification on the scalability of POI interlinking [1]. We found that a suitable simplification setting can reduce interlinking cost with a minimum effect on quality.

5.3 Fusion

The fusion process in SLIPO follows the interlinking of different representations of the same POI across data sources. Fusion addresses the problem of assembling partial and incomplete POI profiles as well as resolving conflicting information in order to derive a more complete, consolidated profile per POI.

Fusion receives as input two POI datasets as well as a set of links between them. The output is a third merged dataset, which contains consolidated descriptions of the linked POIs. Each POI in the fused dataset is described by a set of richer, non-redundant, non-conflicting and complete properties, which have been derived by merging the initial descriptions of the linked POIs. The main challenge in this task is to efficiently apply the most appropriate fusion action in such way that the best elements of individual datasets are kept in the final composite dataset.

To support scalable and quality assured fusion of large POI datasets, we have extended our fusion framework Fagi [14]. Initially, Fagi was a map-based, user-interactive platform for manually performing property matching and fusion actions on individual properties of linked geospatial entities. In SLIPO, we adapted Fagi[18] to effectively handle the fusion of POI data, while we also minimized manual user effort. Specifically, the current version offers the following main features:

- *Advanced fusion facilities for POIs.* Fagi supports the graphical authoring of POI fusion specifications. These sets of rules examine the individual properties of pairs of linked POIs and decide, for each property, the most fitting fusion action. Fagi currently incorporates 25 *condition functions* for examining the properties of linked POIs, including string similarity, geometry comparison, etc. Further, it implements 15 *fusion actions*

[16] https://github.com/dice-group/LIMES

[17] A metric expression is a logical expression that describes when two resources should be linked.

[18] https://github.com/SLIPO-EU/FAGI

(regarding both thematic and geospatial properties) for deciding how to merge the values of matching properties. Fusion actions include: aligning geometries, maintaining the most complex value, maintaining both values for the same property, etc. Finally, combining several condition functions can be used to construct more elaborate fusion rules, while fusion results can also be marked as *ambiguous* for later inspection by the end user.
- *Link validation functionality.* An important aspect of quality assurance lies in validating the fusion input and deciding whether the linked entities should be either fused, further examined, or rejected as erroneous. To this end, in Fagi we define a set of validation actions, as well as a validation rule specification scheme. Similarly to POI fusion specifications, the user can define elaborate link validation specifications that jointly examine several properties of pairs of linked POIs in order to maintain or reject the specific linked POIs.
- *Quality indicators extraction.* Further emphasizing on quality assurance, Fagi supports the extraction of more than 25 quality indicators. The user is able to review several statistics on the input linked POI datasets before performing fusion on them (*pre-fusion statistics*), as well as on the output fused data (*post-fusion statistics*). The former provide an overview of the data at hand, which assists the integrator to properly define and configure the validation/fusion rules. The latter assist the user in the inspection of the fusion results, and potentially guide her into re-configuring and re-executing the fusion process.
- *Recommendation of link validation and fusion actions.* Fagi implements learning mechanisms for training on past user actions and recommending link validation and fusion actions for new POIs. It learns binary (for link validation) and multi-class (for fusion actions) classifiers on a series of extracted training features regarding the properties of the linked POIs. Then, it recommends actions for new pairs of linked POIs.

The aforementioned functionality of Fagi satisfies commercial-level data fusion needs. In a typical fusion scenario, the user can define configurable and re-usable fusion rule specifications of varying complexity, which collect names from different datasets in multiple languages or types (such as official, international, brand-names etc.) and complete other attributes, such as address information, websites, phone numbers, emails, ratings, reviews, opening hours, image links, etc. The resulting fused dataset then contains POIs with the most complete and accurate descriptions, as well as more precise and/or more complex geometries. Additionally, the user is able to examine a plethora of quality indicators and use them to assess and potentially improve the quality of the fusion process.

Fagi v2.0 focuses on satisfying the effectiveness and performance requirements of fusing Big RDF POI data. Thus, an important effort has been made to fine-tune the underlying algorithms in order to increase their efficiency and scalability. The performance of the current implementation of Fagi is tested against real-world commercial POI datasets, by applying a custom partitioning and distributed processing scheme that occupies 10 nodes and takes less than five minutes to fuse 1 million linked POIs, which corresponds to a country-level fusion process.

5.4 Enrichment

Enrichment is one of the main parts of the data integration process. In SLIPO, enrichment focuses on POI entities that are characterized by a set of major properties (e.g. name, coordinates and category) as well as potentially several additional properties (e.g. address, telephone, email, rating, etc.). Enrichment considers one or more input dataset(s) containing POIs. The goal of enrichment is to produce one or more enriched dataset(s), containing better descriptions of the input POIs based on information retrieved from external, third-party RDF data sources (e.g., SPARQL endpoints, DBpedia). That is, each POI entity in the final, enriched dataset must be described by a set of RDF triples that have been derived by merging the initial description for the POI with those generated via various enrichment operations. Note that some enrichment approaches can define a set of triples to be removed from the original POI descriptions. Those removed set of triples are either wrong or inaccurate. The enrichment process can also replace inaccurate triples with ones with correct values. Considering the big picture of the POI integration lifecycle (Figure 2), the enrichment process is tightly interconnected with validation and quality assurance. To this end, the enrichment process needs to incorporate several mechanisms to assess the quality of the proposed enrichment operations and their results.

The enrichment task is carried out via our generic enrichment component Deer[19] [27]. Deer incorporates many approaches for performing efficient enrichment among POI resources. In the context of SLIPO, Deer receives as input one or more RDF POI dataset(s) conforming to the SLIPO ontology. Thus, Deer's input POI data are first transformed by TripleGeo into the proper RDF format and schema. Moreover, Deer input datasets may be linked via Limes prior to be enriched by Deer. Further, Deer requires as input a configuration file containing its configuration parameters. Deer's output consists of one or more files that contain the enriched versions of the respective input datasets.

Deer offers a set of *enrichment operators*, i.e., artifacts in charge of enriching input POI dataset(s). The input for such an enrichment operator is a set of one or more datasets. The output is also a set of one or more enriched datasets. In the following, we highlight some of Deer's enrichment operators:

- *The Dereferencing enrichment operator.* For POI datasets which contain similarity proprieties links (e.g. `owl:sameAs` to DBpedia resources), we deference all links from our source dataset to other datasets (e.g., DBpedia) by using a content negotiation on HTTP. The returned set of triples needs to be filtered for relevant POI resources. Here, we use a predefined list of attributes of interest. Among others, we look for `geo:lat, geo:long, geo:lat_long, geo:line` and `geo:polygon`. This list can be reconfigured via Deer's configuration.
- *The NLP Enrichment Operator* enriches POI resources by extracting embedded POI information hidden within the datatype properties and making it explicit as new triples added to the original POI dataset. For example, find all POIs embedded within the description of all hotel POIs and add them as new triple to the respective hotel POI. The current version of Deer uses the Fox [33] framework for Named Entity Recognition (NER). By default, Deer extracts the POIs based on DBpedia as the background knowledge base. As Deer is a generic POI enrichment framework, the used NER framework can be configured as well as the used background knowledge base.
- *The Geo-Distance Enrichment Operator* aims to enrich a set of POI pairs (not necessarily of the same type) with the great elliptic distance between them. For example, the geo-distance operator can enrich all hotel POIs by adding the distance to the nearest POIs of bus stations/parking lots/hospitals.

[19] https://github.com/dice-group/DEER

5.5 Quality Assurance

Each SLIPO component provides a collection of several quality indicators and statistics. They all produce verbose *execution metadata* that can either be visualized or downloaded for further inspection by the end user. Particular effort has been put in Limes, Deer, and Fagi for POI linking, enrichment and fusion respectively. In particular, both Limes and Deer implement a series of quantitative quality indicators, such as *run-time*, *number of added triples* and *percentage of data increase after linking/enrichment*. Further, both Limes and Deer provide the qualitative quality indicators of *precision*, *recall*, and *F-measure* in cases where benchmark datasets are available. In case no benchmark dasasets are available, Limes is still able to provide the *pseudo-precision*, *pseudo-recall*, and *pseudo-F-measure* first introduced in [23]. The basic assumption behind these pseudo measures is that symmetrical one-to-one links exist between the resources in source and target datasets. Our pseudo-precision computes the fraction of links that stand for one-to-one links and is equivalent to the strength function presented in [15]. The pseudo-recall computes the fraction of the total number of resources (i.e. from both source and target datasets) that are involved in at least one link. Finally, the pseudo-F-measure is the harmonic mean of pseudo-precision and pseudo-recall.

Fagi implements a series of quality indicators (e.g., percentages of fused properties vs. initial POIs/initial links, average numbers of POI property completeness) that compare the linked POI datasets and the resulting fused POIs. In particular, *attribute gain* indicates the percentage of extra properties compared to the original (e.g., a gain of 0.4 on a given POI means it was complemented with 40% additional attribute values). *Confidence* indicates the degree of similarity (in names, geometry, phone number, etc.) between the original features that were fused into a unified one, with values close to 1 indicating almost perfect match. These indicators are utilized both internally in Fagi (similarity measures, learning mechanisms) and as output for the end user, for further inspection and manual validation of fused POIs.

6 VALUE-ADDED POI ANALYTICS

At the end of the POI data integration workflow, various services are provided to perform advanced analytics and extract added value from POIs. Currently available functionality includes *Best Region Search* and extraction of *Areas of Interest*, which can be further modeled using techniques such as LDA or semantic clustering. We describe these functionalities in more detail below.

6.1 Best Region Search

Given a set of POIs $\mathcal{D}$, an $\alpha \times \beta$ rectangle R, and a utility score function $f : \mathcal{P} \rightarrow \mathbb{R}$ that assigns an objective score to any subset $\mathcal{P} \subseteq \mathcal{D}$, the goal of the *Best Region Search* problem is to find the optimal placement of R over the space containing $\mathcal{D}$ such that the value of f over the enclosed subset of POIs $\mathcal{P}$ is maximized [11]. This problem has many applications in various domains, from geomarketing and tourism to real estate and urban planning, facilitating decisions about, e.g., selecting the best location to open a new store or to place an advertisement.

However, the existing state-of-the-art algorithm for this problem [11] only computes the best, i.e., the top-1 result. This is usually not sufficient in practice. For instance, it may not be possible to open a store at the identified best location (no available facilities to rent or purchase), or all hotels in the identified best area may be occupied or too expensive. Then, the user needs to examine alternative solutions in decreasing order of quality, until one is found that meets all desired criteria.

To address this shortcoming, we have introduced the k-Best Region Search (k-BRS) problem, which computes a ranked list of the top-k best regions according to the utility score function. The main challenge in doing so, is that by simply returning a top-k list of results ordered by their objective score, typically produces highly overlapping results. Instead, our proposed algorithm is able not only to compute top-k results progressively, but also to diversify the returned results by either minimizing or completely excluding overlap among them. This is achieved by progressively retrieving subsequent results beyond the top-1, and selecting the next best candidate based on their *marginal gain*, i.e., the added value of each new result in the context of those already selected. A detailed description of the algorithm can be found in [32].

6.2 Extracting and Modelling Areas of Interest

Another functionality for POI data analytics involves the application of spatial clustering to extract Areas of Interest (AOIs) from the integrated and enriched POI dataset and then the use of topic modelling techniques to characterize and compare those areas.

For the first step, we employ *density-based clustering* to identify areas with high concentration of POIs (e.g., shopping malls, transportation hubs, touristic attractions, etc.). We use the DBSCAN [9] or HDBSCAN [4] algorithms for this purpose. DBSCAN can identify clusters of arbitrary shapes. Moreover, it does not require the user to specify the desired number of clusters in advance; instead, the user specifies two parameters that control the density. HDBSCAN extends DBSCAN by offering a mechanism to adjust the density automatically based on the data distribution.

The resulting clusters comprise a set of AOIs but provide no additional information regarding their nature or characteristics. They merely point out that these areas have a higher concentration of POIs compared to the rest of the space. To provide further insights to the user as to what these AOIs are about and how they can be compared to each other, we employ *topic modelling*. Essentially, this draws inspiration from extracting a set of topics over a document collection and representing each document according to those topics.

In our case, we represent each AOI as a “document”, with the contents of the document being a bag-of-words representation of the union (multiset) of terms appearing in the POIs contained in that AOI. These terms may refer to POI categories or tags, or any other terms extracted from POI names, descriptions, reviews, etc. We then perform Latent Dirichlet Allocation (LDA) [3] over this “document” collection. The basic idea behind LDA is that each document can be described by a distribution of topics and each topic can be described by a distribution of words. The result of the process comprises two matrices. The first is a topic-terms matrix that defines each extracted topic as a distribution over POI terms. The second is an AOI-topics matrix that represents each AOI as a distribution over the identified topics.

This approach is quite flexible in practice because it allows to model each AOI as a mixture of topics, instead of assigning each AOI to a single category. This better reflects the fact that typically a region contains a mixture of different types of POIs and serves a mixture of purposes, rather than a single one.

The resulting AOI-topics matrix can be used to compare AOIs to each other, e.g., find AOIs with similar mixture of topics, providing a means to quantify these similarities and differences.

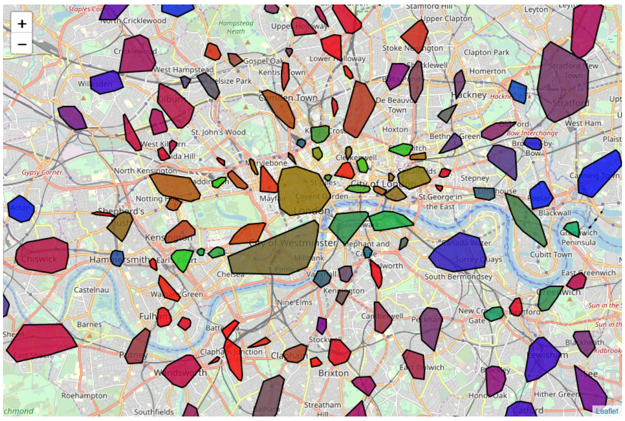

Figure 4: Example of extracted AOIs in London, with colors determined via topic modelling.

Moreover, it allows for intuitive visualizations of the extracted AOIs based on their topic distributions. An illustrative example is provided in Figure 4, where LDA was used to extract 3 topics for a given set of AOIs in London, and then each AOI was assigned a color by determining the RGB values based on its mixture of these 3 topics. Such visualizations allow not only to depict where AOIs are located, but also to intuitively identify similarities and differences between AOIs according to the underlying mixture of different types and attributes of POIs they contain.

6.3 Implicit POI Clustering

We have also developed strategies to group POIs together according to thematic, contextual and/or temporal considerations. For that purpose, we have integrated into SLIPO's toolkit the Power Iteration [19] and K-Means [20] clustering algorithms into Sansa[20] [18] since this semantic-web open-source stack provides these algorithms for RDF data out-of-the-box. We first process the input RDF data using Sansa and then apply the clustering methods. To facilitate the explanation of the algorithms, we use the following example data as input and give the corresponding results. Let's consider three POIs and their associated categories: $P_1(A, B, C)$, $P_2(A, C, D)$ and $P_3(A, B, D)$.

Power Iteration Clustering (PIC). In general, given a set of data points, we could represent the similarity between each pair of data points with a similarity matrix. For example, we could use Jaccard Similarity between two sets of categories that belong to corresponding POIs to represent the similarity between them. Therefore, a similarity matrix S, a diagonal matrix D and a Laplacian matrix $L = D - S$ are created. In Spectral Clustering [35], a subspace matrix consisting of eigenvectors corresponding to the smallest K eigenvalues was derived from the Laplacian matrix. The subspace matrix indicates the clustering results with K clusters. In PIC, the subspace matrix is an approximation to an eigenvalue-weighted linear combination of all the eigenvectors of a normalized similarity matrix [19]. The subspace matrix also indicates the clustering results. In order to prepare the correct input to the algorithm, we first collect the categories for each POI, and then we compute the Jaccard Similarity between category sets for each pair of POIs. Afterwards, we construct a similarity matrix which could be used by PIC algorithm.

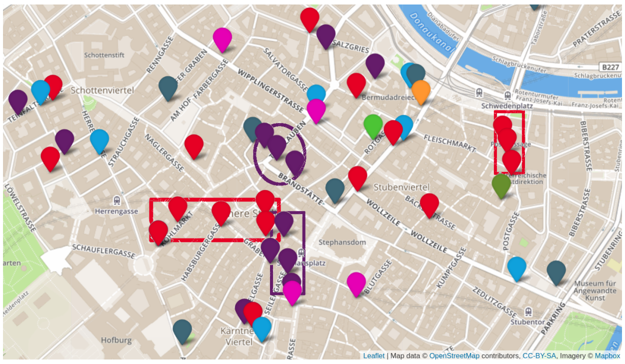

Figure 5: Example of AOIs in Vienna obtained after thematic and spatial clusterings.

K-means. This algorithm partitions POIs into different clusters such that POIs within each cluster have the smallest distance to the cluster centroid compared to placing them into any other cluster. K-means requires a distance metric to represent the distance between POIs. We use the following:

- One *hot encoding* converts categorical values into numerical vectors. Going back to our example, P_1 would be encoded into $(1, 1, 1, 0)$ since it belongs to categories A, B, C and not D.
- *Multidimensional scaling* [34] maps a distance matrix to some vectors in certain dimensions. The relative distances between different POIs are kept.
- *Word2Vec* [21] creates vector representations of words in a text corpus, which here concerns the set of all categories.

Since these methods do not consider the location of the POIs but only focus on implicit links, they produce thematic groups of POIs which are not necessarily geographically close. Indeed, since the groups are computed using categories, clusters might contain POIs sharing the exact same set of categories but actually located in different regions. For instance, Figure 5 represents the results when running PIC over POIs in Vienna. Pins having the same color are part of the same cluster. As expected, it appears that POIs of the same thematic cluster are distributed at various parts of the city center. Then, to get usable AOIs, we pipe together the two considered kinds of clustering to sub-group the thematic clusters according to their geographical locations. Thanks to that strategy, we ensure that the resulting AOIs are composed by POIs that are thematically related. This example demonstrates that the combination of these two approaches allows us to refine the thematic clusters and thus obtain the four AOIs depicted on map.

7 PROTOTYPE IMPLEMENTATION

We have been implementing a comprehensive open source software prototype aiming to support stakeholders in all stages of the POI data value chain. This prototype integrates all aforementioned tools for transforming, linking, fusing, enriching, and analyzing linked POI data. The SLIPO system (currently in beta version[21]) consists of the following main modules:

- *SLIPO Toolkit*: This is a collection of the individual software components (Section 5) applied in quality-assured POI data integration: transformation (TripleGeo), interlinking (Limes), fusion (Fagi), enrichment (Deer) and analytics (Sansa). These software components can be either installed locally or invoked

[20] https://github.com/SANSA-Stack

[21] All software is publicly available at https://github.com/SLIPO-EU

as part of the SLIPO Workbench and APIs functionality explained next.

- *SLIPO Workbench*: This is a web application, which integrates the Toolkit components to implement POI data integration workflows in a coherent, simple to use, and flexible manner. More specifically, it provides utilities for (a) uploading, searching and managing POI datasets in several formats, (b) designing, persisting and managing data integration workflows for POI datasets based on the features provided by the SLIPO Toolkit, (c) scheduling and monitoring the execution of the data integration workflows, and (d) visualizing the results of workflow executions.
- *SLIPO APIs*: This is a collection of RESTful HTTP programming interfaces for invoking SLIPO Toolkit component functionality and integrating it into third-party systems. APIs only support the invocation of simple atomic functions (e.g., POI transformation); otherwise the Workbench web application should be used. Both SLIPO Workbench and APIs are exposed through the same web application server.

Our prototype implements a *workflow engine* that executes data integration jobs and a *scheduler* for initializing workflow executions. A workflow consists of several loosely coupled tasks that together constitute a data integration process over POI datasets. A task may invoke an operation implemented by a Toolkit component (e.g., fusion), or perform secondary operations (e.g., prepare configuration files, update metadata, copy files).

The workflow engine and the SLIPO Toolkit components are deployed over a cloud infrastructure. Workbench and APIs exchange messages with the scheduler to execute workflows. The scheduler propagates requests to the workflow engine, which subsequently initiates the execution of one or more tasks. A task is executed either in-process locally on the scheduler host, or remotely using Docker containers. Each Toolkit component is responsible for providing a scalable implementation for the requested operation, inside the context of the running OS process. A Toolkit component that advertises itself as capable of partitioning its input (and, of course, merging its output) can also scale to multiple Docker containers. The scheduler only controls the total amount of resources allocated to a container, enforcing CPU/memory quotas derived from component-specific requirements and input data size.

Thanks to its modular, service-oriented architecture, SLIPO offers stakeholders the option to directly use the provided functionalities following a *Software-as-a-Service* paradigm. Alternatively, they are able to select specific tools to customize, extend and incorporate in their own POI data management workflows according to their specific needs and requirements. We expect that this will allow the rapid uptake of our innovations in a production setting without affecting any operations and processes already in place.

8 USE CASES

We have been extensively testing and evaluating SLIPO in real-world settings, against various POI data assets. These use cases cover diverse domains (geomarketing, tourism, navigation), ensuring that they reflect the requirements of cross-sector, cross-border and cross-lingual POI data integration. Next, we examine the ability of SLIPO to cope with two typical data integration scenarios against real-world POI datasets in two countries.

Table 1: POI datasets tested in the use cases.

	Dataset	*#POIs*	*Geometry*	*Thematic attributes (# in bold)*	*#triples*
Germany	D_1 (vendor)	35640	point	**(14)**: name(s), category, address, contact details	1114598
	D_2 (vendor)	24416	point	**(13)**: name, address, business data (turnover, #employees, etc.)	1098755
	OSM (open)	45750	point, line, polygon	> **25** *tags*: (multi-lingual) names, address, contact details, image, opening hours, operator, etc.	1130220
	GN (open)	7156	point	**(12):** name(s), city, zipcode, text description, last update	161473
Greece	D_3 (vendor)	72373	point	**(13):** bi-lingual names, address, category, contact details	2517030
	OSM (open)	102159	point, line, polygon	> **25** *tags*: (multi-lingual) names, address, contact details, image, opening hours, operator, etc.	2515476

8.1 Validation Settings

The first use case concerns *hotel POIs* in Germany, whereas the second deals with *general POIs* in Greece. Table 1 lists information concerning the datasets in each scenario. Note that data sources in each use case have different schemata, content and quality. Some datasets are crowdsourced such as OpenStreetMap (*OSM*) or GeoNames (*GN*), while others are offered by commercial vendors (D_1, D_2, D_3)[22]. Through SLIPO, we define integration workflows that deliver an output dataset having:

- *More POIs*, i.e., POIs missing from an original dataset are complemented from the other ones.
- Geometry representations get a *more detailed shape*, e.g., polygons obtained from *OSM* can replace (or complement) the original point (lat/lon) locations of certain POIs.
- *Extra thematic attributes* are derived by bringing together information (e.g., fax numbers, opening hours, links to photos, multi-lingual names) across all original data sources.
- Attribute values per POI are *more accurate* and complete, e.g., missing telephone numbers are filled or updated after checking against each available input.

In each use case, the original datasets are first transformed into RDF according to the SLIPO ontology (Section 4) with suitable attribute mappings. The last column in Table 1 indicates the number of resulting RDF triples. Next, each data *integration cycle* handles a pair of RDF datasets, either transformed from original data or intermediate ones derived from previous cycles. As mentioned in Section 3, a cycle involves these successive stages (cf. Figure 2):

- *Linking* two POI datasets to identify matching POI entities. The resulting RDF graph contains `owl:sameAs` links between their respective URIs.
- *Fusion* of the linked datasets into a new one according to several strategies for fusing spatial and thematic properties per POI.
- *Enrichment* of fused data with extra information from DBpedia.

Once data integration is complete, its RDF output passes through our *reverse transformation* service and delivers the integrated dataset in a traditional POI format (e.g., CSV, shapefile) readily expoitable by stakeholders.

Both scenarios were executed on a virtual machine deployed on top of a cloud stack. This VM offers an Intel® Xeon® E-52600 CPU with 16 virtual cores, 32GB RAM, 16GB swap space, and 200GB disk running Linux Ubuntu 16.04 LTS. In each case, we report data sizes, as well as the qualitative measures discussed in Section 5.5. All tests have been conducted with "cold" caches.

[22] Commercial vendors are anonymized for confidentiality.

8.2 Use Case A: Hotels in Germany

The first use case aims to integrate POIs in Germany concerning *hotels*. We assume that a stakeholder maintains a base POI dataset (D_1) and wishes to enrich it with information from other datasets (Table 1) in three successive integration cycles:

(#1) Integrate D_1 with *OSM*;
(#2) Integrate result of cycle #1 with D_2;
(#3) Integrate result of cycle #2 with *GN*.

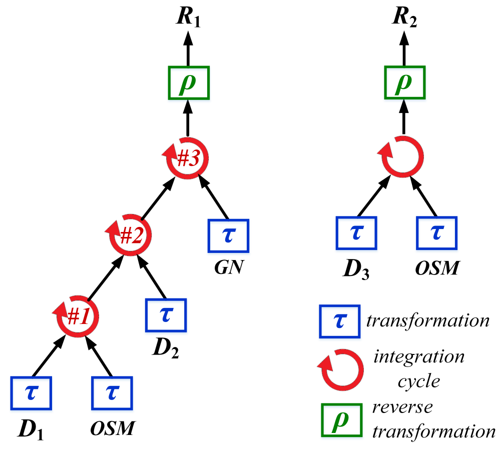
This workflow is illustrated in Figure 6(a). It includes transformation of each input dataset as well as the successive integration cycles (linking, fusion, enrichment). After reverse transformation of the integrated output, the resulting dataset R_1 is obtained. Under this scenario, the stakeholder does not wish to increase the number of POIs in its base data D_1. Instead, it only wants to enhance its content with extra thematic attributes, by filling in missing values and also obtain more detailed geometry representation where available from the other datasets.

Indicative quality and performance measurements for each cycle of Use Case A are listed in Table 2. In this use case, as all data belongs to a specific category (*hotels*), we specified that links between POI profiles should be based strictly on their spatial proximity. This explains the high linking confidence (0.98) in the resulting links. Although this choice can yield erroneous matches (e.g., two hotels may be close, but have different names), we sort them out later during fusion. As no ground truth is available, precision and recall concerning link detection cannot be estimated by Limes. In Table 2, we only provide the respective pseudo-measures (Section 5.5), but they yield rather poor estimates because the source/target datasets involved in linking at each cycle have different sizes (cf. Table 1).

Thanks to its validation rules, Fagi can filter out mismatches not only based on proximity, but also checking with POI names, phone numbers and addresses. The confidence of fused results remains consistently high across all three cycles and demonstrates the similarity among the original POIs that were fused together. At the end of the fusion process, we were able to achieve an increase in the amount of properties per POI, which at the final cycle exceeds 26% on average. Note that there are some POIs where the amount of their attributes increases by up to 47%, acquiring extra properties progressively in each cycle. The more the fused attributes, the faster the confidence stabilizes after each subsequent cycle close to 0.87. It is also important to mention that about a quarter of the POIs get more detailed geometry representations due to integration with the *OSM* data in Cycle #1. Since all other datasets include points only, no further geometric improvement occurs in subsequent cycles. Finally, we stress that the entire workflow concludes in about 6.5 minutes, delivering a unified, richer dataset that otherwise would require considerable human labor.

8.3 Use Case B: POIs in Greece

The second use case concerns general POIs in Greece of *various categories*, i.e., not only hotels as in the previous use case, but also restaurants, cinemas, schools, supermarkets, bus stops, ATMs, etc. As illustrated in Figure 6(b), the goal in this workflow (in one cycle only) is to create a single, integrated dataset R_2 that includes all available information from both input datasets (commercial D_3, open *OSM* data). In particular, apart from richer content (geometries, extra thematic attributes, and filled missing values), the resulting dataset R_2 will grow in size as well, containing many more POIs than any of the original ones.



(a) Hotels in Germany (b) POIs in Greece

Figure 6: Integration workflows for the two use cases.

Table 2: Execution Results.

Measurement	Use Case A			Use Case B
	Cycle #1	*Cycle #2*	*Cycle #3*	
# detected links	33645	15605	6448	29353
Pseudo-precision	0.69	0.81	0.61	0.65
Pseudo-recall	0.57	0.43	0.18	0.22
Pseudo-F-measure	0.62	0.56	0.28	0.33
Avg linking confidence	0.98	0.98	0.98	0.79
# fused pairs	19885	10903	1790	11036
Avg fusion confidence	0.91	0.88	0.87	0.86
Avg attribute gain	0.20	0.26	0.26	0.17
Max attribute gain	0.41	0.47	0.47	0.37
# resulting POIs	35640	35640	35640	159099
# non-point geometries	8728	8728	8728	28236
Execution cost (sec)	224.8	141.4	26.5	823.4

Statistics regarding this workflow are also listed in Table 2. In this use case, interlinking is not just based on spatial proximity but also on POI name similarity in order to avoid matching of possibly dissimilar entities that are next to each other in densely populated areas (e.g., city centers). Due to our relaxed criteria for interlinking, enough potential matches were detected (29353), although with less linking confidence (average: 0.79) compared to the previous use case.

However, we observed that a POI was often linked to multiple other POIs not always having a very similar name, but still close enough in space. During the fusion stage, most of those links were ignored based on our validation rules that also take into consideration more properties (phone, address) in similarity checks. Keeping only 11036 links that were deemed reliable, we derived fused POIs achieving strong confidence (0.86) that they actually concern the same entity. Regarding attribute gain, integrated results denote an average 17% increase in properties per POI. This result may seem poorer compared to Use Case A, but note that crowdsourced content in *OSM* for Greece is less rich than for Germany. Still, the most important outcome of this integration is that the final dataset R_2 includes more than 159 thousand POIs, which is over than double the size of commercial dataset D_3. As

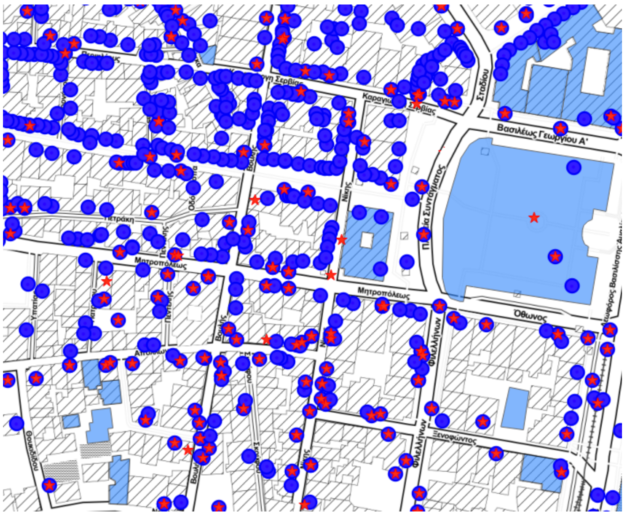


Figure 7: POIs in Athens city center before (red) and after integration (blue).

depicted in Figure 7, integration results (POIs in blue circles) supersede by far and drastically enhance the original information of dataset D_3 (shown with red stars). Furthermore, almost 18% of the resulting POIs now have more detailed geometries (shown as blue polygons) thanks to information extracted from *OSM*. Last, but not least, the fact that this workflow delivers its result in less than 14 minutes, clearly demonstrates the efficiency of SLIPO.

9 CONCLUSIONS AND FUTURE WORK

In this paper, we presented the SLIPO system, a cloud-based application encapsulating Linked Data technologies to efficiently address the challenges of large-scale integration of POI data assets. SLIPO transfers data integration to the Linked Data domain, thus allowing state-of-the-art software to be repurposed and focused to POI data, without requiring domain-specific knowledge from stakeholders or alterations in existing operational workflows. Our tests and evaluations in diverse application domains have shown that SLIPO offers clear advantages in terms of efficient, reliable, quality-assured POI data integration.

Our effort in SLIPO continues along several directions aiming to expand its relevance, efficiency, and value in an industrial setting. First, we will improve the individual software components with additional POI-specific rules and operations to increase performance and effectiveness. Further, we are working with our industrial partners to apply SLIPO in a plethora of domain-specific and cross-border commercial data integration tasks, directly comparing and documenting the gains in productivity, time-to-market, and value. In addition, we are creating periodic world-scale data integration workflows beyond the current reach of the industry, to enable low-cost and streamlined POI-based services. Finally, we are expanding the interoperability of the system to support third-party systems (e.g., signage recognition from street-level imagery) and its quality-assurance services, which will help embed SLIPO in the business workflows of most stakeholders in the value chain.

ACKNOWLEDGMENTS

This work was partially funded by the EU H2020 project SLIPO (#731581).

Executing Entity Matching End to End: A Case Study

Pradap Konda[1], Sanjay Subramanian Seshadri[2], Elan Segarra[3], Brent Hueth[3], AnHai Doan[3]
[1]Facebook, [2]NetApp, [3]University of Wisconsin-Madison, U.S.A.

ABSTRACT

Entity matching (EM) identifies data instances that refer to the same real-world entity. Numerous EM works have covered a wide spectrum, from developing new EM algorithms to scaling them to building EM systems. But there has been very little if any published work on *how EM is carried out in practice, end to end.* In this paper we describe in detail a case study of applying EM to a particular domain end to end (i.e., going from the raw data all the way to the matches).

Specifically, we describe a real-world application for EM in the science policy research community. We describe how our team (the EM team) interact with the science policy team to carry out the EM process, using PyMatcher, a state-of-the-art EM system developed in the Magellan project at UW-Madison. We highlight the communication between the two teams and the zig-zag nature of the EM process. We identify a set of challenges that we believe arise in many real-world EM projects but that current EM systems have either ignored or are not even aware of. Finally, we provide all data underlying this case study, including labeled tuple pairs and documentation supplied by the science policy team, to serve as a good challenge problem for EM researchers.

1 INTRODUCTION

Entity matching (EM) identifies data instances that refer to the same real-world entity, such as (David Smith, UW-Madison) and (D. M. Smith, UWM). EM has been a long-standing challenge in data management [6, 11], and will become even more important in data science. This is because many data science projects need to integrate data from disparate sources before analysis can be carried out, and such integration often requires EM.

Consequently, EM has received enormous attention (see Section 2). Surprisingly, as far as we can tell, there has been very little if any published work on *how EM is carried out in practice, end to end.* The closest that we can find are works that perform EM in a particular domain, e.g., e-commerce, mobile data, patient records, drugs, etc. But these works focus on developing specialized EM algorithms that exploit the characteristics of the target domain, e.g., exploiting product taxonomies (to match e-commerce products) or the spatio-temporal nature of mobile data (to match phone calls).

In this paper we describe in detail a case study of applying EM to a particular domain, end to end (i.e., going from the raw data all the way to the matches). This case study is quite rich, *and it clearly demonstrates many novel challenges for current EM solutions and systems.* We will soon release all the data underlying this case study (to be available at [20]), so that our community can use it as a challenge problem for EM.

Specifically, in summer 2015 we started the Magellan project at the University of Wisconsin-Madison, to build EM systems. We believe that building practical EM systems is critical for advancing the EM field, the way systems such as System R, Ingres, Hadoop, and Spark are critical for advancing the fields of relational data management and Big Data. Subsequently, we built an EM system called PyMatcher [17], which is quite different from EM systems built so far (see Section 2). We then looked for real-world applications to "test drive" PyMatcher.

To do so, we talked with the science policy research community, which has been building a large "data lake" called UMETRICS. Currently UMETRICS collects data from 24 participating U.S. universities, on research grants and the researchers involved in these grants. They use the data to study questions such as "What are the results of investments in research?" and "How do universities affect the regional economy?", and indeed many studies have been published using UMETRICS data (e.g., [30]).

Building UMETRICS requires matching grants across different datasets. The UMETRICS team (at the University of Michigan) has developed and deployed a rule-based EM workflow, but its accuracy is not satisfactory. So we collaborated with a science policy team at UW-Madison to build a more accurate EM workflow, using PyMatcher.

This work was eye-opening to us. Before starting this work, we already felt that existing EM systems were not powerful enough because they failed to address many challenges that arise in real-world EM [17]. That was why we started the Magellan project. Working with UMETRICS suggested to us that we were probably on the right track, but that real-world EM does raise many more challenges that we have also failed to recognize.

These challenges apply equally well to Magellan and other existing EM systems. We discuss the challenges in detail in Section 13, covering the need to develop how-to guides (that provide detailed guidance to the users on how to carry out EM step by step, end to end), new pain points in EM (e.g., labeling, match definition), the need for different EM solutions for different parts of the data, support for easy collaboration among multiple team members (who are often in different locations), handling changes that inevitably arise during the EM process, managing machine learning "in the wild", the need to use both learning and hand-crafted rules, and the need to design a new type of EM architecture. In summary, we make the following contributions:

- We describe a real-world application for EM in the science policy community. We describe what the users want in terms of EM, how their goals change over time, and what end results they are aiming for.
- We describe in detail how our team (the EM team) interacts with the science policy team (the UMETRICS domain expert team) to carry out the EM process, using PyMatcher, a state-of-the-art EM system developed in our group. We highlight the communication between the two teams and the zig-zag nature of the EM process.
- We identify a set of challenges that we believe arise in many real-world EM projects but that current EM systems have either ignored, or are not even aware of, or have not addressed well. While in this paper we have focused on just one case study, in the past few years we have worked with many more real-world EM cases, and the challenges described here also commonly arise in those cases.

- Finally, we provide all data underlying this case study, including all the labeled tuple pairs and documentation supplied by the domain expert [20]. This dataset can serve as a good challenge problem for EM researchers.

Overall, we hope that the case study here can contribute to helping EM researchers understand better the challenges of the EM process and develop more effective EM solutions. The UMETRICS data and Jupyter notebooks will be available at [20], and a technical report with far more details will be available at [19].

2 BACKGROUND & RELATED WORK

We now discuss the EM problem, related work, then PyMatcher, which was used to perform EM for the case study.

Entity Matching: This problem, a.k.a. entity resolution, record linkage, etc., has received enormous attention (see [6, 11] for books and surveys). A common EM scenario finds all tuple pairs (a, b) that match, i.e., refer to the same real-world entity, between two tables A and B (see Figure 1). Other EM scenarios include matching tuples within a single table, matching into a knowledge base, matching XML data, etc. [6].

Most EM works develop matching algorithms, exploiting rules, learning, clustering, crowdsourcing, among others [6, 11]. They try to improve the matching accuracy and reduce costs (e.g., run time). Trying to match all pairs in $A \times B$ often takes very long. So users often employ heuristics to remove obviously non-matched pairs (e.g., products with different colors), in a step called *blocking*, before matching the remaining pairs. Several works have addressed scaling up blocking (e.g., [3, 8, 16, 29]), learning blockers [4, 9], and using crowdsourcing for blocking [13] (see [7] for a survey).

Many works have considered EM for a particular domain, such as e-commerce (e.g., [10, 15, 21, 22]), patient records [24], financial entities [12], medical sciences [5], drugs [26], and more. But they do not focus on the entire end-to-end process, the interaction between the EM team and the domain expert team, and on identifying the challenges for current EM systems, as we do in this paper.

In contrast to the extensive effort on EM algorithms, there has been relatively little work on building EM systems. As of 2016 we counted 18 major non-commercial systems (e.g., D-Dupe, DuDe, Febrl, Dedoop, Nadeef), and 15 major commercial ones (e.g., Tamr, Data Ladder, IBM InfoSphere) [6]. Our examination of these systems (see [18]) reveals the following four major problems: these systems do not cover the entire EM pipeline, they are stand-alone monolithic systems and hence they make it very difficult to exploit a wide range of techniques, it is very difficult to write code to "patch" these systems even though this is often necessary in practice, and these systems provide very little guidance to users on how to execute the EM process. These shortcomings motivated us to develop the Magellan project, which we briefly describe next.

The Magellan Project (PyMatcher and CloudMatcher): In the Magellan project we developed an on-premise Python-based EM system called PyMatcher and a cloud-based self-service system called CloudMatcher. In this paper we only used the PyMatcher system, which we briefly describe below.

Compared to current EM systems, PyMatcher is novel in four aspects. (1) It provides how-to guides that tell users what to do in each EM scenario, step by step. (2) It provides tools to help users do these steps; the tools seek to cover the entire EM pipeline, not just matching and blocking as current EM systems do. (3) Tools are built into the ecosystem of data science tools in Python, allowing PyMatcher to borrow powerful capabilities in data cleaning, visualization, learning, etc. (4) PyMatcher provides a powerful scripting environment to facilitate interactive experimentation and quick "patching" of the system. See [14, 17] for more, and see *sites.google.com/site/anhaidgroup/projects/magellan* for code.

3 PROBLEM DEFINITION

We now introduce the science policy research community, their effort to conduct data-driven research by creating a large data lake called UMETRICS, their need to perform EM to build UMETRICS, and the EM problem considered in this paper.

The Science Policy Research Community: A large country such as the U.S. spends hundreds of billions of dollars on science R&D (i.e., research & development) per year. It is important to be able to track the impact of this spending and develop effective science R&D policies. The science policy research community studies such issues.

UMETRICS: To do so effectively, in the past decade, this community has been building a data science infrastructure centering around a large data lake called UMETRICS, which stands for "Universities: Measuring the Impacts of Research and Innovation, Competitiveness and Science" [2].

Currently UMETRICS collects data from 24 participating universities, specifically data on (a) all people paid and all purchases from vendors and subcontracts for all federally funded grants, and (b) the specific job titles and the source of funding for research projects at the universities. As such, the data can be used to study questions such as "What are the results of investments in research?" and "How do universities affect the regional economy?", and indeed many studies have been published using UMETRICS data (e.g., [30]).

The Need for Entity Matching: While highly promising, building UMETRICS require a lot of work to integrate the data submitted by the 24 participating universities. For example, if UW-Madison submits a table that lists research grants from the National Science Foundation (NSF), then those grants must be matched into existing grants already in UMETRICS.

This matching is highly non-trivial. For example, the same research project can have different research titles recorded in UMETRICS and at universities. As another example, a grant given by a funding agency to a research project may be distributed to many smaller projects in the same university, and this information will be recorded in multiple entries in UMETRICS, so matching these entries is not trivial.

The Need to Improve the Current EM Solution: Currently the UMETRICS team (at the University of Michigan) performs such matching using hand-crafted rules. But the accuracy remains unsatisfactory. As a result, a team led by Professor Brent Hueth (in the Department of Agricultural and Applied Economics at UW-Madison and a co-author of this paper) set out to examine how to improve the accuracy of this EM solution.

Matching the USDA Dataset with the UMETRICS Dataset: As a concrete project, they first selected a dataset that contains grants awarded to UW-Madison from USDA (the U.S. Department of Agriculture) in a certain time period. We will refer to this dataset the USDA dataset.

Next, they wanted to match grants in this USDA dataset into UMETRICS. To do so, they performed a simple selection in UMETRICS to select all grants awarded to UW-Madison by USDA in the same time period (UMETRICS allows such selections). For simplicity, let us call this new dataset the UMETRICS dataset. *Next, the team wanted to match grants between the USDA dataset and the* UMETRICS *dataset. Their goal is to find a new EM workflow that is more accurate than the current rule-based EM workflow (deployed in* UMETRICS*).*

This team, which we will call the UMETRICS team, consisted of Professor Brent Hueth, a Ph.D. student in economics, and an hourly student in CS. Initially, we did not get closely involved in the EM process. Instead, we let the UMETRICS team try to match the two datasets themselves. We only provided advice for specific problems such as debugging the matches and evaluating the match results. However, after multiple meetings, we observed that the UMETRICS team simply did not know how to perform EM in a systematic fashion. They had no idea what to do first, what to do second, etc., even though they had a CS student in the team who has learned about EM in a data science class.

So we decided to get involved. Our team, which we will call the EM team, consisted of Professor AnHai Doan, a Ph.D. student in CS, and an hourly student in CS. Our team took over the matching work. We viewed the UMETRICS team as domain experts, and consulted with them in that capacity (by meeting for an hour per week and via emails). Our goal here is to simulate and understand the collaboration between an EM team and a domain expert team, as such settings commonly occur in real-world matching projects. Henceforth "we" refers to the EM team (in CS), when there is no ambiguity.

We decided to use PyMatcher to perform EM, by following its how-to guide (see the PyMatcher's homepage for this guide). In the following sections, we discuss the steps we followed. We intentionally discuss them in details, to show all the steps that human users must perform. We also discuss them in chronological order to show how zig-zag the process was. Finally, we discuss details such as where the files were stored, how the two teams communicated, to highlight the logistic aspects of executing such an EM project in a distributed fashion.

4 UNDERSTANDING THE DATA

We received the raw data from the UMETRICS team in a Google Drive folder. We started by exploring to understand the tables in the datasets, specifically to understand the "entities" in these tables and the relationships among the entities.

We first opened the raw data and found six CSV tables with the "UMETRICS" prefix and one CSV table with the "USDA" prefix. From the table names, we assumed that the names with the "UMETRICS" prefix correspond to UMETRICS-related tables and the name with the "USDA" prefix corresponds to the USDA table.

Next, we explored each table to obtain a brief understanding of the information included in it and the data values of its columns. Specifically, we browsed a few sample rows that were randomly selected from the table and examined general statistics such as the number of unique values, number of missing values, mean, median, etc., for each column.

UMETRICS

USDAAwardMatching	1915	78

Figure 2: Summary of the original UMETRICS and USDA tables given by the UMETRICS team.

Figure 2 lists the number of rows and columns for each table. Figure 3 shows a few rows from UMETRICS tables, and Figure 4 shows a few rows from the USDA table.

To explore the smaller tables (which have fewer than 300K tuples), we used pandas [25] and MS Excel. To explore the larger tables, we used SQLite. To profile the tables, we used the pandas-profiling tool [1] and custom Python scripts.

The UMETRICS Tables: The schemas of the six UMETRICS tables are as follows:

```
UMETRICSAwardAggMatching(UniqueAwardNumber,AwardTitle,
FundingSource,FirstTransDate, LastTransDate,
RecipientAccountNumber,TotalOverheadCharged,
TotalExpenditures,NumberOfTransactions,
DataFileYearEarliest, DataFileYearLatest,
SubOrgUnit, CampusID)

UMETRICSSubAwardMatching(UniqueAwardNumber, Address,
BldgName, City, Country, DUNS, DomesticZipCode, EIN,
ForeignZipCode, ObjectCode, OrgName, OrganizationID,

Figure 4: Example rows from the USDA table.

included funding information for the research projects in the university. "UMETRICSSubAwardMatching" included information about how the awards are split into multiple sub-awards to fund the research projects.

"UMETRICSOrgUnitsMatching" included information about different organization units to which the awards were given. "UMETRICSEmployeeMatching" included information about the employees in the university, and "UMETRICSVendorMatching" included information about the vendors interacting with the university. We were not clear about the information included in the "UMETRICSObjectCodesMatching" table.

Relationships among the UMETRICS Tables: We observed that "UMETRICSAwardAggMatching" was the central table to which most other tables (except "UMETRICSObjectCodesMatching") could be joined using a key-foreign key relationship. For this table (i.e., "UMETRICSAwardAggMatching"), the attribute "UniqueAwardNumber" was the primary key.

We found that the tables "UMETRICSEmployeeMatching," "UMETRICSVendorMatching," and "UMETRICSSubAwardMatching" included the "UniqueAwardNumber" column, which could be joined with the "UniqueAwardNumber" of the "UMETRICSAwardAggMatching" table. The table "UMETRICSOrgUnitsMatching" included a "CampusId" column that could be joined with "CampusId" in the "UMETRICSAwardAggMatching" table. The table "UMETRICSObjectCodesMatching" included an "ObjectCode" column that could be joined with the "ObjectCode" column in the "UMETRICSEmployeeMatching" table.

The USDA Table: Only one table contained USDA information (see Figure 4). This table has 78 columns. Because of space constraints, a partial schema of this table including a few columns is shown below.

```
USDAAwardMatching(AccessionNumber, ProjectTitle,
SponsoringAgency, FundingMechanism, AwardNumber, ...,
ProjectNumber, ProjectStartDate, ProjectEndDate, ...,
ProjectDirector,  ...,
Financial: USDAContracts, Grants, Coop Agmt)
```

5 UNDERSTANDING MATCH DEFINITION

After exploring the tables, we have obtained an understanding of the entities and their relationships. However, we did not know how to use these tables to match the awards (i.e., grants), e.g., which tables are relevant for matching? What does it mean to be a match between the UMETRICS and USDA datasets?

In response, the UMETRICS team sent us a matching document, which discusses the most relevant tables, provides a matching definition, and provides a few sample matching and non-matching record pairs. This document stated that only three tables (among seven) were most relevant for matching and provided the following matching definition.

- (M_1) If a part of "UniqueAwardNumber" in UMETRICS matches "Award Number" in USDA, then the record pair can be considered a match. Specifically, "UniqueAwardNumber" can take the form "XX.XXX YYYY-YYYY-YYYYY-YYYYY". Thus if "YYYY-YYYY-YYYYY-YYYYY" matches the "Award Number," then the record pair is a match. An example of such a match is shown in Figure 5.
- (M_2) A number of records in USDA do not have values for "Award Number." In such cases, the records may be matched by checking whether the "AwardTitle" in UMETRICS and the "Project Title" in USDA are similar. An example of such a match is shown in Figure 6.
- (M_3) A record pair from UMETRICS and USDA can also be matched by comparing the individuals involved in the project.

From the above matching definition, we could infer one positive matching rule based on M_1. Specifically, for a record pair from UMETRICS and USDA tables, if the second part of "UniqueAwardNumber" in the UMETRICS record matches exactly the "Award Number" in the USDA record, then the record pair could be declared a match.

It is possible to use this positive rule to filter out all the positive matches, then proceed with a smaller set for matching. However, we did not do that because we were not sure if the match definition had been stabilized as yet. Instead, we decided to incorporate this rule as a part of the blocking step (as we will see soon).

Apart from M_1, the other two instructions (M_2 and M_3) in the above matching definition are not precise. For example, in M_2, what does it mean to say "similar"? Further, if the award and project titles match exactly, but are very generic (e.g., "Lab Supplies"), then we still cannot conclude that the records match. So we cannot capture these matching instructions as rules, to be applied to the tables to obtain the matches.

As this example suggests, matching definitions are often written in English, in a verbose and imprecise fashion. Business owners often train analysts to perform matching. These analysts gain experience over time and tune their understanding of a "match." They do this by exploring a wide variety of examples and checking with the business owners when in doubt. *This suggests that understanding a matching definition is an iterative process that involves continuous interaction with the business owners.*

6 PRE-PROCESSING THE DATA

Recall that we were given six UMETRICS tables (describing how the funding from different agencies was used for the research projects at UW-Madison) and one USDA table (describing how the funding from USDA was used for research projects at UW-Madison).

UMETRICS		USDA	
field	*value*	*field*	*value*
UniqueAwardNumber	10.200 2008-34103-19449	Accession Number	214335
AwardTitle	DEVELOPMENT OF IPM-BASED CORN FUNGICIDE GUIDELINES FOR THE NORTH CENTRAL STATES	Project Title	Development of IPM-Based Corn Fungicide Guidelines for the North Central States
FirstTransDate	10/1/08	Award Number	2008-34103-19449
FirstTransDate	10/1/08	Project Start Date	8/15/08
		Project End Date	8/14/11
		Project Director	ESKER, PAUL

Figure 5: A matching pair based on Award Number.

UMETRICS		USDA	
field	*value*	*field*	*value*

AwardTitle	SWAMP DODDER (CUSCUTA GRONOVII) APPLIED ECOLOGY AND MANAGEMENT IN CARROT PRODUCTION	Project Title	Swamp Dodder (Cuscuta gronovii) Applied Ecology and Management in Carrot Production
FirstTransDate	10/1/07	Award Number	-
LastTransDate	12/31/08	Project Start Date	10/1/06
		Project End Date	9/30/08
		Project Director	Colquhoun, J.

Figure 6: A matching pair based on Award Title.

Even with this moderate number of tables, the matching process will be difficult if we have to consider all of them. So we decided to *subset the tables* (i.e., selecting only a portion of information from the tables, perhaps even using just a subset of the tables) and *apply transformations* to obtain only two tables that can be used for matching. To do so, we used the matching document provided by the UMETRICS team.

Specifically, we created two tables "UMERICSProjected" and "USDAProjected" (later we will match these two tables), using the following steps.

(1) First, from the six UMETRICS tables, we selected two tables judged most relevant for matching by the UMETRICS team (as discussed in the matching document): "UMETRICSAwardAggMatching" and "UMETRICSEmployeeMatching". (Naturally we also keep the table "USDAAwardMatching".)

(2) Next, we checked that "UniqueAwardNumber" and "Accession Number" were indeed the key columns in the "UMETRICSAwardAggMatching" and "USDAAwardMatching" tables, respectively. We also checked that "UniqueAwardNumber" was indeed a foreign key in the "UMETRICSEmployeesMatching" table with valid values, and could be joined with the "UMETRICSAggAwardMatching" table. We used PyMatcher and pandas to perform these validations.

(3) Then we checked the four remaining UMETRICS tables to see if they contained any information useful for matching. To do this, we manually examined the names of the attributes of these four UMETRICS tables and compared these names to the names of the attributes of the USDA table, to find attribute pairs with similar names. We found that "Recipient Organization" and

"Recipient DUNS" from the USDA table were similar to "OrgName" and "DUNS" in the "UMETRICSVendorMatching" table[1].

Next, we checked if the attributes with similar names have similar values. Specifically, we checked for any overlap of values and compared the distributions of values using mean, median, etc. We did this using pandas and custom Python scripts. We found that the values of "OrgName"and "DUNS" from the "UMETRICSVendorMatching" table did not overlap with the values of "Recipient Organization" and "Recipient DUNS".

We concluded that the four remaining UMETRICS tables do not share any information with the USDA table, and thus are not useful for matching. Thus, we ignore them in the subsequent pre-processing steps.

(4) Finally, we applied transformations to the selected tables. Specifically, we (a) projected out the UMETRICS and USDA tables to create two tables with relevant columns for matching, (b) matched the columns between the tables and renamed them with the same names, and (c) added an ID column to each table. We now elaborate on these steps.

(4.a) First, we projected and kept from the two tables "UMETRICSAwardAggMatching" and "USDAAwardMatching" only attributes that are relevant for matching (we consulted the matching document and the UMETRICS team about which attributes to keep). This produced the following two tables:

```
UMETRICSProjected(UniqueAwardNumber, AwardTitle,
FirstTransDate, LastTransDate)

USDAProjected(AwardNumber, ProjectTitle, ProjectStartDate,
ProjectEndDate, AccessionNumber, ProjectDirector)
```

The "AccessionNumber" was included in the "USDAProjected" table because the UMETRICS team required the output matches to be listed as pairs of "UniqueAwardNumber" and "AccessionNumber."

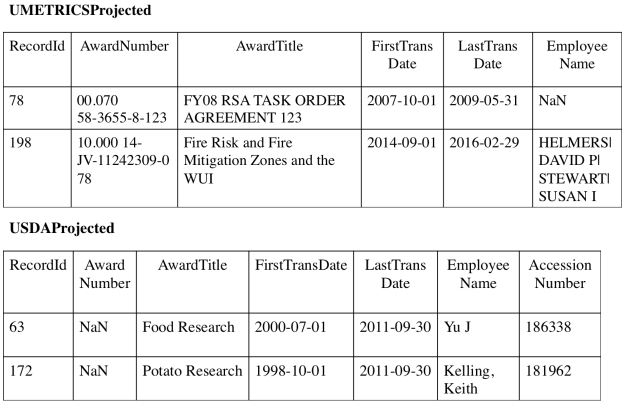
(4.b) Next, we matched the column names between the two tables and renamed them with the same name. Specifically, we matched "UniqueAwardNumber," "AwardTitle," "FirstTransDate," "LastTransDate" from the "UMETRICSProjected" table to "AwardNumber," "ProjectTitle," "ProjectStartDate," "ProjectEndDate," respectively. We named them "AwardNumber," "AwardTitle," "FirstTransDate," "LastTransDate." We renamed "ProjectDirector" in the "USDAProjected" table as "EmployeeName." The updated schemas are shown below.

```
UMETRICSProjected(AwardNumber, AwardTitle,
FirstTransDate, LastTransDate)

USDAProjected(AwardNumber, AwardTitle, FirstTransDate,
LastTransDate, AccessionNumber, EmployeeName)
```

Then we added a new column, "EmployeeName," to the "UMETRICSProjected" table. To do so, we joined this table with the "UMETRICSEmployeesMatching" table on the "AwardNumber" and "UniqueAwardNumber" columns. There were multiple employee names for the same award in the "UMETRICSEmployeesMatching" table. Therefore, for each award, these employee names were concatenated, and each employee name was separated by the | character.

(4.c) Finally, we added an ID column ("RecordId") to both the "UMETRICSProjected" and "USDAProjected" tables, to uniquely identify each record in each table. The final schema of the two tables are (see Figure 7):



UMETRICSProjected

RecordId	AwardNumber	AwardTitle	FirstTrans Date	LastTrans Date	Employee Name
78	00.070 58-3655-8-123	FY08 RSA TASK ORDER AGREEMENT 123	2007-10-01	2009-05-31	NaN
198	10.000 14-JV-11242309-078	Fire Risk and Fire Mitigation Zones and the WUI	2014-09-01	2016-02-29	HELMERS| DAVID P| STEWART| SUSAN I

USDAProjected

RecordId	Award Number	AwardTitle	FirstTransDate	LastTrans Date	Employee Name	Accession Number
63	NaN	Food Research	2000-07-01	2011-09-30	Yu J	186338
172	NaN	Potato Research	1998-10-01	2011-09-30	Kelling, Keith	181962

Figure 7: Sample rows of the UMETRICSProjected and USDAProjected tables.

```
UMETRICSProjected(RecordId, AwardNumber, AwardTitle,
FirstTransDate, LastTransDate, EmployeeName)

USDAProjected(RecordId, AwardNumber, AwardTitle,
FirstTransDate, LastTransDate, AccessionNumber,
EmployeeName)
```

We used pandas, PyMatcher, and custom Python scripts to perform the join and other transformations.

7 BLOCKING

After applying the transformations, the resulting tables, "UMETRICSProjected" and "USDAProjected", have just 1336 and 1915 records, respectively.

Since they are small, can we just match all pairs of records in their Catersian product? In other words, is blocking necessary? It turns out that blocking is still required even in this case. This is because to perform learning-based matching and to evaluate the match results, we must first take a sample from this set (of record pairs in the Cartesian product) and label them.

In our case, however, the Cartesian product of the input tables has 2.5M record pairs, and most of them would be non-matches. Random sampling from this set will result in very few matches. Therefore, we still have to perform blocking to remove obvious non-matching record pairs, so that later when we sample we can obtain more matches in the samples.

We used the matching definition provided by the UMETRICS team to guide the blocking step. We proceeded as follows:

(1) First, we applied a blocking scheme to include all record pairs that satisfy M_1. This is because if M_1 is indeed a positive matching rule, then all record pairs satisfying M_1 must be included in the candidate set (to be fed into the matching step).

Recall that M_1 declares a record pair a match if the second half of the "AwardNumber" attribute of the "UMETRICSProjected" table matches exactly the "AwardNumber" attribute of the "USDAProjected" table. To find all record pairs that satisfy M_1, we applied an attribute equivalence (AE) blocker to these tables. This blocker includes a record pair (in the candidate set) only if the blocking attributes of both input tables agree.

In our case, the AE blocker cannot be applied directly because the "AwardNumber" from "UMETRICSProjected" and "USDAProjected" cannot be compared for an exact match. So we first used a regular expression to extract the suffix of "AwardNumber" of the "UMETRICSProjected" table and stored the result as a temporary column, "TempAwardNumber," in the same table. Then we applied the AE blocker using "TempAwardNumber" from the

[1] What we did here is essentially schema matching [27]. But we did it manually due to the relatively small sizes of the tables.

"UMETRICSProjected" table and "AwardNumber" from the "USDAProjected" table as blocking attributes. Finally, we removed the temporary column ("TempAwardNumber") from the "UMETRICSProjected" table. This blocking scheme produced a candidate set of record pairs C_1.

(2) Next, based on the matching definition M_2, we decided to include the record pairs that have similar award titles. We examined a sample of the award titles in the "USDAProjected" and "UMETRICSProjected" tables, and observed that the titles often have multiple tokens (i.e., words in this case).

Intuitively, two similar award titles should share at least a few tokens. So we applied an overlap blocker to the input tables using "AwardTitle" as the blocking attribute. This blocker discards a record pair if the number of shared tokens (in the blocking attribute) is less than an overlap threshold K.

Specifically, we normalized all the strings in the "AwardTitle" column by lower casing and removing special characters (e.g., single/double quotation marks, hash symbols, exclamation marks, round/curly braces, etc.). Then we performed overlap blocking using a word-level tokenizer, using the overlap threshold 3 after trying a few other thresholds (e.g., the threshold of 1 resulted in 200K record pairs, and a threshold of 7 resulted in a few hundred record pairs). This produced a candidate set C_2.

(3) The overlap blocker drops a record pair if the number of tokens in the blocking attribute was less than the overlap threshold K (in our case, K was 3). So we examined the award titles between the two tables to see if similar titles with fewer than 3 tokens exist, and we found quite a few such title pairs[2].

To include these record pairs, we applied an overlap-coefficient blocker, using "AwardTitle" as the blocking attribute. For any two strings X and Y we have $overlap\_coefficient(X, Y) = |X \cap Y| / \min(|X|, |Y|)$ (assuming X and Y have been tokenized into two sets). This blocker is similar semantics-wise to the overlap blocker. However, it returns a score between 0 and 1, regardless of the title length, and thus can handle the case where a title has fewer than 3 tokens. To apply this blocker, we first lower cased all the strings in the "AwardTitle" column, removed special characters, then performed overlap-coefficient blocking using a word-level tokenizer and a threshold of 0.7 (after trying a few other thresholds). This produced a candidate set C_3.

(4) Next, we unioned C_1, C_2, and C_3 to obtain a consolidated candidate set C, which has 3177 record pairs[3].

We then checked for any potentially missing matches in C using the blocking debugger of PyMatcher [23]. Briefly, this debugger takes the two input tables ("UMETRICSProjected" and "USDAProjected") and the candidate set C, and returns the list of record pairs that (a) are in the Cartesian product of the two tables but not in C, and (b) are judged to be potential matches by the debugger. These pairs are ranked in decreasing likelihood of being matches. If the user does not see many true matches in this list (e.g., by manually examining the top 100 pairs), then he/she can conclude that the blocking process probably has not killed off many true matches. See [23] for details, including how the debugger performs the above process fast.

In our case, we observed that the top record pairs returned by the blocking debugger were not matches, and hence we decided to stop modifying the blocking pipeline. We used PyMatcher for blocking, and used custom Python scripts and pandas commands to preprocess the columns before applying blocking[4].

8 SAMPLING AND LABELING

After blocking, we wanted to obtain and label a sample of record pairs from the candidate set C. (Later we need this labeled sample to select the best learning-based matcher and then train this matcher to predict matches in the candidate set C.)

Sampling and labeling is not straightforward because the candidate set C has relatively few matches and the match definition is still evolving. Further, since we had to ask the UMETRICS team to label, we had to manage the logistics for labeling.

Setting Up: We first emailed the UMETRICS team, then followed up with a face-to-face meeting to discuss the logistics. Initially, we proposed to email the record pairs as a CSV file that they could download and use tools such as MS Excel to label pairs as a match or a non-match. The UMETRICS team wanted a tool with better UI that multiple team members could use. So we developed a simple cloud-based labeling tool with a good UI, but the tool was limited in that only one person could label at any time. The UMETRICS team accepted this and said they would discuss the matter internally and schedule the labeling.

Sampling and Labeling: Next, we performed sampling and labeling iteratively. Our goal was to obtain a sufficient number of positive matches in the labeled set. We first took a random sample of 100 record pairs from the candidate set C, uploaded the sampled pairs into the cloud-based labeling tool, then asked the UMETRICS team to label the record pairs as "Yes", "No", or "Unsure"[5].

The UMETRICS team trained a student to label using the tool. Meanwhile, we labeled the same set of record pairs, using our own understanding of the match definition. Afterward we cross-checked their labels against ours and observed 22 mismatched labels. Specifically, one record pair was labeled a non-match despite satisfying the matching rule M_1. The other 21 pairs had similar award titles, but labeled as a mix of match, non-match, and primarily unsures.

In a face-to-face meeting, the UMETRICS team confirmed that the record pair satisfying M_1 must be declared as match (they also confirmed that M_1 is indeed a positive matching rule). For others, they mentioned that, though the award titles were similar, some of them were not unique enough to be declared matches.

They said that they would have a closer look at the mismatches. After the discussion, we shared the record pairs with mismatched

[2] Specifically, we first used PyMatcher to find all title pairs whose Jaccard score (over a 3-gram tokenization) exceeds a threshold. Next, we kept only those pairs where at least one title has fewer than 3 words. Finally, we took a random sample of these pairs and manually examined the sample.

[3] It turned out that we want both C_2 and C_3 in the consolidated candidate set. C_2 and C_3 have 2,937 and 1,375 record pairs, respectively. $|C_2 \cap C_3|$ = 1,140, $|C_2 - C_3|$ = 1,797, and $|C_3 - C_2|$ = 235. Our examination revealed that if two titles are similar but share few tokens, the overlap blocker will include the pair, but the coefficient blocker will discard it. So we cannot just use C_3 and discard C_2.

[4] PyMatcher's blocking methods use string filtering techniques where appropriate to speed up the blocking process.

[5] It turned out that for many real-world datasets that we have seen, even domain experts had troubles labeling certain pairs, due to dirty, incomplete, or cryptic data. Hence the option "Unsure". As we will see, we ignore "Unsure" pairs in training and evaluating learning-based matchers. Our reasoning is that if even domain experts cannot label these pairs, it is unfair to ask learning algorithms to handle them. And if we can ask learning algorithms to label these pairs, how can we evaluate their accuracy, given that even the domain experts cannot label them?

We also believe that if the number of "Unsure" pairs is too high, that indicates that the dataset is too dirty, incomplete, or cryptic, and the domain experts should clean the dataset before EM is attempted. In this case, as we will see, 300 pairs were labeled for selecting/training matchers, out of which 32 were labeled "Unsure". Later 400 pairs were labeled for evaluating matchers, out of which 16 were labeled "Unsure". The UMETRICS team said they were okay with the quality of this dataset (i.e., judging the EM result from this dataset to be still useful for their domain science research).

labels using Google Sheets. The UMETRICS team updated 4 labels to "Yes" (keeping the labels of the remaining pairs). After the updated labels were submitted, 15 pairs were labeled as "Yes", 66 labeled "No" and 19 labeled "Unsure".

Next, because we had only 15 positive matches, we decided to obtain more labeled pairs. We discussed (via email) and asked the UMETRICS team to label at least 100-200 more record pairs to obtain a sufficient number of positive matches. Following this, we internally decided to obtain labeled record pairs in two iterations, with 100 record pairs per iteration[6]. The first iteration produced 29 "Yes" pairs, 64 "No", and 7 "Unsure". The second iteration produced 24 "Yes", 72 "No", and 4 "Unsure".

We now have 300 labeled pairs, consisting of 68 "Yes", 202 "No", and 30 "Unsure". Because we have obtained a sufficient number of positive matches, we stopped seeking more labeled pairs.

Debugging the Labeled Sample: Next, since the labeled pairs will be used to select and train a matcher, any labeling errors can impact the predicted matches. To minimize this impact, we decided to debug the labels.

To do so, we used leave-one-out cross-validation: we trained an ML matcher on all labeled record pairs except one, applied the matcher to predict the label for the left-out record pair, compared this predicted label with the label given by the UMETRICS team, and repeated the process. We used random forest as the ML matcher, and removed the unsure and sure matches (record pairs that satisfy M_1) from the labeled data before debugging[7]. We observed the following discrepancies:

(D_1) Record pairs were predicted matches, but labeled non-matches if the award titles were very similar but the award title in the "USDAProjected" table included the suffix "NC/NRSP."

(D_2) Record pairs were predicted matches but labeled non-matches if the award numbers were different but the award titles were the same or very similar.

(D_3) Record pairs were predicted matches but labeled a mix of matches and non-matches if the award number was missing from "USDAProjected" but the award titles were very similar.

We shared example record pairs (using Google Sheets) for each of the above discrepancies, and discussed via email and face-to-face meetings with the UMETRICS team. This team (based on their domain knowledge) decided that all labels in D_1 should be updated as unsure (even they did not know if these were matches). All labels in D_2 should be retained. For D_3, the labels must be updated as matches if the transaction dates for the awards are within a difference of few years (e.g., two years). This produced a final set of 300 labeled pairs, consisting of 68 "Yes", 200 "No", and 32 "Unsure."

9 MATCHING

We now use the above set of 300 labeled record pairs to find matches between the "UMETRICSProjected" and "USDAProjected" tables. Specfically, we used this labeled set to select a good learning-based matcher, then applied this matcher to the pairs in the candidate set C (obtained after blocking) to predict matches.

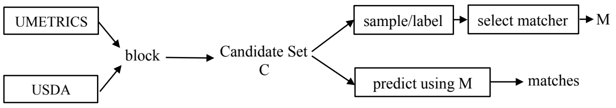


Figure 8: The initial EM workflow for matching the UMETRICS and USDA datasets.

Selecting a Good Matcher: To do this, we used PyMatcher. Let G be the set of 300 labeled pairs. First, we removed the pairs labeled "Unsure" and sure matches (i.e., pairs satisfying M_1) from G, then converted G into a set of feature vectors H (each pair was converted into a feature vector; we used PyMatcher to automatically generate a set of features F, then used F to generate feature vectors).

PyMatcher uses the scikit-learn package, and learning methods in this package cannot work with missing values in the feature vectors. So in the next step we filled in the missing values in the feature vectors in H (with the mean values of the respective columns).

Next, we selected the best (i.e., the most accurate) matcher using five-fold cross validation on H. Among decision tree, SVM, random forest, logistic regression, naive Bayes, and linear regression matchers (supplied by PyMatcher; these matchers in turn use corresponding learning methods in scikit-learn), we found the random forest (RF) matcher had the highest F_1 accuracy (averaged over the five folds).

Next, we debugged the RF matcher to try to improve its accuracy. Again, we used the debugging method described in PyMatcher. This method tried to find the mismatches, i.e., those pairs where the RF matcher predicted incorrectly, then examine these mismatches and take actions to fix them (see [17]). Toward this goal, we randomly split H into two sets I and J, trained the RF matcher on I, then applied it to J and identified mismatches in J, i.e., pairs in J where the label given by the RF matcher differs from the label given in the sampling and labeling process described earlier. We then trained the RF matcher on J and applied it to I, to identify the mismatches in I.

It turned out many mismatches occurred due to award titles having different letter cases. So we added more features to handle this problem[8]. We then performed cross validation to select the best matcher again. Now the decision tree performed the best with 97% precision, 95% recall, and 94.7% F_1, on average. We debugged this matcher using the decision tree matcher debugger of PyMatcher, but were not able to improve accuracy. So we stopped and selected this matcher as the best matcher.

Applying the Selected Matcher: We first trained the decision tree matcher M on the set of feature vectors H (i.e., the set of 300 labeled record pairs). Next, we removed the record pairs satisfying the positive matching rule M_1 from the candidate set C (which was obtained after blocking). There were 210 record pairs that satisfy M_1. Next, we converted the revised set C into a set of feature vectors C' (each pair becomes a feature vector) and imputed the missing values with the mean of the respective columns. Finally, we applied the trained matcher M to C'. This produced 807 matches. Figure 8 shows the overall EM workflow.

Counting also the record pairs that satisfy the positive matching rule, we obtained a total of 1,017 matches. We shared these matches in a CSV file with the UMETRICS team and discussed them in a face-to-face meeting.

[6] Since labeling is time consuming, we wanted to do this in iterations (rather than asking the UMETRICS team to label all 200 pairs in one shot) to make sure we can catch and handle any possible labeling glitches early.

[7] For cross validation, we need to convert each record pair into a feature vector. To do this, we applied PyMatcher to the schemas of the two tables "UMETRICSProjected" and "USDAProjected" to automatically generate a large set of features, which include both string related features (e.g., Jaccard over 3grams, edit distance, etc.) and numeric features (e.g., absolute difference, exact match, etc.). See the PyMatcher homepage for a description of how these features are automatically generated. We then used these features to convert each record pair into a feature vector.

[8] We did not not lowercase all words in the pre-processing step, because our experience with many EM projects suggests that that often resulted in a loss of information. So we only lowercased where necessary.

10 HANDLING MANY COMPLICATIONS

What happened next were many complications regarding whether the current match definition (i.e., what it means to be a match) is incorrect and should be revised, and how to acommodate more data (for the tables), which was accidentally omitted earlier.

Should We Match at the Cluster Level? During the discussion with the UMETRICS team, we observed a gap between their definition of a match between the UMETRICS and USDA awards and our understanding of the same. Specifically, in our set of 1,017 matches, there are many one-to-many matches, e.g., a record in the "UMETRICSProjected" table matches many records in the "USDAProjected" table. The UMETRICS team insisted that matches should be one-to-one, i.e., a record in "UMETRICSProjected" should match at most one record in "USDAProjected".

We were confused by this requirement. Recall from Section 3 that a grant given to a project may be distributed to many smaller projects (e.g., one per an academic year, or one per CS and one per biology) in the same university, and this information will be recorded in multiple entries. For instance, multiple records in "USDAProjected" can contain information about the exact same award, but for different academic years (e.g., a research group may receive a 3-year award; it can send 3 annual reports to USDA, resulting in 3 records in USDA about this award). Given this, a record in "UMETRICSProjected" can match many records in "USDAProjected" and vice versa.

Upon further discussion, it turned out that what the UMETRICS team really wanted is this. As mentioned earlier, a project may last for many years, and may be associated with many sub-awards. Each sub-award is captured by a record in a table. So the UMETRICS team wanted to cluster the records in each table, such that all sub-awards go into the same cluster. They then wanted to match these clusters. At this level, insisting that the matches be one-to-one, i.e., a cluster in "UMETRICSProjected" match at most one cluster in "USDAProjected" makes sense.

Unfortunately, since this desire was not conveyed to us earlier (they were not even aware of this sub-award problem originally), we already performed matching at the record level (not at the cluster level), and at this level one-to-many and many-to-one matches make sense.

We then analyzed the one-to-one, one-to-many, and many-to-one match predictions and shared our analysis with the UMETRICS team. Our goal was to show examples of these and their frequency in the set of matches. Tthe reasoning is that if a problem affects only a small number of matches, then it is not worth spending a lot of effort to solve that problem.

We had another discussion with the UMETRICS team. There they decided that the problem does not affect many matches and so probably would have an insignificant effect on their domain science (which relies on these matches). So they opted to keep matching at the record level, and kept the definition that one record in the "UMETRICSProjected" table can match many records in the "USDAProjected" table, and vice versa. This would avoid a redo of the project, i.e., starting by clustering the records, then trying to match the clusters.

Revising the Match Definition: Recall that the current UMETRICS repository already has a rule-based matching system, and that our goal is to beat that system. To do so, the UMETRICS team logged into UMETRICS and applied the rule-based matching system to the same data (i.e., the "UMETRICSProjected" and "USDAProjected" tables) to obtain matches. The idea was to compute and compare the precision and recall of the rule-based system to those of our system.

During this process, they discovered that another positive matching rule existed: *"If the award number in UMETRICS matches the project number in USDA, then the record pair is considered a match".* This rule could be used to pull more sure matches directly from the "UMETRICSProjected" and "USDAProjected" tables[9].

Thus, the match definition was revised to include this rule. The question is how would this complicate the EM process. The how-to guide of PyMatcher spells out a well-defined sequence of steps for EM (e.g., blocking, sampling, etc.). We trained the students to follow this sequence. By default, a revised match definition would trigger a re-do of this sequence, which is time consuming. For example, blocking can be easily revised by just using the new positive matching rule to add more record pairs to the candidate set C. But sampling and labeling would be time consuming. We need to take a *random* sample of the candidate set C, and since C has changed, we need to re-do the random sampling and label any new pair in the sample (that has not been labeled before). *While labeling a small number of pairs seems trivial, in practice it can take days, as we need to upload the pairs to the cloud-based labeling tool, then wait for the* UMETRICS *team, which often cannot label right away, due to other obligations.*

Thus, we did not want to redo the EM process from scratch. To avoid this, first we checked whether the ML matcher was already learning the above positive rule from the labeled data. Specifically, we checked and found that there were 411 pairs in C that satisfy that rule, and out of those 397 were predicted as matches. Thus, our matcher correctly predicted most of the pairs that satisfy the rule as matches. Next, we checked if blocking discarded any pairs that satisfy the new rule. We found that the Cartesian product of the "UMETRICSProjected" and "USDAProjected" tables contain 473 such pairs, but C included only 411. Thus, blocking discarded too many pairs. So the new positive matching rule does have an effect on the EM process, and something must be done.

Our solution was to leave the current EM workflow alone and create a new EM workflow (which will be used together with the current EM workflow). In this new workflow, we wrote a Python script to apply the new matching rule directly to the input tables "UMETRICSProjected" and "USDAProjected" to obtain the sure matches. *This new EM workflow can be viewed as a "patch" of the current EM workflow.* If a pair is predicted by both the old and new workflows, then we take the prediction of the new workflow. *An advantage of this approach is that we did not have to label any new pairs.*

Handling More Data: When the UMETRICS team inspected the matches produced by the rule-based matcher at UMETRICS, they found new award numbers that they had not seen before. Further inspection revealed that the original table "UMETRICSAwardAggMatching" was incomplete, missing 496 records.

We received these extra records in a CSV file. Revising the table "UMETRICSAwardAggMatching" (to add these records) and redoing the EM process following the PyMatcher's how-to guide would be time consuming (all the steps, blocking, sampling, labeling, matching, etc. must have been redone). So we followed the same strategy used to handle a change in the match definition. *We keep the current EM workflow "as is" or make only minimal changes to it, then "patch" it with new EM workflows.* This way

[9] "AwardNumber" is already in table "UMETRICSProjected". "ProjectNumber" is not in table "USDAProjected". However, it is in table "USDAAwardMatching" and thus can be easily added to "USDAProjected".

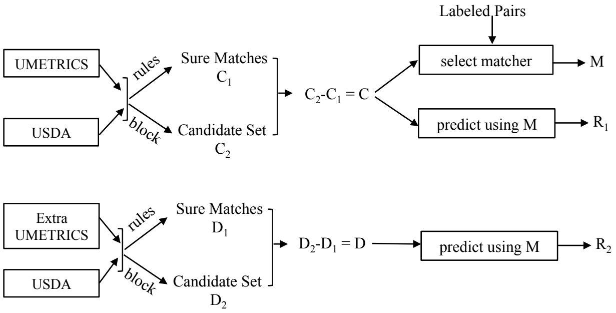

Figure 9: The updated EM workflow to accommodate extra data and positive matching rules.

we minimized the changes we had to make to our existing workflow, and minimized the total human effort. This resulted in the following procedure (see Figure 9):

1. Apply the sure-match rules to the original input tables. Specifically, apply rule M_1 (from the match definition) and the positive matching rule involving award number and project number to obtain a set C_1.
2. Apply blocking as before to obtain a candidate set C_2.
3. Remove the sure matches (C_1) from C_2 to obtain a set C; this set C is what will be predicted as matches and non-matches.
4. Use the labeled set without the sure matches to train the best matcher and predict on C, and call the resulting matches R_1.
5. Repeat Steps 1-3 for the extra records in UMETRICS and the whole USDA table until a set of sure matches D_1 and a candidate set D are obtained.
6. Apply the best matcher obtained using labeled data (in Step 4) to D to get a set of match predictions R_2.
7. Return the union of C_1, D_1, R_1, and R_2 as the set of matches.

The above procedure produced 1,137 matches. Specifically, we first applied the sure-matches rule to obtain 683 sure matches from the original input tables and 55 sure matches from the additional records. Then we applied blocking and removed the sure matches. This resulted in a candidate set from the original input tables having 2,556 record pairs and a candidate set from the extra records having 1,220 record pairs. Next, we removed the sure matches from the labeled set and selected the best matcher, which was a decision tree matcher. Finally, we applied this matcher to the candidate sets and obtained 399 matches from the original tables and no matches from the additional records.

11 ESTIMATING ACCURACY

Now that we had finally obtained the matches in our approach (and praying that no more complications arise), we were ready to estimate the accuracies of our solution and the rule-based matcher deployed at UMETRICS, which we will call the IRIS matcher (IRIS is the organization that manages UMETRICS).

Ideally, if we have the true labels for the record pairs in the Cartesian product of the input tables, then we can compute the accuracy, i.e., precision and recall. However, having the true labels would mean that there was no need to do EM in the first place. To address this, we met with the UMETRICS team and decided to follow the accuracy estimation approach described in the Corleone paper [13]: We proceeded as follows:

(1) To use the Corleone approach, both the IRIS matches and our predicted matches *must be from the same candidate set of record pairs*. So we looked for any award number-accession number pairs from the IRIS matches that were not included in our consolidated candidate set (from the original and extra records), which is $E = C_1 \cup C_2 \cup D_1 \cup D_2$ (see Figure 9). We found only one such pair. The UMETRICS team said that the award number in question was a terminated award (no longer valid) and could be discarded safely.

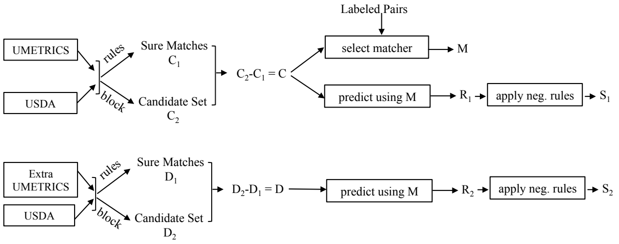

Figure 10: The final EM workflow with negative rules applied to the results of the learning-based matcher.

(2) We took a random sample of 200 record pairs from the consolidated candidate set E, uploaded it to the cloud-based labeling tool, and asked the UMETRICS team to label. Then we used E to estimate precision and recall, using Formulas 2-3 in Section 6.1 of the Corleone paper [13]. We estimated that our matcher had precision in the range (79.6%, 86.01%) and recall in (96.8%, 99.42%). The IRIS matcher had precision in the range (100%, 100%) and recall in (52.7%, 62.07%). Thus, the IRIS matcher had higher precision, but lower recall, compared to our matcher.

(3) To reduce the large interval sizes of the estimated precision and recall, we asked the UMETRICS team to label another 200 randomly sampled record pairs. Applying the same estimation procedure to all 400 labeled pairs[10], we estimated that our matcher had precision in (75.2%, 80.3%) and recall in (98.1%, 99.6%). The IRIS matcher had precision in (100%, 100%) and recall in (65.1%, 71.8%). The UMETRICS team liked the fact that our matcher was able to find more matches than the IRIS matcher.

12 IMPROVING ACCURACY USING RULES

Though we received positive feedback from the UMETRICS team, we had an internal discussion on how to improve the precision of our matcher. We decided to apply hand-crafted rules to the output of our learning-based matcher. The rules would allow us to make "localized changes". This hopefully would improve precision without reducing recall a lot.

Specifically, we wanted to solicit domain-specific rules from the domain experts (the UMETRICS team) to reduce the number of false positives, then apply these rules to the predictions of our learning-based matcher. To do so, we had an email conversation with the UMETRICS team to understand how to reduce the number of false positives. The UMETRICS team examined the predicted matches, then defined a negative rule (i.e., the rule will flip matches to non-matches), which we discuss next.

The Negative Matching Rule: This rule states that a record pair is considered a non-match if one of the following conditions is satisfied:

- Award numbers from UMETRICS and USDA are "comparable," (defined below), and they are not the same.
- Award number from UMETRICS and project number from USDA are "comparable," and they are not the same.

[10] The set of 400 labeled pairs consists of 92 "Yes", 292 "No", and 16 "Unsure". The estimation procedure ignores the "Unsure" pairs.

Here "comparable" means that the award numbers are considered (for this rule) only if they have the same pattern. For example, the UMETRICS award number "03-CS-112313000-031" and the USDA award number "2001-34101-10526" are not comparable because they follow different patterns (i.e., "##-XX-########-###," and "YYYY-#####-#####", respectively, where "#" is any number, "X" is any character, and "YYYY" is a four-digit year).

The UMETRICS award number "WIS01560" and the USDA project number "WIS04509" are comparable because they follow the same pattern "WIS#####" (but because the values are different this pair will be considered a non-match). The UMETRICS team gave us the list of possible patterns for the award numbers from UMETRICS and USDA as well as the project numbers from USDA (not shown for space reasons).

Applying the Negative Matching Rule: We applied the negative rule (provided by the UMETRICS team) to the matches and estimated the accuracy again. Conceptually, the learning-based matcher followed by rules could be considered just another matcher like the IRIS matcher. The updated EM procedure is shown in Figure 10. Here, we applied the negative rules to the sets of matches R_1 and R_2 (obtained from the learning-based matcher). The final set of matches is the union of C_1, D_1, S_1, and S_2.

We consider this new workflow a new matcher. Because the candidate set of this new matcher is the same as that of the learning-based matcher from our previous iteration, we can reuse the labeled set (of 400 pairs). Again, we used the Corleone approach to estimate the new precision and recall.

We found that our new matcher (decision tree followed by negative rules) had precision (96.7%, 98.8%) and recall (94.2%, 97.05%). In contrast, the learning-based matcher (without negative rules) had precision (75.2%, 80.3%) and recall (98.1%, 99.6%). The IRIS matcher had the precision (100%, 100%) and recall (65.1%, 71.8%). Thus, compared to the IRIS matcher, our learning-based matcher followed by rules has slightly lower precision, but much higher recall. The final result set has 845 matches, and was shared with the UMETRICS team in a CSV file that uses "UniqueAwardNumber"and "Accession Number" pairs to capture the matches.

The UMETRICS team was delighted with the result, and their director sent the following email:

> *That is really stupendous news! I'm surprised to see how much you were able to raise the precision and recall ... Thanks for all your brilliant work on this.*

The Next Steps: As the next immediate step, the UMETRICS team wanted us to package the matcher so that they could move it into the UMETRICS repository to do matching for other data slices. It is similar to moving a workflow that was developed in the development stage into production.

This step raises three challenges. First, the EM workflow is rather complex. It has rules at multiple places (to find sure matches and to update the predictions from the learning-based matcher) and a machine learning-based matcher. So we need to find out how to represent it effectively. Second, the new data may be dirty, so we need to monitor the accuracy of the match results[11]. Finally, if the accuracy is not good enough, we need a way to move back to the development stage and update the EM workflow. Currently, we are working with the UMETRICS team to address these challenges.

13 CHALLENGES FOR CURRENT ENTITY MATCHING SOLUTIONS

The end-to-end EM case study that we have just described raises many challenges for the current EM solutions and systems. In what follows we discuss the main challenges[12].

The Need for How-To Guides: It should be clear from the case study that it is extremely hard, if not impossible, to fully automate the EM process, end to end. The fundamental reason is because at the start, the user does not even fully understand the data, the match defition, and even what he or she wants.

Here, for instance, initially the users were not aware that some records were missing, or that the match definition was incomplete, or that they actually wanted to match at cluster level, and more. *As a result, most EM projects are really a "conversation" between the EM team and the domain expert team, and this conversation moves forward as new results were produced and discussed.*

If this is the case, then it follows that it is critical to have some how-to guides that tell both teams how to conduct this conversation, what to do first, what to do second, and so on.

Such guides are completely missing from most current EM solutions and systems. While PyMatcher does have an initial how-to guide, as this case study makes clear, that guide is still quite preliminary. It does not provide guidance to many steps such as how to converge on a match definition, and how to collaboratively label effectively, among others. In practice, guides are likely to be complex, as users want to do so many different things, and complications will arise (as seen in this study).

Many New Pain Points: Current EM work has largely focused on blocking and matching. This study makes clear that there are many pain points, i.e., *steps that require a lot of work from users*, that current EM research has ignored or not been aware of. For example, how to effectively explore, understand, and clean the tables? While data exploration and cleaning have received significant attention, most of this work has been carried out "in isolation", independently of work in EM, based on the implicit argument that these problems are orthogonal to EM. We believe, however, that *these problems should be solved in an EM-centric way*, i.e., we should not just try to understand the tables for understanding's sake, but rather to understand *only things that are important for subsequent EM.*

Other examples of pain points, which require a lot of work from users, include how to quickly converge to a match definition, how to label collaboratively, and how to update an EM workflow if something (e.g., data, match definition) has changed. We argue that more effort should be devoted to addressing these real pain points in practice.

Different Solutions for Different Parts of the Data: The vast majority of current EM works treat the input data as of uniform quality, but in practice, this is rarely the case. Instead, the data commonly contains dirty data of varying degree, incorrect

[11] This is typically done by taking a random sample of the predicted matches at regular intervals, manually labeling it, then using the labeled sample to estimate the accuracy. See [28] for an example of monitoring the accuracy of an e-commerce product classification system in production.

[12] In addition to this case study, in the past 3.5 years we have also worked on more than 20 other EM cases for 12 companies and domain science groups [14]. The challenges that we discuss here are not specific to the case stufy of this paper. They arise in many of these other EM cases as well. Further, even though we used PyMatcher in this case study, given the detailed examination of 33 other free and paid EM tools conducted in [18], we believe many of the challenges discussed here would also arise if we were to use these other EM tools.

data, and incomplete data that even domain experts cannot match. It makes no sense trying to debug the system, then spending more time and money to match incorrect and incomplete data. As a result, it is important to have tools that help the user explore and understand the data, then ways to help the user "split" the data into different parts and develop different EM strategies for different parts of the data, as illustrated in this case study (e.g., see Figure 10).

Support for Easy Collaboration: We found that in many EM settings there is actually a team of people wanting to work on the problem. Most often they collaborate to label a data set, debug, clean the data, etc. For example, in this case study the UMETRICS team collaboratively labeled and helped debug the labeled data. However, most current EM tools are rudimentary in helping users collaborate easily and effectively. Since users often sit in different locations, it is important that such tools are cloud-based, to enable easy collaboration.

Handling Changes Along the Way: No matter how careful we are at the start, changes will likely arise along the way, as the users gain more knowledge and may change their mind. So any effective EM solution need to have good ways to handle such changes. This case study suggested a way to do so, by minimally modifying existing EM workflows and patching them by adding more EM workflows. More research is necessary to evaluate and develop solutions for this problem.

Managing Machine Learning "in the Wild": It is clear that ML can be quite effective. This case study suggests that it can help significantly improve recall while retaining high precision, compared to rule-based EM solutions. But the study also shows that deploying even the simplest ML method "in the wild" raises all kinds of challenges, such as labeling, coping with new data, etc. Further, the study also suggests that *the best EM solutions are likely to involve a combination of ML and rules (such as the negative matching rule in this study).*

Designing EM System Architectures: Finally, this case study raises fundamental questions about what should be the "right" EM system architecture. It implies that a stand-alone monolithic EM system is not likely to work well, because the users often want to try so many different things and many complications often arise.

Observe that in this study, every time there was a complication, we had to devise a new EM workflow and then wrote Python script (that uses PyMatcher's commands) to implement the new workflow. This is more difficult to do with a stand-alone systems. Instead, the study suggests that an "open-world" EM architecture, such as the one PyMatcher has adopted, where the system is a set of tools that interoperate with one another and also with data science tool in PyData, is more promising. But far more studies and research are necessary to settle this question. For a more detailed discussion on this topic, see our recent work [14], which discusses the system aspects of Magellan.

14 CONCLUSIONS

In this paper we have described in detail a case study of entity matching, from raw data to the matches. We have highlighted aspects that previous EM work has ignored. Our case study clearly demonstrates many challenges for current EM work and systems. We hope that this case study on how "sausage is made" can help EM researchers understand better the challenges of the EM process, and thus develop more effective EM solutions.

Acknowledgments: We thank the anonymous reviewers for invaluable suggestions that significantly improve this paper. This work is supported by UW-Madison UW2020 grant and NSF grant IIS-1564282, and by Google, Informatica, Johnson Controls, American Family Insurance, and WalmartLabs.

ABSTRACT

Copernicus is the European programme for monitoring the Earth. It consists of a set of complex systems that collect data from satellites and in-situ sensors, process this data, and provide users with reliable and up-to-date information on a range of environmental and security issues. Information extracted from Copernicus data is made available to users through Copernicus services addressing six thematic areas: land, marine, atmosphere, climate, emergency and security. The data and information processed and disseminated puts Copernicus at the forefront of the big data paradigm and gives rise to all relevant challenges: volume, velocity, variety, veracity and value. In this paper we discuss the challenges of big Copernicus data and how the Copernicus programme is attempting to deal with them. We also present lessons learned from our project Copernicus App Lab, which takes Copernicus services information and makes it available on the Web using semantic technologies to aid its take up by mobile developers. We also discuss open problems for information retrieval, database and knowledge management researchers in the context of Copernicus.

1 INTRODUCTION

Earth observation (EO) is the gathering of data about our planet's physical, chemical and biological systems via satellite remote sensing technologies supplemented by Earth surveying techniques. The Landsat program of the US was the first international program that made large amounts of EO data open and freely available. *Copernicus*, the European programme for monitoring the Earth, is currently the world's biggest EO programme. It consists of a set of complex systems that collect data from satellites and in-situ sensors, process this data and provide users with reliable and up-to-date information on a range of environmental and security issues. The data of the Copernicus programme is provided by a group of missions created by ESA, which is called *Sentinels*, and the *contributing missions*, which are operated by national, European or international organizations. Copernicus data is made available under a free, full and open data policy. Information extracted from this data is also made freely available to users through the *Copernicus services* which address six thematic areas: land, marine, atmosphere, climate, emergency and security.

The Copernicus programme offers myriad forms of data that enable citizens, businesses, public authorities, policy makers, scientists, and entrepreneurs to gain insights into our planet on a free, open, and comprehensive basis. By making the vast majority of its data, analyses, forecasts, and maps freely available and accessible, Copernicus contributes to the development of innovative applications and services that seek to make our world safer, healthier, and economically stronger. However, the potential (in both societal and economic terms) of these huge amounts of data can only be fully exploited if using them is made as simple as possible. Therefore, the straightforward data access every downstream service developer requires must also be combined with in-depth knowledge of EO data processing. The Copernicus App Lab[1] aims to address these specific challenges by bridging the digital divide between the established, science-driven EO community and the young, innovative, entrepreneurial world of mobile development.

*Work performed while at VITO

[1] http://www.app-lab.eu/

Copernicus App Lab is a two year project (November 2016 to October 2018) funded by the European Commission under the H2020 programme. The consortium consists of the company AZO[2] (project coordinator), the National and Kapodistrian University of Athens[3], the companies Terradue[4] and RAMANI[5] and the Flemish research institute VITO[6]. The main objective of Copernicus App Lab is to make Earth observation data produced by the Copernicus programme available on the Web as *linked data* to aid its use by users that might not be Earth observation experts.

Copernicus App Lab targets the *volume* and *variety* challenges of Copernicus data, and it follows the path of previous research projects TELEIOS[7], LEO[8] and MELODIES[9]. Under the lead of the National and Kapodistrian University of Athens, these three projects pioneered the use of linked geospatial data in the EO domain, and demonstrated the potential of linked data and semantic web technologies in the Copernicus setting by developing prototype environmental and business applications (e.g., wild-fire monitoring and burn scar mapping [18, 20], precision farming [9], maritime security [8] etc.).

Copernicus App Lab goes beyond these projects in the following important ways:

- It develops a software architecture that enables on demand access to Copernicus data using the well-known OPeNDAP framework and the geospatial ontology-based data access system Ontop-spatial [5]. Now users and application developers do not need to worry about having to download data or having to learn the details of sophisticated data formats for EO data.
- It brings computing resources close to the data by making the Copernicus App lab tools available as Docker images that are deployed in the Terradue cloud platform as cloud services. The platform allows application developers to access Copernicus data and carry out massively parallel processing without the need to download the data in their own servers and carry out the processing locally.
- It enables search engines like Google to treat datasets produced by Copernicus as "entities" in their own right and store knowledge about them in their internal knowledge graph. In this way, search engines will be able to answer sophisticated users questions involving datasets such as the following: "Is there a land cover dataset produced by the European Environmental Agency covering the area of Torino, Italy?"

A demo paper describing the application scenario presented in this paper won the "best demo award" prize at CIKM 2018 [3]. Shorter presentations of the Copernicus App Lab project also appears in [2]. Compared with the present paper, these papers emphasize only the semantic technologies developed and only the big data dimensions respectively.

The above innovations of Copernicus App Lab are discussed in detail in the rest of the paper, which is organized as follows. Section 2 presents the related work. Section 3 presents the conceptual architecture of the Copernicus integrated ground segment and the software architecture of Copernicus App Lab. Section 4 presents a simple case study which demonstrates the technologies of Copernicus App Lab. Section 5 discusses lessons learned by the use of these technologies and discusses open problems that need to be tackled by future research. Finally, Section 6 concludes the paper.

2 RELATED WORK

Open EO data that are currently made available by the Copernicus and Landsat programs are not following the linked data paradigm. Therefore, from the perspective of a user, the EO data and other kinds of geospatial data necessary to satisfy his or her information need can only be found in different data silos, where each silo may contain only part of the needed data. Opening up these silos by publishing their contents as RDF and interlinking them with semantic connections will allow the development of data analytics applications with great environmental and financial value.

Previous projects TELEIOS, LEO and Melodies funded by FP7 ICT, have demonstrated the use of linked data in Earth Observation. The European project TELEIOS was the first project internationally that has introduced the linked data paradigm to the EO domain, and developed prototype applications that are based on transforming EO products into RDF, and combining them with linked geospatial data. TELEIOS concentrated on developing data models, query languages, scalable query evaluation techniques, and efficient data-management systems that can be used to prototype the applications of linked EO data [18]. The European project LEO was to go beyond TELEIOS by designing and implementing software supporting the complete life cycle of linked open EO data and its combination with linked geospatial data and by developing a precision farming application that heavily utilizes such data [9]. The MELODIES project developed new data-intensive environmental services based on data from Earth Observation satellites, government databases, national and European agencies and more [7]. We focused on the capabilities and benefits of the project's "technical platform", which applied cloud computing and Linked Data technologies to enable the development of services, providing flexibility and scalability.

One of the most important objectives achieved by the aforementioned projects, was capturing the life cycle of open EO data and the associated entities, roles and processes of public bodies that make this data available, and bring the linked data paradigm to EO data centers by re-engineering a complete data science pipeline for EO data [16, 19].

3 THE COPERNICUS APP LAB ARCHITECTURE

Figure 1 presents the conceptual architecture of the *Copernicus integrated ground segment* and the Copernicus App Lab software architecture. A *ground segment* is the hardware and software infrastructure where raw data, often from multiple satellite missions, is ingested, processed, cataloged, and archived. The processing results in the creation of various *standard products* (level 1, 2, and so forth in EO jargon; raw data is level 0) together with extensive metadata describing them.

In the lower part of the figure, the Copernicus *data sources* are shown. These are Sentinel data from ESA, Sentinel data from the European Organisation for the Exploitation of Meteorological Satellites (EUMETSAT), satellite data from contributing missions

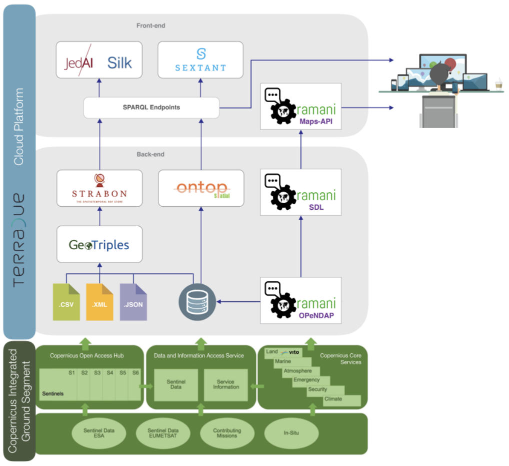

Figure 1: The Copernicus integrated ground segment and the Copernicus App Lab software architecture

(e.g., the RADARSAT-2 mission of Canada or the PROBA-V mission of Belgium) and in-situ data (e.g., data from sensors measuring major air pollutants). The next layer makes Copernicus data and information available to interested parties in three ways: via the Copernicus Open Access Hub, via the Copernicus Core Services and via the Data and Information Access Service (most often known by its acronym DIAS).

The Copernicus Open Access Hub[10] is currently the primary means of accessing Sentinel data. It offers a simple graphical interface that enables users to specify the extent of the geographical area one is interested in (by drawing a bounding box or a polygon). The user may also complete a search interface with information regarding the sensing period, the satellite, the platform, the sensor mode, the polarization etc. If a relevant product is found, the product can be downloaded to the user's computer.

The six core Copernicus services (land, marine, atmosphere, climate, emergency and security) are administered by European entrusted entities (e.g., the Copernicus App Lab partner VITO administers the global land service), whose job is to process Copernicus data and produce higher-level products (*information* in the Copernicus jargon) that are of importance in the corresponding thematic area (e.g., leaf-area index data in the case of the global land service).

The DIAS is not yet fully developed. In December 2017, the European Commission has awarded four contracts to industrial consortia for the development of four cloud-based DIAS platforms. A fifth DIAS is developed by EUMETSAT in collaboration with the French company Mercator Ocean and the European Center for Medium-Range Weather Forecasts (ECWMF). The five DIAS will bring computing resources close to the data and enable an even greater commercial exploitation of Copernicus data. The first versions of the five DIAS are now open to demo-users.

As we have already mentioned in the introduction, the goal of Copernicus App Lab is to make earth observation data produced by the Copernicus programme available as linked data to aid its use by developers that might not be experts in Earth Observation. The software architecture presented in the top two layers of Figure 1 has been designed for achieving this goal. Since none of the DIAS platforms was available when Copernicus App Lab started, all the software components of the project run in the Terradue cloud platform[11]. Terradue Cloud Platform is built as a Hybrid Cloud platform. The primary purpose of the Hybrid Cloud Platform is to facilitate the management of elastic compute resources, with low cost scale-out capabilities. It relies on the concept of an application integration environment (PaaS, or Platform-as-a-Service) and a production environment. Terradue Cloud Platform builds on three major outcomes of the recent developments in Computer Science and Web technology - Cloud Computing, Open Data repositories, and Web Services interoperability. The platform allows cloud orchestration, storage virtualisation, and virtual machine provisioning, as well as application burst-loading and scaling on third-party cloud infrastructures. Within the Terradue cloud platform, the developer cloud sandbox service provides a platform-as-a-service (PaaS) environment to prepare data and processors. It has been designed with the goal to automate the deployment of the resulting EO applications to any cloud computing facility that can offer storage and computing resources (e.g., Amazon Web services). In this manner, the AppLab Cloud Architecture provides the infrastructure (cloud environment) to bring together all the elements of the Copernicus App Lab, and ensure operations.

In Copernicus App Lab, access to Copernicus data and information can be achieved in two ways: (i) by downloading the data via the Copernicus Open Access Hub or the Web sites of individual Copernicus services, and (ii) via the popular OPeNDAP framework[12] for accessing scientific data. In the first case (workflow on the left part of the two top layers of Figure 1), the downloaded data should then transformed into RDF using the tool GeoTriples [23] or scripts written especially for this task. GeoTriples enables the transformation of geospatial data stored in raw files (shapefiles, CSV, KML, XML, GML and GeoJSON) and spatially-enabled RDBMS (PostGIS and MonetDB) into RDF graphs using well-known geospatial vocabularies e.g., the vocabulary of the Open Geospatial Consortium (OGC) standard GeoSPARQL [27]. The performance of GeoTriples has been studied experimentally in [22] using large publicly available geospatial datasets. It has been shown that GeoTriples is very efficient especially when its mapping processor is implemented using Apache Hadoop.

After Copernicus data has been transformed into RDF, it can be stored in the spatiotemporal RDF store Strabon [6, 21]. Strabon can store and query linked geospatial data that changes over time. It has been shown to be the most efficient spatiotemporal RDF store available today using the benchmark Geographica in [6, 15].

Copernicus data stored in Strabon may also be interlinked with other relevant data (e.g., a dataset that gives the land cover of certain areas might be interlinked with OpenStreetMap data for the same areas). To do this in Copernicus App Lab, we use the interlinking tools JedAI and Silk. JedAI is a toolkit for entity resolution and its multi-core version has been shown to be scalable to very large datasets [25]. Silk is a well-known framework for interlinking RDF datasets which we have extended to deal with geospatial and temporal relations [28].

The above way of accessing and using Copernicus data as linked data, has been introduced in previous projects TELEIOS, LEO and MELODIES discussed in the introduction, and it is not the focus of this paper. The *novel way of accessing Copernicus data and information* in Copernicus App Lab is captured by the

[10] https://scihub.copernicus.eu/

[11] https://www.terradue.com/portal/

[12] https://www.opendap.org/

workflow on the right part of the two top layers of Figure 1, and it is based on the popular *OPeNDAP framework* for accessing scientific data. OPeNDAP provides a powerful data translation facility so that users do not need to know the detailed formats of data stored in servers, and can simply use a client that supports a model they are comfortable with. The *streaming data library (SDL)* implemented by RAMANI communicates with the OPeNDAP server and receives Copernicus services data as *streams*. In the rest of this section, we describe how we can access Copernicus data on-the-fly using this workflow.

3.1 Enhance Cataloguing of Copernicus data streams

Copernicus Service Providers (CSP) publish their data holdings in a variety of data formats and access protocols (ftp, http, dap), with various metadata co-existing, and data and metadata either separate or combined in one container. In order to enrich the metadata coupled with the CSP's offerings, we set a minimum metadata standard which should be followed by interested parties in order to streamline the classification, mapping and RDF linkage. We present a mediation approach that facilitates multiple Metadata Standards to co-exist but are semantically harmonized through SPARQL Query. A command-line tool was build and published, entitled "DRS-validator", that validates a CSP's datasets exposed through the OPeNDAP interface by checking for compliance with the Data Reference Syntax (DRS) metadata. Given the proliferation of various metadata standards, a tool was developed that can translate between metadata conventions. In order to harvest the metadata, a Content Management System (CMS) was developed and published as a service allowing the CSP's to manage the metadata of their datasets, which allows them to mutate as and when they choose to expose them through the DAP. Completeness of metadata can be checked globally at SDL level or at an individual dataset level. Since we also use the netCDF variable attributes and global attributes to perform machine-to-machine communication of metadata, the publishing and then harvesting of metadata from CSPs is recurrent by design. For communicating metadata, we use the NetCDF Markup Language (NcML) interface service. This extends a dataset's OPeNDAP Dataset Attribute Structure (DAS) and Dataset Descriptor Structure (DDS) into a single XML-formatted document. The DDS describes the dataset's structure and the relationships between its variables, and the DAS provides information about the variables themselves. The returned document may include information about both the data server itself (such as server functions implemented), and the metadata and dataset referenced in the URL. To ensure that metadata contributes to the discoverability of a datasets, a tool was implemented that provides recommendations for metadata attributes that can be added to datasets exposed through the DAP to facilitate discovery of those using standard metadata searches.

Depending on the requirements imposed upon us by the other open-data, additional analytical functionality is created to ensure the geospatial data streams are commensurate with these requirements. We added a software layer to the SDL, entitled RAMANI Cloud Analytics, allowing on-the-fly spatial and temporal aggregations such that downstream services may request for derived variables to be returned, such as a long-term (moving) average (summer-time) or spatial central tendency (city-average), ensuring that the return is fully commensurate with the intrinsic requirements of the other data to be linked. The technology being used in this stage consists of background IP (BIPR) of RAMANI B.V., with the development of an additional layer for supporting Open Linked Data and Web Coverage Service (WCS). We designed a backend solution capable of providing analytics on data via linked relations. Basic analytical modelling processes can be represented straightforwardly by starting with data and do calculations/analysis that result in more data, which we eventually synthesize into a pithy result, like part of an App or a presentation. Also, the analysis can easily be rerun, if, for example, the data is extended in time, otherwise modified, or is replaced by a different data source providing similar variables based on semantically provided heuristics (e.g. based on "hasName" or "hasUnit"). To allow fast processing we developed a set of containers of the server-side analytics package. Then we used Kubernetes[13] for managing the containerized applications across multiple hosts, that provides the mechanisms for deployment, maintenance, and scaling of the RAMANI Cloud Analytics backend services. Kubernetes builds upon a decade and a half of experience at Google running production workloads at scale using a system called Borg, combined with best-of-breed ideas and practices from the community.

The SDL is also extended with Semantic Web standards providing a framework for explicitly describing the data models implicit in EO and other GRIDded data streams to enhance downstream display and manipulation of data. This provides a framework where multiple metadata standards can be described. Most importantly, these data models and metadata standards can be interrelated, a key step in creating interoperability, and an important step in being able to map various metadata formats in compliance with other standards, e.g. as put forward by the INPIRE Spatial Data Services Working Group. First we developed an Abstract Model capable of providing the basis of the semantics for the linked RDFS. Based on a proof-of-concept use case, an example of a RDF/XML expression for a remote OPeNDAP dataset[14] sourced from the Copernicus Land Monitoring programme was created. This dataset is published using a local deployment of the DAP at VITO. We then implemented a vetted RDF crawler that handles non-standard metadata and supports reasoners, query languages, parsers and serializers. The query languages can create new triples based on query matches (CONSTRUCT) and reasoners create virtual triples based on the stated interrelationships, so we have a framework for creating crosswalks between metadata standards, as well as creating code that is independent of the metadata standards. Finally, in case metadata at the source cannot be made compliant with ACDD, the CMS will allow for post-hoc augmentation using NcML blending metadata provided by the source and those required as-per the DRS validator.

In the current version of the Copernicus App Lab software, VITO -as prime contractor of the Copernicus Global Land Service-has engaged with RAMANI and now provides access to the Copernicus Global Land Service using a remote data access protocol facilitating discovery, viewing, and access of their unique Land Monitoring data-products. OPeNDAP and SDL are installed and configured by VITO on a virtual machine running on the VITO hosted PROBA-V mission exploitation platform[15], which has direct access to the data archives of the Copernicus global land service. The original data sources (i.e. Leaf Area Index, from PROBA-V) have been added to the Streaming Data Library (SDL) so their temporal and spatial characteristics are exposed in a queryable manner. Three Copernicus datasets as well as one

[13] http://kubernetes.io

[14] http://land.copernicus.eu/global/products/lai

[15] https://proba-v-mep.esa.int

Proba-V dataset were configured in the initial setup. These are BioPar BA300 (Burnt Area), LAI (Leaf Area Index) and NDVI (Normalised Difference Vegetation Index). The S5 (five-daily composite) TOC (Top of Canopy, i.e. after atmospheric correction) NDVI 100M was supposed to be implemented as a Proba-V dataset. Each dataset also contains a netCDF NCML aggregation, which is automatically updated when new data (a new date) becomes available. Three different services are exposed for each dataset: the OPeNDAP service, the NetcdfSubset service and the NCML service. The installation of OPeNDAP was done using Docker and access to the Copernicus global land and PROBA-V datasets via OPeNDAP is realised by mounting the necessary disks on the virtual machine.

3.2 Querying Copernicus data on-the-fly using GeoSPARQL

The geospatial ontology-based data access (OBDA) system Ontop-spatial [4] is used to make Copernicus data available via OPeNDAP as linked geospatial data, without the need for downloading files and transforming them into RDF. Ontop-spatial is the geospatial extension of the OBDA system Ontop[16] [10]. OBDA systems are able to connect to existing, relational data sources and create virtual semantic graphs on top of them using ontologies and mappings. An ontology provides a conceptual view of the data. Mappings encode how relational data can be mapped into the terms described in the ontologies. The mapping language R2RML is a W3C standard and is commonly used to encode mappings, but a lot of OBDA/RDB2RDF systems also offer a native mapping language. Since Ontop-spatial follows the OBDA paradigm in the geospatial domain, it can be used to create virtual semantic RDF graphs on top of geospatial relational data sources using ontologies and mappings.

Then, the Open Geospatial Consortium standard GeoSPARQL can be used to pose queries to the data using the ontology. As documented in [4], Ontop-spatial also achieves significantly better performance than state-of-the-art RDF stores. An extension of this work described in [5] shows how the system was extended to support raster data sources as well (support for raster data sources has not been foreseen in the GeoSPARQL standard) and it also describes how, using the OBDA approach, one can query both vector and raster data sources combined in a purely transparent way, without the need to extend the GeoSPARQL query language further.

In the context of the work described in this paper, we extend the OBDA paradigm even more, by enabling an OBDA system not only to connect to a non-relational data source, but also to query data sources that are available remotely, without accessing or storing the data locally (e.g., import the datasets into database); the data can be available through a REST API, for example, and can be accessed by the system only after a GeoSPARQL query is fired. Ontop-spatial has been extended with an adapter that enables it to retrieve data from an OPeNDAP server, create a table view on-the-fly, populate it with this data and create virtual semantic geospatial graphs on top of them. In order to use OPeNDAP as a new kind of data source, Ontop-spatial utilizes the system MadIS[17] as a back-end. MadIS is an extensible relational database system built on top of the APSW SQLite wrapper [11]. It provides a Python interface so that users can easily implement user-defined functions (UDFs) as rows, aggregate functions, or virtual tables. We used MadIS to create a new UDF, named `Opendap`, that is able to create and populate a virtual table on-the-fly with data retrieved from an OPeNDAP server. In this way, Ontop-spatial enables users to pose GeoSPARQL queries on top of OPeNDAP data sources without materializing any triples or tables. We stress that the relational view that is created is not materialized. The intermediate SQL layer facilitates the data manipulation process, in the sense that we can manipulate the data before they get RDF-ized. In this way we can perform “data cleaning” without (i) changing the data that arrive from the server (ii) changing any intermediate code, such as the opendap function and (ii) without requiring any extra pre-processing steps. In order to be able to integrate MadIS as back-end system of Ontop-spatial, apart from implementing the OPeNDAP virtual table function, we also had to extend its jdbc connector and make several modifications in the core of Ontop code so that it allows connections to non-relational data. The design choice behind our approach to implement the OPeNDAP adapter as a virtual table is that it improves the extensibility of the system, as more adapters could be added in the same way by implementing more UDFs in the MadIS system. The integration of the MadIS system to Ontop-spatial is a gateway to support any API in the future that could serve as a new data source to the system.

To improve performance, the OPeNDAP adapter also implements a caching mechanism that stores results of an OPeNDAP call in a cache for a time window w, so that if another, identical OPeNDAP call needs to be performed within this time window, the cached results can be used directly. The length of the time window w is configured by the user in the mappings and it is optional. In the context of the application scenario described in Section 4, we provide more details about the implementation and use of this new version of Ontop-spatial.

3.3 Visualization

Data can be visualized using the tools Sextant [24] or Maps-API.[18] Sextant is a web-based and mobile ready application for exploring, interacting and visualizing time-evolving linked geospatial data. What we wanted to achieve is develop an application that is flexible, portable and interoperable with other GIS tools. The core feature of Sextant is the ability to create thematic maps by combining geospatial and temporal information that exists in a number of heterogeneous data sources ranging from standard SPARQL endpoints, to SPARQL endpoints following the standard GeoSPARQL defined by the Open Geospatial Consortium (OGC), or well-adopted geospatial file formats, like KML, GML and GeoTIFF. In this manner we provide functionality to domain experts from different fields in creating thematic maps, which emphasize spatial variation of one or a small number of geographic distributions. Each thematic map is represented using a map ontology that assists on modelling these maps in RDF and allow for easy sharing, editing and search mechanisms over existing maps.

The Maps-API is similar to Sextant in terms of visualization functionality, but it takes its data from SDL and it cannot deal with linked geospatial data sources accessed by SPARQL or GeoSPARQL. Once data has been discovered, it can be consumed in the VISual Maps-API using any of the following data request-methods: getMetadata, getDerivedData, getMap, getAnimation, getTransect, getPoint, getArea, getVerticalProfile, getSpectralProfile (in case of multi-spectral EO-data), getMapSwipe, and getTimeseriesProfile. This is mainly intended for App Developers who wish to

[18] https://ramani.ujuizi.com/maps/index.html

integrate and consume the Copernicus services' products in their favourite mobile platform(s) using straightforward visualization, e.g. as layers on a map-view or as independent graphics (w/o associated geometries on the map).

A more detailed discussion of the linked data tools introduced above and their use in the life cycle of linked Earth observation data is given in the survey papers [14, 17]. All tools are open source and they are available on the following Web page: http://kr.di.uoa.gr/#systems

4 A COPERNICUS APP LAB CASE STUDY

We will now present a simple case study which demonstrates the functionality of the Copernicus App Lab software presented in the previous section. The case study is the same as the scenario presented in the demo paper [3]. However, the presentation here is much more detailed and concentrates on the technical challenges and contributions of the case study.

The case study involves studying the "greenness" of Paris. This can be done by relating "greenness" features of Paris using geospatial data sources such as OpenStreetMap (e.g., for features like parks and forests) and relevant Copernicus datasets. The most important source of such data in Copernicus is the *land monitoring service.*[19] The data provided by this service belongs to the following categories:

- *Global*: The Copernicus Global Land Service (CGLS) is a component of the Land Monitoring Core Service (LMCS) of Copernicus, the European flagship programme on Earth Observation. The Global Land Service systematically produces a series of qualified bio-geophysical products on the status and evolution of the land surface, at global scale and at mid to low spatial resolution, complemented by the constitution of long term time series. The products are used to monitor the vegetation, the water cycle, the energy budget and the terrestrial cryosphere. These datasets are provided by the Copernicus App Lab partner VITO via its satellite PROBA-V. They include a series of bio-geophysical products on the status and evolution of the Earth's land surface at global scale at mid and low spatial resolution.
- *Pan-European*: The pan-European component is coordinated by the European Environment Agency (EEA) and produces satellite image mosaics, land cover / land use (LC/LU) information in the CORINE Land Cover data, and the High Resolution Layers. The CORINE Land Cover is provided for 1990, 2000, 2006 and 2012. This vector-based dataset includes 44 land cover and land use classes. The time-series also includes a land-change layer, highlighting changes in land cover and land-use. The high-resolution layers (HRL) are raster-based datasets which provides information about different land cover characteristics and is complementary to land-cover mapping (e.g. CORINE) datasets. Five HRLs describe some of the main land cover characteristics: impervious (sealed) surfaces (e.g. roads and built up areas), forest areas, (semi-) natural grasslands, wetlands, and permanent water bodies. The High-Resolution Image Mosaic is a seamless pan-European ortho-rectified raster mosaic based on satellite imagery covering 39 countries.
- *Local*: The local component is coordinated by the European Environment Agency and aims to provide specific and more detailed information that is complementary to the information obtained through the Pan-European component. The local component focuses on different hotspots, i.e. areas that are prone to specific environmental challenges and problems. It will be based on very high resolution imagery (2,5 x 2,5 m pixels) in combination with other available datasets (high and medium resolution images) over the pan-European area. The three local components are Urban Atlas, Riparian Zones and Natura 2000.
- *Reference data*: Copernicus land services need both satellite images and in-situ data in order to create reliable products and services. Satellite imagery forms the input for the creation of many information products and services, such as land cover maps or high resolution layers on land cover characteristics. Having all the satellite imagery available to cover 39 countries of EEA (EEA39), the individual image scenes have been processed into a seamless pan-European ortho-rectified mosaics. The Copernicus Land Monitoring Service also provides access to Sentinel-2 Global Mosaic service. A lot of in-situ data is managed and made accessible at national level. However, due to issues such as data access and use restrictions, data quality and availability across EEA39 countries, Copernicus services and particularly Copernicus Land Monitoring Service also relies on pan-European in-situ datasets created and/or coordinated at European level. These datasets are needed for the verification and validation of satellite data in the land monitoring service portfolio.

For our case study, the most relevant datasets from the land monitoring service of Copernicus are the leaf-area index dataset (global), the CORINE land cover dataset (pan-European) and the Urban Atlas dataset (local).

Leaf area index (LAI) is a dimensionless quantity that characterizes plant canopies and it is defined as the one-sided green leaf area per unit ground surface area in broadleaf canopies[20]. LAI may range from 0 (bare ground) to 10 (dense coniferous forests). LAI information from the global land service of Copernicus is made available as a NetCDF file giving LAI values for points expressed by their lat/long co-ordinates.

The *CORINE land cover dataset* in its most recent version (2012) covers 39 European countries[21]. Land cover is characterized using a 3-level hierarchy of classes (e.g., olive groves or vineyards) with 44 classes in total at the 3rd level. The minimum mapping unit is 25 hectares for areal phenomena and 100 meters for linear phenomena. It is made available in raster (GeoTIFF) and vector (ESRI/SQLite geodatabase) formats.

The *Urban Atlas dataset* in its most recent version (2012) provides land use and land cover data for European urban areas with more than 100.000 inhabitants[22]. It covers 800 urban areas in 28 European Union countries, the 4 European Union Free Trade Association countries (Switzerland, Iceland, Norway and Lichtenstein), Turkey and the West Balkans. Land cover/land use is characterized by 17 urban classes (e.g., discontinuous very low density urban fabric) with minimum mapping unit 0.25 hectares, and 10 rural classes (e.g., orchards) with minimum mapping unit 1 hectare. It is made available in vector format as ESRI shapefiles.

In addition to the above datasets, our case study utilizes data from OpenStreetMap and the global administrative divisions dataset GADM. OpenStreetMap is an open and free map of the

[21] https://land.copernicus.eu/pan-european/corine-land-cover/view

[22] https://land.copernicus.eu/local/urban-atlas/view

whole world constructed by volunteers. It is available in vector format as shapefiles from the German company Geofabrik[23]. For our case study, information about parks in Paris has been taken from this dataset.

GADM is an open and free dataset giving us the geometries of administrative divisions of various countries[24]. It is available in vector format as a shapefile, a geopackage (for SQLlite3), a format for use with the programming language R, and KMZ (compressed KML).

The first task of any case study using the Copernicus App Lab software is to develop INSPIRE-compliant ontologies for the selected Copernicus data. The *INSPIRE directive* aims to create an interoperable spatial data infrastructure for the European Union, to enable the sharing of spatial information among public sector organizations and better facilitate public access to spatial information across Europe[25]. *INSPIRE-compliant ontologies* are ontologies which conform to the INSPIRE requirements and recommendations. The INSPIRE directives provide a set of data specifications for a wide variety of themes. Our purpose is to categorize our datasets into INSPIRE themes, construct an ontology that follows the respective data specification and then extend this generic ontology to create a specialized version in order to model our datasets. Our initial approach was to reuse existing inspire-compliant ontologies , such as the ones described in [26], but since these efforts are not as close to the INSPIRE specifications as we would like to, we decided to create our own INSPIRE-compliant versions, following the data specifications as closely as possible. Our aim is to reuse these ontologies for other datasets that belong to the same INSPIRE themes and also publish them so that others can reuse these ontologies for their geospatial datasets as well.

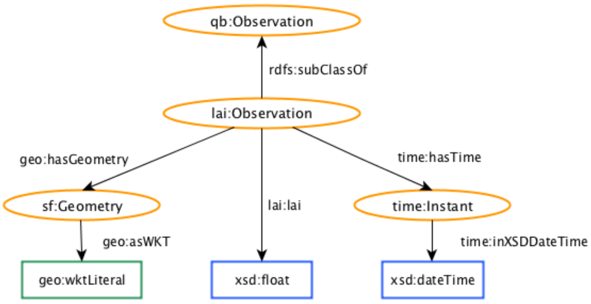

Figure 2: The LAI ontology

A simple ontology for the LAI dataset is shown in Figure 2. We have re-used classes and properties from the Data Cube ontology[26] (namespace `qb`) specializing them when appropriate. We also used classes and properties from the GeoSPARQL ontology [27] (namespaces `sf` and `geo`), from the Time Ontology[27] (namespace `time`), and datatypes from XML-Schema. The class and properties introduced by us use the prefix `lai`.

Once the LAI ontology is created, a user following the workflow depicted on the left, in the Copernicus App Lab software architecture of Figure 1, can use it to transform into RDF the most recent LAI dataset that is made available by the Copernicus global land service[28]. Since GeoTriples does not support NetCDF files as input, the translation was done by writing a custom Python script.

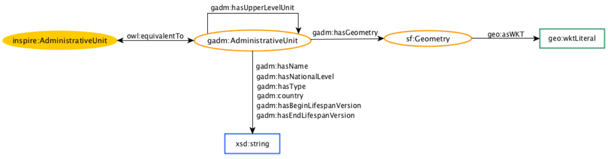

Figure 3: The GADM ontology

Figure 3 shows the ontology that we created for the GADM dataset by extending the GeoSPARQL ontology [27] (namespaces `sf` and `geo`). For the class and properties that we introduced we use the prefix `gadm`[29].The GADM ontology can be used so that a GADM dataset[30] can be either converted into RDF or queried on-the-fly.

A similar process can be followed for datasets CORINE land cover, Urban Atlas, and OpenStreetMap. The ontology which we constructed for the CORINE land cover dataset is not shown here due to space considerations but it is available online [31]. Among other entities (i.e., a class hierarchy corresponding to CORINE land cover categories), it includes the following elements:

- `clc:CorineArea`. This class is a subclass of the class `inspire:LandCoverUnit` of the INSPIRE theme for land cover.
- `clc:hasCorineValue`. This property associates a `clc:CorineArea` with its land cover, as characterised by CORINE.
- `clc:CorineValue`. This class is the range of the property `clc:hasCorineValue` and it is superclass of all the land cover classes of the CORINE hierarchy e.g., `clc:Forests`.

The CORINE land cover ontology can be used to model CORINE land cover data, either materialised as RDF dumps, or virtual RDF graphs created by an OBDA system.

Similarly, we have defined ontologies for Urban Atlas[32], and OpenStreetMap[33]. In the past OpenStreetMap data have been made available in RDF by project LinkedGeoData[34] [29] in the context of which a SPARQL endpoint for OpenStreetMap data was also created. However, the data in this endpoint is not up-to-date (the current version is from 2015), and also this endpoint does not support GeoSPARQL queries. Therefore, we constructed a new ontology for OpenStreetMap by following closely the description of OpenStreetMap data provided by Geofabrik[35] and made it available also in OWL[36]. Using this ontology, we have transformed OpenStreetMap data in shapefiles format into RDF using the tool GeoTriples.

Once all the above datasets are available in RDF, they can be stored in Strabon enabling users to pose interesting, rich queries against the combined dataset. For example, assuming appropriate PREFIX definitions, the GeoSPARQL query shown in Listing 1

retrieves the LAI values of the area occupied by the Bois de Boulogne park in Paris.

Listing 1: LAI in Bois de Boulogne

```
SELECT DISTINCT ?geoA ?geoB ?lai WHERE
{  ?areaA osm:poiType osm:park .
   ?areaA geo:hasGeometry ?geomA .
   ?geomA geo:asWKT ?geoA .
   ?areaA osm:hasName
   "Bois de Boulogne"^^xsd:string> .
   ?areaB lai:lai ?lai .
   ?areaB geo:hasGeometry ?geomB .
   ?geomB geo:asWKT ?geoB .
    FILTER(geof:sfIntersects(?geoA, ?geoB))
}
```

Similarly, in Figure 4, we have used Sextant to build a temporal map that shows the "greenness" of Paris, using the datasets LAI, GADM, CORINE land cover, Urban Atlas and OpenStreetMap. We show how the LAI values (small circles) change over time in each administrative area of Paris (administrative areas are delineated by magenta lines) and correlate these readings with the land cover of each area (taken from the CORINE land cover dataset or Urban Atlas). This allows us to explain the differences in LAI values over different areas. For example, Paris areas belonging to the CORINE land cover class `clc:greenUrbanAreas` overlap with parks in OpenStreetMap and show higher LAI values over time than industrial areas. Paris enthusiasts are invited to locate the Bois de Boulogne park in the figure.

Figure 4: The "greenness" of Paris

All RDF datasets that have been discussed above are freely available at the following Web page: http://kr.di.uoa.gr/#datasets

The "greenness of Paris" case study can also be developed using the workflow on the right in the Copernicus App Lab software architecture of Figure 1. In this case, the datasets of interest can be queried using Ontop-spatial and visualized in Sextant without having to transform any datasets into RDF. In this case, the developer has to write R2RML mappings expressing the correspondence between a data source and classes/properties in the corresponding ontology. An example of such a mapping is provided in Listing 2 (in the native mapping language of Ontop-spatial which is less verbose than R2RML).

Listing 2: Example of mappings

```
mappingId opendap_mapping
target lai:{id} rdf:type lai:Observation .
       lai:{id} lai:lai {LAI}^^xsd:float;
                time:hasTime {ts}^^xsd:dateTime .
       lai:{id} geo:hasGeometry _:g .
       _:g geo:asWKT {loc}^^geo:wktLiteral .
source SELECT id, LAI, ts, loc
       FROM (ordered opendap
      url:https://analytics.ramani.ujuizi.com/
      thredds/dodsC/Copernicus-Land-timeseries-
      global-LAI%29/readdods/LAI/, 10)
       WHERE LAI > 0
```

In the example mappings provided in 2, the `source` is the LAI dataset discussed above which provided through the RAMANI OPeNDAP server of the Copernicus App Lab software stack. The dataset contains observations that are LAI values as well as the time and location for each observation. The MadIS operator `Opendap` retrieves this data and populates a virtual SQL table with schema `(id,LAI,ts,loc)`. The column `id` was not originally in the dataset but it is constructed from the location and the time of observation. The LAI column stores LAI values of an observation as `float` values. The attribute `ts` represents the timestamp of an observation in date-time format. In the original dataset times are given as numeric values and their meaning is explained in the metadata. For example, it can be days or months after a certain time origin. The `Opendap` virtual table operator converts these values to a standard format. Because of the fact that the `Opendap` operator is implemented as an SQL user-defined operator, it can be embedded into any SQL query. In the above mapping, we also refine the data that we want to be translated into virtual RDF terms by adding an filter to the query to eliminate (noisy) negative or zero LAI values. The value `10` that is passed as argument to the `Opendap` virtual table operator is the length of the time window w of the cache that is used (in minutes). In this case, if $|w|$ is the length of the time window w, then $|w| = 10$ minutes. This means that results of a every OPeNDAP call get cached every 10 minutes. If a query arrives resulting in an OPeNDAP in time t, where $t < 10$ minutes later than a previous *identical* OPeNDAP call (resulting from a same or similar query that involves the same OPeNDAP call), then the cached results can be used directly, eliminating the cost of performing another call to the OPeNDAP server.

The `target` part of the mapping encodes how the relational data is mapped into RDF terms. Every row in the virtual table describes an instance of the class `lai:Observation` of the LAI ontology in Figure 2. The values of the LAI column populate the triples that describe the LAI values of the observation, and the values of the columns `ts` and `loc` populate the triples that describe the time and location of the observations accordingly.

Given the mapping provided above, we can pose the GeoSPARQL query provided in Listing 3 to retrieve the LAI values and the geometries of the corresponding areas.

Listing 3: Query retrieving LAI values and locations

```
SELECT DISTINCT ?s ?wkt ?lai
WHERE { ?s lai:hasLai ?lai .
        ?s geo:hasGeometry ?g .
        ?g geo:asWKT ?wkt }
```

Using queries like the one described in Listing 3, Sextant can again visualize the various datasets and build layered maps like the one in Figure 4. The visualization of the case study in Sextant is available on line at the following URL: http://test.strabon.di.uoa.gr/SextantOL3/?mapid=m8s4kilcarub1mun_

5 LESSONS LEARNED, FUTURE PLANS AND OPEN PROBLEMS

In this section, we discuss lessons learned, future plans and open problems in the following areas of research and development of the project: the cloud platform, the use of OPeNDAP for accessing global land service and PROBA-V data at VITO, the linked geospatial data technologies and the use of our technologies by users that are not experts in Earth Observation.

The Terradue cloud platform. The use of this platform has provided the Copernicus App Lab project with the ability to manage all software components as cloud appliances, manage releases of the project software stack, deploy on demand this software stack on target infrastructures (e.g., at VITO), monitor operations (by each partner for its part), provide a development and integration environment, and manage solution updates and transfer to operations via cloud bursting. In this way, when the five DIAS will be operational, the Copernicus App Lab software will also be able to run on them. To demonstrate this, we will be working closely with EUMETSAT and Mercator Ocean to make the Copernicus App Lab software run on their DIAS.

The AppLab Cloud solution is operated through both the AppLab Front-end service for Mobile App developers, and the AppLab Back-end service for partnerships with data providers. The concept of operation of the AppLab Cloud solution supports mobile App developers and provides an AppLab capacity "as-a-service" to them. Considering the strength of having several technology providers contributing to the AppLab architecture, the challenge is about how to streamline a deployment scenario that can be replicated on different Copernicus Collaborative Ground Segment (CCGS) partner environments. Each individual deployment must be configured for the target environment, in order to enable some specific data management functions. All together, these deployments also have to be configured on top of the CCGS data repositories, in order to deliver a "value adding" service, aimed at Mobile App developers, over the Copernicus Services data products. Terradue Cloud Platform supports this "AppLab service" integration work, based on the contributed Docker services and on standard protocols, and deploys it "as-a-Service" on a selected target environment. A pre-operational capacity, is providing managed services on Terradue Cloud Platform. For the back-end services, Terradue Cloud Platform supports the deployment (Cloud bursting) of tailored data access services onto the Cloud Computing layer of a selected CCGS provider. The deployment scenario relies on using Terradue Cloud Platform as a reference platform for evolutive maintenance and versioning of the whole AppLab solution, and its updates as new deployments on the selected data providers' environments (e.g. a Copernicus DIAS).

Deploying OPeNDAP at VITO. The use of OPeNDAP offers better data access capabilities specifically for application developers that are not experts in Earth Observation, and thus it a clear benefit. OPeNDAP and SDL provide streaming data to the end user and have some significant advantages over the OGC Web Coverage Service standard which is already offered by VITO. First of all, from a data provider perspective, OPeNDAP is easier to use, as it is able to deal with a wider variety of grid types. Furthermore, OPeNDAP can be easily extended with different conventions, allowing for easier integration of different dataset and without overhead like file conversion. Also, OPeNDAP enables the loose coupling of different Copernicus data sources into one data model, providing the user easy access through a single access point that uses this data model. Finally, when using the Web Coverage Service, there is limited possibility to obtain client-specific parts of the datasets (one is limited to, for example, a bounding-box). In contrast, OPeNDAP allows for the caching of datasets by serialization based on internal array indices. This increases cache-hits for recurrent requests of a specific subpart of the dataset which can be very useful, e.g., in a mobile application scenario, where the viewport of the application could be defaulting to a specific, user-configurable area of interest with only modest panning and zooming interaction. Also, OPeNDAP ensures that metadata is intrinsically embedded in the TCP/IP response, regardless of container type (GeoTIFF, NetCDF, HDF, grib, etc.), which is beneficial for the semantic enrichment process that may happen at higher layers of the architecture. For the remaining duration of the project, the OPeNDAP deployment at VITO will be improved by offering a more sophisticated access control facility.

In order to deploy DAP at VITO we created several Virtual Machines (VMs) to build a private cloud in the VITO data center and used Docker images for the configuration. To provide access to the Copernicus and Proba-V datasets via the DAP, these datasets are mounted on the virtual machine. The data available on these storage volumes will be exposed by the DAP. Copernicus data uses the netCDF extension while tiff extension is used for Proba-V data. During the implementation of the DAP at VITO, it became clear that the directory structure used for the Copernicus Global Land datasets is not supported by the DAP, so we had to create a virtual directory structure to be compliant with the DAP. The reason why the Copernicus dataset could not be supported is that this directory structure contains multiple versions of data for the same day: the production centre reprocesses data at several days when more accurate meteorological data becomes available. The DAP could not handle this deviation, so VITO made a script to create a directory structure that uses symbolic links to point at the most recent version of the data, as that is the only one that needs to be exposed. Also, to ensure security we used tokens that allow accessing the datasets throught the RAMANI API. Every user has to register an account on the RAMANI platform. Without proper registration users will not have any access to the datasets to ensure map uptake monitoring capabilities and to avoid abuse. Furthermore, this will allow the tracking of which users access which datasets.

The linked geospatial data tools. The linked geospatial data tools presented in Section 3 have been used to develop environmental applications not only in Copernicus App Lab but also in previous projects TELEIOS, LEO and MELODIES [14, 17]. The linked geospatial data tools have been welcome by users who could see the value of developing applications using semantic technologies. The most popular tools have been Sextant and Ontop-spatial. Sextant has been irreplaceable as there is currently no other tool for visualizing linked geospatial data. Ontop-spatial has been attractive for users given that most of them were not in favour of transforming their data into RDF and storing it in Strabon. The fact that Ontop-spatial is also faster than Strabon on most of the queries of the benchmark Geographica [4] has been another reason users preferred it over Strabon.

The most innovative, but also challenging, aspect of using Ontop-spatial in Copernicus App Lab has been its ability to give access to Copernicus data (e.g., LAI data) through the OPeNDAP framework. When the data gets downloaded at query-time, query execution typically takes two orders of magnitude more time than in the case where the data is materialized in a database or an RDF store. When data is stored in a database connected with Ontop-spatial, DBMS optimizations and database constraints are taken into account and query plans are optimized. This does not happen in the case where Ontop-spatial retrieves data on-the-fly from OPeNDAP, especially since data is preprocessed before it gets translated into virtual triples using Ontop-spatial. However, in the cases when we want to access Copernicus data that gets frequently updated, the virtual RDF graphs approach is useful as it avoids the repeated translation steps that have to be done by the data provider. For more costly operations (e.g., spatial joins of complex geometries), it is better to materialize the data. In our current work, we are developing further optimizations to improve the performance of this mechanism using techniques such as caching. We are also working on enabling Ontop-spatial to query other kinds of data e.g., HTML tables and social media data, since this functionality has been requested by users.

The following open problems will also be considered in the future:

- Although Strabon has been shown to be the most efficient spatiotemporal RDF store available today[37], much remains to be done for Strabon to scale to the *petabytes* of Copernicus data or the linked geospatial data typically managed by a national cartographic agency (e.g., Ordnance Survey in the United Kingdom or Kadaster in the Netherlands; they both use linked geospatial data). We plan to extend a scalable RDF store like Apache Rya[38] with GeoSPARQL support taking into account the lessons learned by similar projects in the relational world [13].
- It will usually be the case that different geospatial RDF datasets (e.g., GADM and OpenStreetMap) will be offered by different GeoSPARQL endpoints that can be considered a federation. There is currently no query engine that can answer GeoSPARQL queries over such a federation. The only system that comes close is SemaGrow which has been shown to federate a single Virtuoso endpoint and a single Strabon endpoint in [12]; more research is needed in this area for developing a state-of-the-art federation engine for GeoSPARQL.
- It is important to extend GeoTriples to be able to transform data in SQLite and ESRI geodatabases into RDF. The same should be done for scientific data formats such as NetCDF. The problem of representing array/gridded data in RDF has recently received attention by the W3C/OGC Spatial Data on the Web Working Group and some interesting working group notes were produced[39]. In a similar spirit an extension of SPARQL, called SciSPARQL, for querying scientific data has been proposed in the Ph.D. thesis of [1].

Using the Copernicus App Lab tools. Participants of the ESA Space App Camps that were organised in September 2017 and 2018 had the opportunity to use the Copernicus App Lab technologies to implement demo applications. ESA Space App Camps[40] are yearly events that bring together programmers to develop innovative applications based on satellite data. The objective is to make EO data, particularly from Copernicus, accessible to a wide range of businesses and citizens. Twenty-four developers from 14 countries attended the 2017 ESA App Camp in Frascati, Italy. It is important to note that these were the first two ESA Space App Camps that introduced the Copernicus App Lab tools and in both competitions he winning applications utilized the Copernicus App Lab technologies. The winning app of 2017 named AiR, displays an interactive projection of the Earth's surface to airplane travelers using Copernicus satellite imagery, letting them see information about the cities and landmarks they pass over during their flight, without the disruptions of clouds or parts of the plane getting in the way. The developers of AiR used Copernicus App Lab tools to access and integrate data from different sources (Copernicus land monitoring service data, OpenStreetMap data and DBpedia data about landmarks). In 2018 the winning app named Urbansat aims to guide greener, more ecological urban planning. It provides a range of data for planners, including information on green spaces, terrain and biodiversity and more. The app′s map interface has a drag and drop feature, which would allow users to compare scenarios pre and post build for their construction projects, through the generation of relevant data, largely derived from Sentinel satellites. This would allow them to see the anticipated impact of constructing a building on local air quality, for example. The developers of Urbansat used Copernicus App Lab tools to process data from different sources (Copernicus land monitoring service data, Urban Atlas data, Natura 2000 data and data provided from GADM). Another interesting application that was developed was Track Champ. Track Champ combines Earth observation data with data about points of interest from OpenStreetMap to find the perfect time and place to exercise while tracking personal performance over time.[41]

One of the lessons that we learned from the 2017 and 2018 ESA Space App Camps, after compiling user feedback, was that the capability of integrating Earth observation data together with linked open data (e.g., landmarks, points of interest) was very important in some applications. In all of the applications that were based on combining Copernicus data with open data, developers chose to use the Copernicus App Lab tools. Given the limited time they had available for coding, they found it easier to access the available GeoSPARQL endpoints rather than the original heterogeneous data sources. On the other hand, some developers also reported that getting familiarized with the Copernicus App Lab technologies required some effort, given that they did not have background knowledge in Semantic Web technologies or geospatial data management. These users suggested that this issue could be addressed by improving documentation material.

Google has recently activated the beta version of its dataset search (https://toolbox.google.com/datasetsearch), where the datasets that are indexed using schema.org (https://schema.org/), as proposed by Google, show up. Schema.org is a vocabulary created from the collaboration of four major search engines: Bing, Google, Yahoo, and Yandex. It aims to provide a unique structured data markup schema which would include a great amount of topics, including people, organizations, events, creative works such as books and movies, etc. The on-page markup allows search engines to understand information included in web pages, while it provides rich search features for users. We have followed these guidelines and annotated all the datasets used in the use case of Section 3, and made them available at the

[37] We have shown this in papers [6, 15] in 2013. The situation has not changed since then, according to recent experiments of our team.

[38] https://rya.apache.org/

[41] All the applications developed are presented in more detail at the following Web page: https://www.app-camp.eu/winner-frascati-2017/

following link: http://kr.di.uoa.gr/#datasets. We have also recommended that the same practice is followed by the Copernicus services we have worked with (land monitoring, global land and atmosphere services).

Currently, EO datasets are hidden in the archives of big EO organizations, such as ESA, NASA, etc. These datasets are only available through specialized search interfaces provided by the organizations. It is important to make major search engines like Google able to discover EO datasets and not only general datasets, in the same way they can discover information about movies, concerts, etc. To achieve this goal, we designed an extension to the community vocabulary schema.org, appropriate for annotating EO data in general and Copernicus data in particular, by extending the class Dataset with subclasses and properties, which cover the EO dataset metadata defined in the specification OGC 17-003 for annotating EO product metadata using GeoJSON(-LD) (http://geo.spacebel.be/opensearch/myDocumentation/doc/index-en.html). The OGC 17-003 is based on the specifications OCC 10-157r4 (http://docs.opengeospatial.org/is/10-157r4/10-157r4.html) and UMM-G (https://wiki.earthdata.nasa.gov/display/CMR/CMR+Documents), and it is expected to be standardized by OGC during 2018. The OGC 10-157r4 - Earth Observation Profile of Observations and Measurements (O&M) provides a standard schema for encoding EO product metadata in order to describe and catalogue products from the sensors of EO satellites. The Unified Metadata Model for Grabules (UMM-G) is an extensible metadata model for Granules, that provides the mappings between NASA's Common Metadata Repository (CMR) supported metadata standards.

The schema.org extension for encoding EO metadata can be used by EO organizations like ESA for the encoding of the metadata of their EO datasets. In this way, EO datasets will be discoverable by search engines. In addition, this schema.org extension for EO products can be used by webmasters who want to annotate their webpages, so that search engines can find the EO datasets they provide. It is important to make this EO data available on the Web as linked data in order to increase their use by developers that might not be experts in EO. In this way, great amounts of data that are generated fast, can be made "interoperable" and more valuable when they are linked together.

6 SUMMARY

In this paper we argued that Copernicus data is a paradigmatic source of big data giving rise to all relevant challenges: volume, velocity, variety, veracity and value. The Copernicus App Lab project targets all these challenges with special focus in variety and volume, and has developed a novel software stack that can be used to develop applications using Copernicus data even by developers that are not experts in Earth observation. We presented a case study developed using the Copernicus App Lab software stack and discussed lessons learned, future plans and open problems.

ABSTRACT

Vast amounts of data are being generated daily with the adoption of Internet-of-Things (IoT) solutions in an ever-increasing number of application domains. There are problems associated with all stages of the lifecycle of these data (e.g., capture, curation and preservation). Moreover, the volume, variety, dynamicity and ubiquity of IoT data present additional challenges to their usability, prompting the need for constructing scalable data-intensive IoT data management and processing platforms. This paper presents a novel approach to model and build IoT data platforms based on the characteristics of an Actor-Oriented Database (AODB). We take advantage of two complementary case studies – in structural health monitoring and beef cattle tracking and tracing – to describe novel software requirements introduced by IoT data processing. Our investigation illustrates the challenges and benefits provided by AODB to meet these requirements in terms of modeling and IoT-based systems implementation. Obtained results reveal the advantages of using AODB in IoT scenarios and lead to principles on how to effectively use an actor model to design and implement IoT data platforms.

1 INTRODUCTION

Internet-of-Things (IoT) systems enable data interactions through machine-to-machine communication stemming from supporting devices connected to the Internet [13]. IoT systems generate a potentially huge amount of data from devices that dynamically enter and leave the IoT environment, with very high-speed data flow and processing. Data, in turn, are generated by a wide variety of devices, thus giving rise to highly heterogeneous data streams. In this paper, we distinguish between *IoT systems* (i.e., the entire software ecosystem involved in an IoT scenario) and *IoT data platforms* (i.e., the data and data management software modules that are part of an IoT system). Our work focuses on the latter.

Enormous challenges need to be addressed in order to realize the full potential of IoT. First, there is a tension between effective data management and fulfillment of performance requirements in IoT data platforms. Indeed, many IoT systems are processor-intensive and require processing a massive amount of highly concurrently generated data. The management of these interactions among data with low latency remains an open research problem. Second, being able to deal with dynamic scaling while guaranteeing protection of data from different entities is another significant challenge. Therefore, we focus our investigation on how to manage the data from large volumes of devices and, at the same time, ensure the dynamic and flexible development of applications. This dual aim must be achieved while respecting application constraints for low latency in interactive functionality as well as data protection and access control.

Given these characteristics, we propose that actor-oriented databases (AODBs) are ideally suited to manage the data of real-world IoT systems. Actors comprise a model of computation specifically aimed at high concurrency and distribution [1]. To that effect, actors keep their private states and can modify states by communicating with each other via immutable asynchronous messages [19]. As such, actors are natively applicable to support the management of an arbitrary number of independent and heterogeneous streaming data sources. AODBs, in turn, enrich actors with classic RDBMS functionality by integrating data management features, such as indexing, transactions, and query interfaces, into actor runtimes [17]. These features make AODBs attractive for building an IoT data platform. In more detail, AODBs stand out for several reasons. First, IoT systems comprise many different devices with distinct functionality. This requirement is directly met by the actor model, through the principle of assigning different logic and tasks to actors. Second, in IoT, data changes frequently; actors provide a natural alternative to conventional concurrency models that rely on synchronization of shared mutable state using locks. Third, the characteristics of non-blocking interactions via immutable messages between actors match well with the demands of IoT systems. Fourth, the number of actors can scale out quickly without consuming excessive resources. Dynamic scaling is a common situation in IoT in which all kinds of sensing devices (including humans!) can quickly enter – but also leave – a system.

There are several examples of the use of actors in IoT scenarios [4, 38, 41, 43]. However, these previous studies concentrate on implementation aspects, neither providing guidance on how to model IoT data platforms with actors nor analyzing the fit of AODB to the requirements and challenges brought about by IoT. By contrast, to the best of our knowledge, this paper is the first that builds an end-to-end case for the suitability of AODBs to manage IoT data, going from requirements and modeling to implementation and performance evaluation. Our work covers a wide gamut of issues to justify and showcase the adoption of AODBs as an appropriate solution to meet the main challenges of data management in IoT systems. Our main contributions are therefore:

(1) We discuss core requirements of IoT data platforms, and challenges to be met in their implementation. We illustrate

this discussion through the analysis of two real world IoT case studies.
(2) We present a methodology and guidelines to model an AODB for such platforms.
(3) We develop a prototype of one of the case studies and present its evaluation to show the effectiveness of adopting AODBs for IoT data platforms.

The remaining of this paper is organized as follows. Section 2 presents two case studies of IoT systems, which we use to extract functional and non-functional requirements, and to present some of the major challenges to be faced. Section 3 justifies our choice of AODBs as an appropriate technology to meet such requirements and challenges. In Section 4, we provide a detailed discussion of the challenges of modeling such platforms, and show how these challenges can be overcome for the running cases. Sections 5 and 6 respectively present our prototype for one of these cases and its evaluation. Section 7 revisits the paper by contrasting it with related work. Finally, Section 8 presents conclusions and ongoing work.

2 IOT DATA PLATFORM CASE STUDIES

In this section, we discuss the requirements for an IoT data platform and analyze two specific case studies. There are several scenarios in IoT data platforms, such as healthcare, personal security, traffic control, environmental monitoring, and disaster response. The two IoT data platform cases that we focus on are drawn from our experience with a structural health monitoring system (cf. Subsection 2.1) and a beef cattle tracking and tracing system (cf. Subsection 2.2). We have worked directly with these case studies, helping us validate common non-functional requirements for IoT data platforms as well as collect illustrative functional requirements for these applications.

For the first study, we have cooperated with SenMoS [45] in the area of structural health monitoring for large constructions, e.g., bridges. SenMoS is a Danish company that provides users with entire monitoring solutions, including requirement elicitation and cloud data management. The developers at SenMoS have participated in the design and implementation of the IoT data platform for the Great Belt Bridge [50]. The second case focuses on the management of cattle produce (and in particular the beef supply chain) from the perspective of traceability. This study is based on previous work with domain experts from the Brazilian agricultural research corporation Embrapa [28] that studied traceability in food for supply chains [35], and on interactions within the Danish Future Cropping partnership [30], particularly with experts from the agriculture solution provider SEGES [44]. Both of these organizations have substantial experience in the agricultural sector and are key players in agricultural extension systems of the respective countries. Both case studies concern the development of a scalable data platform that collects and stores data from IoT devices, processes operations, and provides information services to different users. Although these two IoT platforms target different scenarios, they present several common aspects and non-functional requirements. In particular, the systems should operate as Software-as-a-Service (SaaS) solutions and thus manage the data from several different tenants. Moreover, it is desired that scalability to large data volumes or users be achieved without a high burden on the data platform developers.
Non-Functional Requirements for IoT Data Platforms. We elicited the following common non-functional requirements shared by different IoT data platforms:

(1) **Data ingestion from endpoints**. The IoT data platform must have the capability to receive and store data from IoT devices, e.g., GPS collars on cows.
(2) **Multi-tenancy**. The IoT data platform must provide varied information services to different users.
(3) **Support for heterogeneous data**. The IoT data platform must be modular in its support for data ingested from IoT devices and allow for communication employing different data formats.
(4) **Cloud-based deployment**. The IoT data platform can be distributed in the cloud for ease of operation, management, and maintenance.
(5) **Scalable data platform**. The IoT data platform must not degrade in functionality or performance while expanding. This must occur without modifying existing software components.
(6) **High efficiency**. The IoT data platform must process massive amounts of concurrently generated data effectively.
(7) **Access control and data protection**. The IoT data platform should support data protection, enforcing authentication and access control over different users and profiles.

In addition to the requirements above, it is often the case that IoT data platforms must serve queries over historical data accumulated from devices over long time periods. In this paper, we focus, however, on online data ingestion and querying in SaaS scenarios. We note that at present, there is only limited support for declarative multi-actor querying in AODBs [17], and thus complex historical analyses could still be served by a data warehouse.

2.1 Case 1: Structural Health Monitoring

Structural Health Monitoring (SHM) systems aim to identify damaged sections on parts of large constructions that can cause safety concerns. SHM systems can help organizations save time on inspections by gathering and processing data so that the system can generate alerts when problems arise or suggest actions that can prevent faults. SHM systems are equipped with a set of sensors, e.g., to measure a bridge's extension, inclination, temperature, wind speed, and wind direction. Each sensor is connected to a data logger that converts the sensors analog signal into a digital one. The platform must collect, process and store data from the sensors. Figure 1 presents a context diagram of the Structural Health Monitoring Data Platform. This design is based on a real case study. Sensors provide data to different stakeholders, e.g., engineering experts monitoring the structure, data analysts, or the

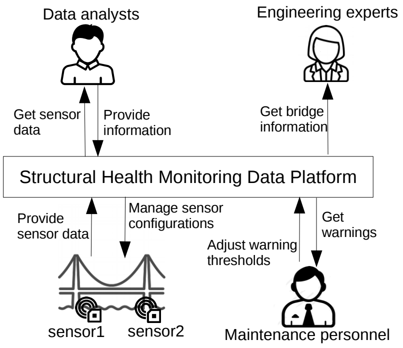

Figure 1: Context Diagram for Structural Health Monitoring Case Study.

maintenance personnel who manages the monitoring projects. The SHM system must meet the following functional requirements:

(1) The system must control several construction structures (e.g., bridges) using the same data platform.
(2) The system must be structured to support data storage, i.e., data must be saved in a way that allows for further data manipulation and analysis.
(3) The data platform must be able to maintain data from multiple sensors, users, projects, and organizations.
(4) The data platform must calculate the accumulated change for each data stream from a sensor, e.g., to gauge how far elements have moved when using extension sensors.
(5) The data platform must send customized alerts to users when thresholds are met, depending on individual sensors or sensor types. Thresholds can be used for determining the need for maintenance, or to call attention to ongoing events.
(6) The data platform must support plots providing statistical aggregates to help users spot meaningful events in time series. Besides, online plotting of recent raw sensor data is required to let personnel explore events interactively.
(7) The data platform must allow for browsing of live data from sensors, along with continuously derived equations, to provide a view of the current state of the structure.

2.2 Case Study 2: Beef Cattle Tracking and Tracing

Agricultural supply chains involve a complex network of producers, retailers, distributors, transporters, storage facilities, and consumers in the sale, delivery, and production of a particular product. Trackability and traceability are essential requirements in food marketing [24]. Tracking refers to following the path of an entity from the source to destination. Tracing refers to identifying original information regarding an entity and tracing it back in the system [37]. Systems for tracking and tracing agricultural products increase consumer confidence on provenance and quality of the food they buy, while at the same time helping retailers and certification authorities to monitor products.

The ability of IoT to collect data from sensors as well as trace entities is a crucial enabler for monitoring such chains. Systems that automate tracking and tracing in an agricultural supply chain should not only collect data, but also connect users and objects at any place and time. Data integration, processing, analysis and service support present many challenges in this context. For the sake of feasibility, we assume for this case study, similarly to other food tracing systems [33], that a global standard for supply chain messages, GS1 [32], is adopted by participants that connect with the IoT data platform. As such, we do not discuss the data integration problem in this paper.

Our case study refers to a part of the beef cattle supply chain, concentrating on cow tracking and meat product tracing, providing tracking information and helping consumers trace meat products. Figure 2 presents the entities interacting within the data platform. The system must provide multi-tenancy services to host the data of different participants and supply chains. From a high-level point of view, there are five kinds of tenants in our system: farmers, slaughterhouses, distributors, retailers, and consumers. Each involved part is the source of different types of data in the system to enable the tracing of the whole life-cycle of a given meat product.

Figure 2: Context Diagram for Beef Cattle Tracking and Tracing Case Study.

Full-fledged cattle sensor-based systems involve the deployment of very many kinds of sensors – both in individual animals and in their environment. For instance, each animal has external sensors (e.g., collars, earrings) to measure movement, speed, location. Cattle often also have sensors inside their digestive tract (usually swallowed, sometimes implanted), to measure factors such as temperature, metabolic variables, or digestive characteristics. Environmental sensors may monitor factors such as cattle weight, or soil humidity. Additional sensors along the supply chain include devices that provide trackability (e.g., in transportation), but also traceability and quality (e.g., monitoring temperature inside warehouses). Without loss of generality, we have simplified this scenario to consider only a few of these sensing sources, keeping only enough distinct sensors to illustrate actual data and sampling rate heterogeneity. This simplified scenario must fulfill the following functional requirements:

(1) The data platform must store the data from animal and environment sensors, such as collars bound to each individual cow, to enable retrieval of location, motion, and other facts regarding traceable entities.
(2) Farmers need to track each cow's trajectory and behavior, and thus the data platform must record the locations of each cow over time. Geo-fencing can help identify whether a cow is in an appropriate area (e.g., when rotating pasture grounds) [20].
(3) Slaughterhouses wish to access services that provide information about cows that will be slaughtered. For instance, it must be possible to access tracing information such as the provenance of the cows and tracking information about where the meat cuts produced after slaughter are transferred to.
(4) Distributors wish to get tracing information of a meat cut and tracking information of where those cuts are to be sent to.
(5) Retailers aim to know the source of the meat cuts and manage their transformation into meat products for consumers.
(6) Consumers wish to get tracing information about meat products over the whole supply chain.

2.3 Challenges for IoT Data Platforms

The functional and non-functional requirements discussed in this section render the modeling and building of IoT data platforms a non-trivial undertaking. The construction of such a platform involves technical issues related to capturing, identifying and storing relevant events, managing associated constraints, processing varied types of queries, etc. Further complexity arises from taking into account the necessities of different stakeholders, and issues related to data precision, synchronization and availability.

Choosing the right database architecture is therefore a key decision for the success of an IoT data platform project. Virtualized deployment for efficiency and ease of scaling to large request volumes are significant obstacles [46]. Moreover, support for multi-tenancy needs to be carefully designed. While physical sharing of tenant data lowers overhead and increases efficiency [7], this strategy opens up security risks, which are related to the lack of modularity at the database level [47].

Thus, several questions need to be addressed when building IoT data platforms. First, a vast amount of data is concurrently generated from IoT devices. How can this data be managed and processed in the data platform? Second, how can data protection and access control across different entities be enforced while sharing data effectively? Third, our case studies suggest that a variety of queries, including analyses of time series from bridge sensors, spatial queries for cow locations, or graph navigation for tracing, need to be efficiently supported over IoT data. How can applications be modeled and built to support different types of queries? Fourth, it is necessary that the system be easily scaled without affecting functionality and performance. How can the platform be architected to easily scale out when it becomes necessary to manage more users and data? In this investigation, we observe that the issues regarding modularity and scalability pointed out in this section can be simultaneously addressed by AODBs [17]. We design cloud-centric actor-oriented database backends for the two IoT case studies introduced in this section. As a first step, we explain the motivation of taking an approach based on AODBs in the next section.

3 WHY ACTOR-ORIENTED DATABASES?

We argue that an actor-oriented database is the ideal organization for an IoT data platform, enabling fulfillment of all common non-functional requirements identified in Section 2. Moreover, AODBs ease the achievement of functional requirements by providing a modular, stateful, and scalable substrate for the modeling, design and implementation of an IoT data platform. The following characteristics of an AODB illustrate its suitability to address the challenges of IoT data platforms.

AODBs facilitate the management of distribution and the encapsulation of data. Actors are logically distributed, and can thus naturally map to dispersed entities such as sensors. The latter promotes the expression of parallelism in the application logic responsible for data ingestion into the platform. Moreover, an AODB-centric design functionally decomposes the data platform into different actors. State is encapsulated within each actor, and can only be communicated by asynchronous messages. As such, actors provide a mechanism for isolation of different functions and data, enabling efficient support for multi-tenancy.

Actor modularity in AODBs supports representation and sharing of heterogeneous data. Actors are the unit of modularity in an AODB. By encapsulating state and supporting specification of user-defined APIs, actors abstract heterogeneous data representations. Moreover, arbitrary data transformations can be coded in actor methods, enabling asynchronous exchange of data across heterogeneous actors. As such, actors offer an attractive model to capture heterogeneity of data formats and representations originating at multiple IoT devices.

AODBs employ multiple actor types and concurrent execution among actors to achieve scalability. The support for multiple actor types enables the representation of different kinds of entities in the IoT data platform. When a new entity type is added to the system, it is represented by a new actor type added to the data platform. AODBs thus support a gradual extension of the platform through new actors and actor types with minimal impact on existing components. The use of actors makes scaling out easier, since new actors can be deployed over additional hardware components to avoid violation of performance constraints. The resulting concurrent and distributed execution facilitates efficient use of computational resources to bolster scalability.

Parallelism across actors in AODBs allows for processing of massive amounts of concurrently generated data. By identifying tasks and associated logic among entities, we can model entities as independent actors, so that they can perform tasks concurrently. When independent tasks are then run in parallel across actors deployed on separate hardware components, data platform performance can be improved. Since sensors are naturally modeled as different actors, parallel execution can be leveraged in processing data from a large number of data streams.

Encapsulation and modularity in AODBs support data protection and access control. As data in one actor are invisible to others, access permissions can be checked when data are exchanged by asynchronous messaging [40]. In other words, data are protected inside an actor, and mechanisms for access control can ensure data are only shared with authorized users.

4 MODELING THE CASE STUDIES WITH ACTOR-ORIENTED DATABASES

AODBs provide scalable data processing, management, and storage over a set of application-defined actors [17]. However, to the best of our knowledge, there is scant guidance on how to model applications to reap the benefits of AODBs. In this section, we fill this gap by an in-depth modeling discussion of the two IoT case studies described in Section 2. We contribute to the construction of IoT data platforms in two ways: (1) we provide guidelines for modeling IoT data platforms with AODBs; and (2) we explain how an actor model affects the system both in design and implementation.

It is believed that application modeling helps to preserve and reuse information in other projects, as well as facilitates the automated generation of a system from models [51]. To support the latter aim, we leverage UML notation [53] to create models of actors, their encapsulated state and their operations. These data-centric models harken back to conceptual modeling approaches in databases, enabling both specifications of data requirements and, in the future, code generation for AODB platforms. To support the former aim, we focus on documenting database actors and their asynchronous interactions. In addition to database actors, the classic architecture of an IoT data platform contains a stateless tier that mediates the interaction with users or devices. The analysis of this tier is outside the scope of our work; we abstract its functionality as stateless actors operating as proxies and omit this tier from our models.

In the presented models, we represent the minimal necessary information to emphasize techniques for actor-oriented database design. Application details that would make the presentation unnecessarily complex are thus omitted, and simplifications are made where appropriate. In the sections that follow, we identify each core modeling question encountered in the two IoT data platform case studies and discuss lessons learned.

4.1 How can Actors be Identified?

A variety of entities exist in any system, and these entities either perform or collaborate to achieve different tasks. Moreover, these entities have different life cycles, distinct types, and varied needs regarding heavy computation or communication [14]. To take advantage of the actor programming model as well as achieve high availability and performance, it is an essential question to decide which entities or entity sets should be modeled as actors.

To appreciate a concrete example of this challenge, consider the beef cattle system introduced in Section 2, where many entities perform different tasks to satisfy multiple requirements. For instance, a collar sensor that is bound to a cow continuously collects real-time geo-data for this cow and sends it to the data platform. A historical trajectory for each individual cow is thus updated based on this sensor data. Besides, additional information may be needed, such as the cow's identifier or health-related data. In this sense, we can observe both collar and cow as separate entities engaged in cooperation to provide real-time and historical geo-information to farmers and slaughterhouses. The question is whether these two entities, the collar sensor, and the cow, should be one or two independent actors.

Actors comprise a model of computation for concurrency and distribution [1]. So not only should actors encapsulate state, as it is the case with non-actor objects, but they should also abstract concurrent tasks that need to be processed by the system. In our experience, we found it useful to answer the following questions when attempting to identify actors: (a) What services are provided by the system being modeled? (b) Who should provide these services and who are their users? (c) What is the output and input of every single task performed and can these tasks be executed concurrently?

Take our beef cattle tracking and tracing system as an example. Typically one actor is designed to carry out one specific real-world task with associated logic, such as slaughter or distribute. Different actors then capture simultaneous tasks. For instance, farmers would like to obtain information on cows and manage the herds that they own. Slaughterhouses would like to obtain information about cows that will be slaughtered and record how these cows get transformed into meat cuts. Farmers and slaughterhouses can thus be conceptualized as users of cow information services, which a cow ought to provide. Moreover, the interactions between farmers, slaughterhouses, and cows are concurrently executed by independent entities in the real world. In particular, farmers manage cows and their respective information, and slaughterhouses slaughter cows and record their transformation into meat cuts. Cows are associated with their sensor data, which are continuously updated by their collars. As such, we model farmers, slaughterhouses, and cows as independent actor types. Since each collar is bound to a cow, we encapsulate this sensor information inside cow actors.

Figure 3 shows the data platform model for the beef cattle system. Every actor encapsulates its state and communicates with other actors via asynchronous messages. Therefore, simple accesses to data in the state of an actor are rendered as asynchronous communication events across actors. As we can see from the figure, we model one cow as a *Cow* actor. A Cow actor has an aggregation relationship with many collar sensor readings indicating the GPS locations of the cow, and each such sensor reading is bound to exactly one cow. In other words, we use aggregation relationships to indicate that the objects of a non-actor class are encapsulated in the referred actors. Since cows are modeled as actors, real-time locations are reported to Cow actors, which serve this information to all interested readers along with other associated cow state data such as the cow identifier.

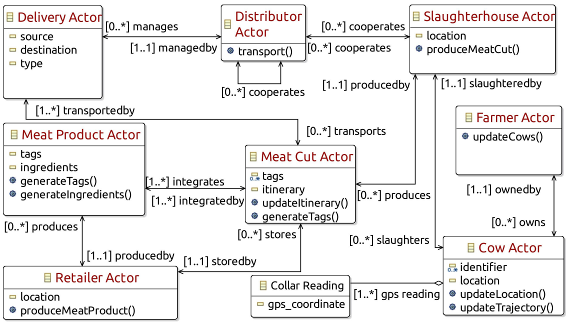

Figure 3: Actor Model of Beef Cattle Tracking and Tracing Data Platform.

We model one farmer or several farmers who work together (e.g., a cooperative) as one single *Farmer* actor because the state of this farmer or these farmers is organized as a unit.[1] One cow is owned by one farm unit, but one farm unit can own many cows. The Farmer actor can read the properties of any Cow actor that is associated with it through message passing. If such messages are exchanged under a security model with authentication, then we can enforce that cow information is only visible to its owner farmer tenant or properly authorized slaughterhouse.

A physical slaughterhouse is modeled as a *Slaughterhouse* actor. A cow can only be slaughtered once in exactly one slaughterhouse, but a slaughterhouse is responsible for slaughtering many cows. This constraint is reflected in the association between Cow and Slaughterhouse actors, and as above a Slaughterhouse actor can read data from any Cow actor via asynchronous messaging. The Slaughterhouse actor processes such data to derive *Meat Cut* actors, which represent units of beef to be distributed as a whole.

A Meat Cut actor processes updates to its itinerary property generated by *Delivery* actors as meat cuts are transported. In our model, a *Distributor* actor manages multiple Delivery actors, which themselves manage a transportation process with different source and destination locations. For example, a logistics company is modeled as a Distributor actor, and transportation processes in this company are modeled as various Delivery actors managed by the Distributor actor. A Delivery actor tracks a meat cut delivery from a source to a destination location using a given vehicle at a well-defined time. A meat cut can be delivered many times by one or several distributors during the whole itinerary, and a distributor is responsible for delivering many meat cuts.

We model the final destination of a meat cut to be a retailer, e.g., a supermarket chain, whose information is managed by a *Retailer* actor. Retailer actors can create *Meat Product* actors by disaggregating or combining meat cuts. Thus, Meat Product actors have a many-to-many association with Meat Cut actors.

Based on the above modeling process, we can summarize a general **principle of how to identify actors**:

> Typically, one actor is designed to carry out one specific real-world task with associated logic. Different actors capture different simultaneous tasks.

[1] Notice that this unit can be broken down into smaller units at will, depending on the focus of an application – e.g., individual farmers unite to provide beef, but a cooperative handles each farmer individually.

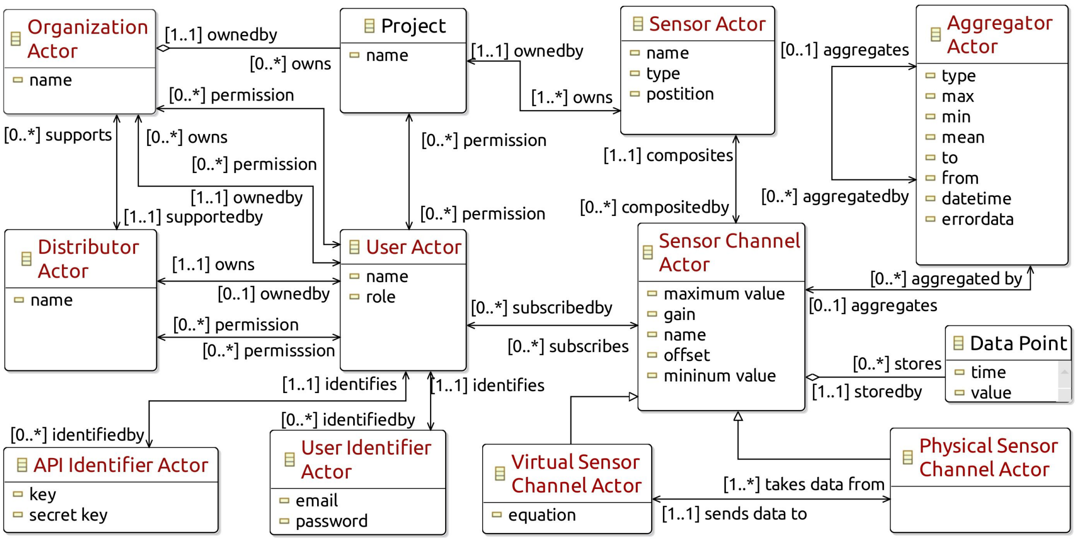

Figure 4: Actor Model of Structural Health Monitoring Data Platform.

4.2 What should the Granularity of Actor State be?

In an AODB, we allocate different tasks into separate actors, as this organization can help increase concurrency. However, if a single actor concentrates too much state or too much of the application logic, i.e., if an actor is *coarse-grained*, then it becomes increasingly difficult to reap the benefits of concurrency stemming from the application of the actor model. At the other extreme, since actors do not share state and communicate only through asynchronous messaging, an excessively *fine-grained* actor design can introduce unnecessary overheads in state manipulation as well as increased communication overhead. Moreover, a fine-grained design may cause the actors in the system to explode in number, e.g., one actor per data item or record in the system, which can challenge efficiency in an AODB platform. So deciding the granularity of actors is an essential problem when modeling any application with actor-oriented databases.

Previously, we have formulated a principle to identify actors out of the entities in an application scenario. However, we should balance this principle against the potential effect of actor granularity on application performance. In particular, we wish to keep concurrency high, but at the same time avoid unnecessary overheads and reduce the complexity of application modeling. To balance these goals, our experience has been that it is natural to make actors more fine-grained when they represent *active entities* for which detailed tracking is required by the application.

Figure 4 presents the data platform model for the structural health monitoring system. We observed during modeling that organization entities own project entities representing different constructions and that each such construction project is associated with some installed sensors. Note that only organizations are active, as they initiate and manage construction activities, while projects are passive structural schemes used by organizations. As such, we create *Organization* actors that encapsulate project information, as displayed by an aggregation relationship with a non-actor Project class, instead of utilizing separate actors. This modeling decision minimizes message exchange when there is no clear advantage in having the two entities run concurrently.

This notwithstanding, sensors are themselves active entities in that they may be relocated, leading to change of position, and also may generate multiple data streams originating from different physical sensor channels (e.g., if we consider a regular smartphone as a sensor, then the accelerometer and microphone would be sensor channels). Moreover, messaging is minimal between sensors and sensor channels, as data streams arriving at the platform can be disaggregated by proxies directly by sensor channel instead of being relayed through sensor entities. As such, we model separate *Sensor* and *Sensor Channel* actors. Sensor Channel actors hold a window of data points originating in the respective data stream. The data points are captured as non-actor objects since these entities are not active.

To help structure information about data points, additional actors are included. First, Sensor Channel is specialized into *Physical Sensor Channel* and *Virtual Sensor Channel* actor classes. Whereas the former represents a channel in a physical sensor, the latter represents a computation over potentially multiple physical channels (e.g., in our smartphone example, an equation merging the data from accelerometer and microphone sensor channels). While a virtual sensor channel provides data at the finest level of detail, it is necessary to provide statistical aggregates for online queries posed by data analysts at various levels of detail (e.g., per hour, day, or month). Since there can be parallelism in computing these aggregations across levels of detail (e.g., hourly aggregates serving as input to daily aggregates), it is useful to conceptualize them as active entities. We thus introduce *Aggregator* actors in the model.

Based on the above modeling process in the context of our case studies, we summarize a general **principle of how to decide on actor granularity**:

> An actor should represent the functionality of one active entity for which detailed tracking is required.

4.3 What is the Trade-Off between Employing Actors or Non-actor Objects for Frequently Accessed Entities?

We discussed the issue of actor granularity, which may result in decisions where entities from the domain are modeled as actors or alternatively as non-actor objects. The modeling principle for actor granularity calls our attention to active entities. By contrast, there are a number of entities that store data but do not proactively perform tasks. We call them *inanimate entities*, and they are exemplified in the beef cattle tracking and tracing case study by meat cuts and meat products. In Figure 3, we model these inanimate entities as actors. However, these actors only encapsulate state and manage corresponding queries and updates originating from active entities such as slaughterhouse, distributor or retailer, e.g., when meat cuts and products are created or transported. As such, a natural question is whether these inanimate entities could have been modeled as non-actor objects instead of actors.

For example, suppose a distributor wishes to obtain information about a meat cut that it transports. The corresponding Distributor actor would have to send a message to the respective Meat Cut actor to fetch this information. Furthermore, when a meat cut is transported, the Meat Cut actor has to communicate with a number of other source or destination actors, such as Slaughterhouse, Distributor, or Retailer actors. As such, a Meat Cut actor frequently interacts with other actors in the system. Since all information on meat cuts needs to be exchanged across actors through asynchronous messaging, casting meat cuts as actors can generate a considerable communication overhead.

To explore this question, we have created an alternative model for the beef cattle tracking and tracing case study (cf. Figure 5). In this alternative model, we capture inanimate, but frequently updated entities, such as meat cuts and meat products, as non-actor objects instead of actors. Actors are marked in red in Figures 3, 4 and 5, while the non-actor objects are marked in black. The non-actor objects represent a state and thus cannot exist in an AODB independently of some actor. To capture state mutation as meat cuts and products move across the supply chain, we create object versions that are always associated with a responsible actor at every stage. Consider how a meat cut is transferred from a slaughterhouse to a distributor. The meat cut is the same real-world entity, but the slaughterhouse and distributor may identify the meat cut differently. Upon transfer, the object representing the meat cut will be copied from the Slaughterhouse actor to the Distributor actor, where this new object version can be updated. Since each actor keeps a separate object version of the meat cut throughout the supply chain, communication to obtain meat cut information is obviated. All the actor logic that reads this information can now access the encapsulated entities in the respective actor state. For frequently accessed entities, this reduction in communication may pay off with respect to the overhead of copying non-actor objects. Furthermore, potentially more concurrency can be exploited in reading local object versions across several actors independently. However, some degree of data redundancy may be introduced in the model.

Based on the above modeling process, we can summarize a general **principle of when to model frequently accessed entities as non-actor objects instead of actors**:

> Frequently accessed entities can be modeled as actors or non-actor objects, and the latter representation should be preferred when reductions in communication overheads and gains from concurrency offset the disadvantages of copying overhead and data redundancy.

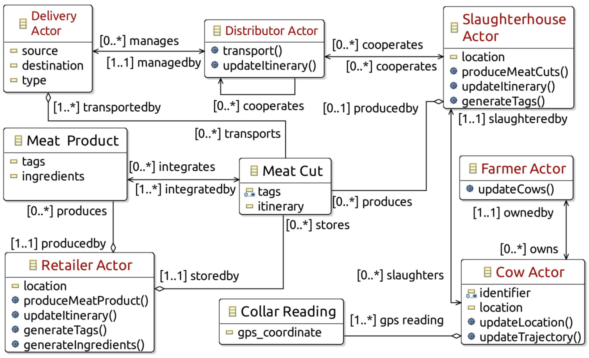

Figure 5: Alternative Actor Model of Beef Cattle Tracking and Tracing Data Platform.

4.4 How can Relationship Constraints be Enforced across Actors?

Because actors encapsulate state and only communicate through asynchronous messaging, relationships between actors are conceptually distributed. For instance, in the model of Figure 3, a farmer may own many cows, but a cow belongs to at most one farmer. In a typical implementation, each direction of this relationship would be represented as properties in Cow and Farmer actors. When performing updates to this relationship, we need to update both sides and make sure these two properties in different actors remain consistent. In particular, when a farmer sells a cow, the Cow actor should have its *ownership* relationship changed to the next owner, and the properties in the two affected Farmer actors ought to reflect that only one farmer retains the ownership of that cow. Since communication between actors is asynchronous, it is a challenge to keep consistency across actors in the presence of updates.

The consistency problem can be addressed by a transaction facility in the AODB, when available, or alternatively by a workflow that ensures that all actors in a relationship change are eventually updated to a consistent state. These options are similar in spirit to the proposal for indexing support in AODBs [17]. Since some actor systems, such as Akka, no longer support transactions [52], and update workflows operate under relaxed consistency, a final alternative is to keep all data related to a relationship, or more generally constraint, encapsulated in a single actor. This discussion leads us to our final **principle of how to enforce constraints when using actors**:

> Employ transactions to update data across actors consistently; however, in the absence of transactions, keep data related to a constraint in a single actor or design a multi-actor workflow for updates.

5 IMPLEMENTATION

In this section, we discuss the implementation of the IoT data platform for the first case study of Section 2 with an AODB. We choose the Structural Health Monitoring Data Platform (SHMDP) since the resulting implementation has been transitioned to the company SenMoS. However, the lessons learned and discussion extend more broadly to the applicability of AODBs to IoT data platforms in other domains, e.g., in beef cattle supply chains, among others.

Choice of AODB. Our implementation of the structural health monitoring data platform was based on the model of Figure 4 [18].

The first implementation challenge to be overcome was to find an appropriate platform supporting actor and non-actor object constructs, as well as the AODB approach. The vision for AODBs [17] was proposed in the context of the Orleans project [16], and we thus elect this actor runtime for the SHMDP. Orleans has also been used successfully in the context of other scalable applications [38], and can thus support real-world deployments. Unlike many other actor programming languages or frameworks such as Erlang [29] or Akka [3], Orleans employs the concept of *virtual actors*, i.e., named actors that are logically in perpetual existence. The Orleans actor runtime automatically creates activations of these virtual actors for processing whenever functions are asynchronously invoked on them, and eliminates activations when there is pressure on resources. As such, virtual actors simplify actor lifecycle management for an application built on Orleans.

In addition to virtual actors, Orleans provides an explicit storage model for actor state. In particular, actors run in a stateful middle-tier that can be conceptualized as an in-memory cache of actor state enriched with application code expressed as actor functions. Whenever persistence of actor state is required, a cloud storage system is employed by Orleans. The concrete storage system is specified through annotations in actor code. To meet the vision for AODBs, additional features are currently being implemented in Orleans to close the gap between actor runtime and DBMS functionality, e.g., indexing [17] and ACID transactions across actors [27].

Data Platform Architecture. A second implementation challenge was to architect an IoT data platform based on AODBs that fulfills all of the non-functional requirements of Section 2. Ideally, an AODB should handle online data ingestion and querying as well as analyses of historical data. However, as pointed out in Section 2, declarative querying functionality is still incomplete in AODBs currently [17]. Thus, we identify three core components for the SHMDP: actor runtime, cloud storage system, and analytical database system. The actor runtime was implemented by Orleans and provides the virtual actor abstraction. It also keeps any necessary in-memory data structures for online data processing and analysis as expressed in the model of Figure 4. The storage system provides durability of actor state, and allows large amounts of historical data to be archived. A key-value database system with efficient data ingestion [36] is useful for this purpose. Finally, data recorded in the storage system can be exported into a classic star schema implemented in the analytical database [34]. The latter component is targeted at analytical queries over historical data, and its description is outside the scope of this paper. The former two components comprised the online data ingestion, processing, and analysis functions of the SHMDP.

Support for Non-Functional Requirements. The AODB architecture supports the non-functional requirements listed in Section 2 as follows:

(1) **Data ingestion from endpoints**. Data from different endpoints was managed by distinct actors in Orleans, and recorded in the cloud storage system for durability.
(2) **Multi-tenancy**. Modularity, data encapsulation, and asynchronous communication were provided by virtual actors in Orleans, allowing isolation of functions and data sensitive to different users.
(3) **Support for heterogeneous data**. Orleans virtual actors support a number of data types and structures, e.g., representing simple alerts or real-time derived data for virtual sensors. In addition, Orleans was used to query time ranges of raw data, and to build aggregates for low latency requests over time periods. The problem of using Orleans for these functionalities was that declarative queries cannot access data across actors, and thus needed to be decomposed by the developer.
(4) **Cloud-based deployment**. Orleans was built to scale out on servers, and extend over multiple geographical locations. It is, moreover, open-source and designed with cloud deployment as a primary target.
(5) **Scalable data platform**. Modularization allows scalability in the number of actors, thus easily enabling the addition of more endpoints or users to the data platform.
(6) **High efficiency**. All processing in virtual actors occurs in-memory. Orleans employs multi-core and multi-server architectures to execute application logic in different actors in parallel.
(7) **Access control and data protection**. Authentication and access control were implemented at the application level by building on actor modularity features.

Virtual actor durability and deployment. Further implementation challenges arise from ensuring that the IoT data platform can effectively ingest and process the large number of concurrent update streams originating from devices. Two issues may impact performance substantially: enforcing durability and deploying actors over multiple machines in a cloud infrastructure.

Orleans virtual actors are called grains, and managed automatically by the Orleans runtime. When a grain has work to do, the grain is activated; when the grain has been standing idle for too long, the grain's resources are reclaimed by the system, removing it from memory. To provide durability, grains in Orleans may have a state storage class. This class defines all variables the developer wishes to store persistently. The developer can force the current state to persistent storage by invoking the WriteStateAsync grain method or configure the grain class to store state persistently when Orleans deactivates a grain. Whenever the Orleans runtime re-activates a grain, the runtime retrieves by default the latest grain state from cloud storage, if available. As such, Orleans lets the developer decide when state is written to persistent state storage.

In the SHMDP, durability requirements may vary depending on the task being implemented. Certain tasks require that the state of actors be immediately made durable, e.g., for creating structural entities such as organizations, sensors, projects, and sensor channels. Other tasks, such as gathering sensor data, can collect a window of updates before forcing them to storage. For example, in the Great Belt Bridge [50], the structural health monitoring project consisted of more than 200 sensor channels, with a typical requirement for live data being a reporting rate of one packet of readings per sensor per second. So if we wrote state to persistent storage after each request, we would need 200 write requests every second to the cloud storage system.

Activated grains in Orleans get distributed across a set of silos, where each silo is typically deployed in a server in a cluster of machines. The distribution of grain activations to silos is by default random, which is adequate for most use cases since it will spread load. However, this actor deployment can increase the cost of communication when certain actors interact frequently. Orleans suggests using prefer-local activation in these cases. For our data platform, we have had to change the activation placement strategy away from random placement for our sensor channels and aggregators. The prefer-local placement in these instances minimizes the need to perform remote procedure calls when processing incoming requests.

6 EXPERIMENTAL EVALUATION

Our goal in the experiments is to assess if the AODB-based implementation of our model from Figure 4 yields an IoT data platform that can scale in the number of sensors simulated and at the same time support low-latency online query functionality. In the following, we present our setup and the obtained results.

6.1 Setup

Benchmarking Tool. To stress-test the SHMDP, we created a command line tool in .NET that uses the Orleans framework client directly. This tool simulates data requests from sensors and users in order to generate variable load for the data platform. Sensors are simulated by tasks that each call a sensor grain and insert 10 data points. This procedure is repeated each second if all sensors have finished their calls, so as to adhere to the behavior expected in the real scenario based on our experience.

Even though we simulate sensors for experimentation with the benchmarking tool above, we envision that ingestion of sensor data points will be based on a REST interface in a production deployment. This way, sensors can send HTTP calls to the data platform. As part of data ingestion, message queues can be employed to accommodate for bursty behavior in sensor measurements [6]. To limit the scope of our evaluation, however, we focus on stressing only the virtual actor implementation of the IoT data platform, and not other layers related to communication with sensor devices.

The benchmarking tool stores data from each request sent to the data platform in a log. Each log entry includes the latency for the request, which request was sent (data insertion, live user data, or user data request), the sampling rate, and a timestamp. With this information, we can derive detailed throughput and latency statistics for the experiments.

Summary of Software. We needed the execution of several components for the experiments. The first one was the *Orleans silo*, typically with one instance deployed per server, where virtual actors are activated and run all application logic. We also employed *Amazon RDS* [12] for Orleans system storage, which keeps track of silo instances, reminders, and general system state. *Amazon DynamoDB* [9] was used for Orleans grain state storage. Besides, the C# benchmarking tool described above is invoked to generate load to silos.

Cloud Service and Deployment. To characterize the SHMDP's data ingestion and processing capabilities, we set up our benchmarking environment on Amazon AWS [8], employing the Amazon DynamoDB and RDS services [9, 12] as stated above and EC2 on-demand instances [10] for all remaining components. Given our budget, two types of instances were employed: T2 for low cost and burst performance features as well as M5 for more stable performance. All instances were running Windows Server 2012 R2 and Orleans 1.5.0. The configuration, unless otherwise mentioned, was designed to simulate a possible future production deployment of the data platform based on our previous experience with the project for the Great Belt Bridge [50]: m5.xlarge instances were employed for the Orleans silos, RDS db.t2.small for Orleans system storage, DynamoDB with 200 writes and 200 reads per second for Orleans grain storage, and an m5.2xlarge instance for the benchmarking tool.

Environment Configuration. For the experiments, we simulate sensors with two sensor channels each; every tenth sensor has a virtual sensor channel that is a summation of the two other sensor channels on the corresponding sensor. The latter choice reflects that only a subset of sensor data require additional processing to create a derived virtual sensor stream, which is close to the real life scenario from the Great Belt Bridge. We populated our actor-oriented database with synthetic data for users, organizations, projects, sensors, and sensor channels simulating a realistic scenario. For every 100 sensors, a new organization was constructed with a single user and a single project. Following the sensor configuration, these 100 sensors represent 210 sensor channels in total, out of which 200 are physical sensor channels and 10 are virtual sensor channels. This structure was used for all experiments, so that we can calculate exactly how many organizations, projects, users, and sensor channels are created given a number of sensors. Employing 100 sensors with 210 sensor channels in total is a configuration similar in size to the one in our previous experience with the Great Belt Bridge.

To achieve our experimental goal related to low latency queries, the upload of data points to the grain state storage has been configured to only happen when the Orleans silo service is shut down. This configuration ensures that we are not benchmarking DynamoDB storage, but rather the execution of in-memory actors. When using the system in production, the grains have to be configured to store data points to grain storage at an acceptable rate as explained in the considerations for durability in Section 5.

Load was offered to the SHMDP by sending requests with 20 data points for each sensor currently being simulated (i.e., 10 data points were generated for each physical sensor channel in each sensor). The requests were sent at a rate of 1 request per second. This frequency simulates sensors sampling data at 10 Hz, as specified in the Great Belt Bridge project for most sensors. As an example, consider that we wish to simulate 500 sensors: this number of sensors would correspond to 1,000 physical sensor channels and 50 virtual sensor channels. Thus, the resulting load would be of 500 requests per second being used to transmit 10,000 data points per second, and leading to the calculation of 500 virtual data points each second.

For each experiment, Figures 6, 7, 8 and 9 present the results. A single point on the figures aggregates 10 minutes of the whole service configuration running. The data was split into windows of 1 minute, and the first minute was removed to make sure the platform had started up correctly before measurement. In addition, the last minute was removed to ensure that only whole minutes were used. The average latency or throughput was then calculated as a measurement, and depicted along with standard deviation as error bars where appropriate.

6.2 Experimental Results

How many sensor readings can the SHMDP ingest using a single cloud server? In our first experiment, we aimed at establishing a relationship between the number of simulated sensors and the hardware utilization at the data platform, so that we can create a baseline load for the other experiments. In particular for these measurements, we employed the smallest VM size in the M5 series, the m5.large instance, and observed when the instance cannot process any more data insertion requests. We have chosen the smallest server size so that the experiment can be used for both scale up and scale out baselines.

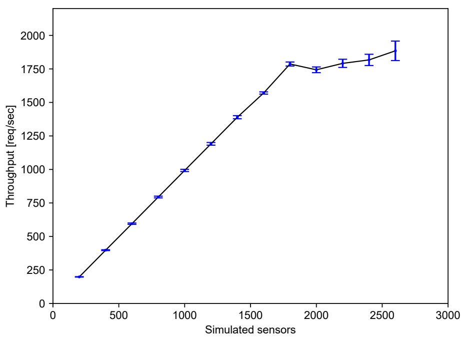

Figure 6: Single-server throughput experiment.

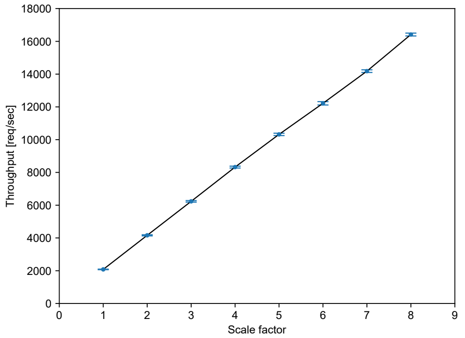

Figure 7: Scale out experiment over multiple servers.

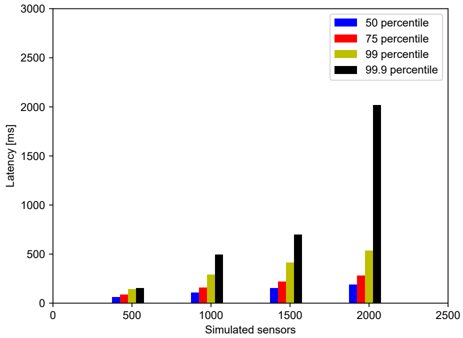

Figure 8: Latency percentiles for raw sensor channel data point time range requests.

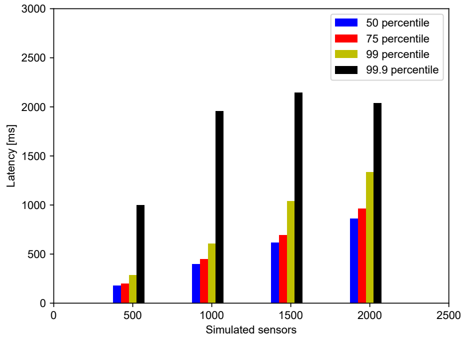

Figure 9: Latency percentile for organization live data requests.

Figure 6 shows the results from this single-server throughput experiment. Because each simulated sensor in the experiment was configured to send one request every second, note that the SHMDP deployment was processing all requests as long as the throughput is equal to the amount of simulated sensors. We observe that the ratio between simulated sensors and throughput is close to one until the number of simulated sensors reaches 2,000. At that point, throughput ceases to increase even if more load is offered. By monitoring the VM instance when performing the experiment, we have remarked that CPU Usage in Windows Task Manager was at 100% when the number of simulated sensors was above 1,800.

Does the SHMDP scale simultaneously on the number of sensors and servers? Our second aim was to verify whether the data platform can scale out in the number of data requests that it can ingest from simulated sensors by utilizing the computing power of more servers. To simulate a production environment, we employed larger m5.xlarge VMs as described in the experimental setup. From our single-server throughput experiments, we can estimate a baseline load to be offered per server. Based on this baseline, we can proportionally scale the load, number of servers, and organization structure in the experiment.

To estimate baseline load, we note that in a production environment, we wish to leave some CPU resources for user interaction. We chose to leave roughly 20% utilization for handling user online query requests and creating statistical aggregates. From the single-server throughput experiment of Figure 6, we know that roughly 1,800 requests per second can be processed by a m5.large instance. By removing 20% and rounding to the nearest 100 requests per second, we obtain 1,400 requests per second. Now, we can scale that number by the difference in computing power between the m5.large and m5.xlarge instances, which is estimated by their EC2 Compute Unit (ECU) values to be of a factor 1.5x. So the baseline for a single server corresponds to the load offered by 2,100 simulated sensors. This configuration is employed for a scale factor of one. As the scale factor is increased, we proportionally increase the number of simulated sensors and the number of servers used for Orleans silos.

Figure 7 shows that the throughput sustained by the data platform scales close to linearly with the scale factor. To illustrate this observation, consider that at a scale factor of five, we have five server instances and 10,500 simulated sensors. We observe as expected a throughput above 10,000 requests per second. Similarly, for a scale factor of eight, we have eight server instances and 16,800 simulated sensors, and a throughput above 16,000 requests per second is observed.

The results indicate that the data platform can potentially scale out even further than the 8 servers used in this experiment, since we did not hit any bottlenecks. We expect that the behavior can be maintained as we add a larger number of servers, since there are no dependencies across organizations and there is enough processing slack left to support eventual online user queries and calculation of statistical aggregates.

Does the SHMDP deliver low latency on online query functions concurrently with data ingestion? We have simplified the previous experiments by removing any user interactions, and made all sensors sample data at 10 Hz sending 1 request each second to the data platform. This scenario is close enough to our experience with a real deployment that we can observe how the data platform scales as we increase the number of sensor insertion requests. However, we still need to show that the 80% utilization rate chosen earlier will indeed leave enough room for the processing of online user queries. Furthermore, we aimed at better characterizing user request latencies under this target utilization level to make informed decisions when creating a production environment in the future.

To simulate user requests to the data platform, we estimated a relationship between simulated sensor requests and user interaction requests. We know from the requirements for the SHMDP that requests for live data as well as raw data kept in the sensor channel actors need to be supported. Requests for live data retrieved the most recent values from all sensor channels of a given organization, while requests for raw data retrieved the time series in a given sensor channel actor in an organization. From actual user interactions observed at the Great Belt Bridge project, we expect these online queries to be generated by at most one person looking at live data for each organization requesting data once every second, and at most one request for raw data a second for each organization. Since a deployment in that project would have around 100 sensors, we thus generate roughly 1% of the requests for live data from all sensor channels in a organization, 1% for raw data, and the remaining 98% as sensor data insertions.

Figures 8 and 9 show that the latency of online query requests increase, as expected, for higher percentiles of the latency distribution. This growth is especially pronounced for 99.9th percentile latency; however, even these extreme tail latencies can be ameliorated if utilization is reduced in the machine by offering load from less sensors. For example, for 500 simulated sensors, 99.9th percentile latency is minimal for raw data requests, and under 1 sec for live data requests. It is expected that latency of user interactions on the website be kept within a few seconds. This requirement can be fulfilled by the data platform even with the targeted 80% utilization load offered by 2,000 simulated sensors and at extreme latency percentiles. Moreover, the latency of raw data requests is often substantially below 0.5 sec, while that of live data requests is often below 1 sec at 2,000 simulated sensors.

7 RELATED WORK AND DISCUSSION

This section discusses research efforts related to our work. To the best of our knowledge, the literature lacks contributions explicitly justifying why and discussing how AODBs meet the challenges of IoT data platforms. However, earlier approaches have explored how to support different aspects of IoT data management employing a variety of data-centric system abstractions.

Approaches based on data stream management systems (DSMSs), in particular, are a commonly used solution in the context of IoT systems [11, 21, 31, 48]. DSMSs are apt at transforming multiple input streams, through a topology of data flow operators, into output streams containing, e.g., alerts and notifications for further processing. One challenge in these systems has been flexibility in responding to dynamically changing conditions as typical in IoT, e.g., through the addition or removal of input sources [49]. Actor-based streaming implementations have been proposed to address these concerns [5, 39], as adaptability is a built-in feature of the actor model [1]. However, a problem with data streaming approaches has been to additionally provide for data storage and online queries [22, 26]. In the context of IoT, AllJoyn Lambda explored a lambda architecture for IoT data storage analytics. Adnan et al. combined streaming and historical data to perform predictions in IoT systems based on machine learning models [2]. In contrast to AODBs, which abstract storage management with virtual actors and storage annotations, these approaches require developers to master complex APIs, often spanning across data stream and database systems. Moreover, while these systems provide for low-latency alerts, online queries are non-trivial to support efficiently. By contrast, an AODB acts as an in-memory, programmable cache where complex analyses can be executed in parallel over the encapsulated state of multiple actors employing user-defined methods.

Another class of solutions explored by previous work is that of cloud-centric actor-based IoT middleware, such as Ptolemy Accessor [42] and Calvin [41]. In these systems, every IoT device is modeled as an actor so that those multiple IoT components can be easily integrated into a potentially complex edge-cloud system. However, these middleware platforms lack integration with data management features that are central to an IoT data platform, such as efficient data storage with support for multi-tenancy and data protection. In addition to middleware, specific IoT applications have also been directly built over actor runtimes [4, 38]. For example, Pegasus is a cloud-based project aimed at gathering data with high-altitude balloons [23]. The system employs the Orleans actor runtime so as to simplify the development process of building a parallel, interactive and dynamic cloud service [15]. In contrast to our work, these previous implementation efforts do not provide any insights on data modeling decisions, nor do they analyze case studies to connect requirements for IoT data platforms with the necessary support from an actor-based solution. Even though there have been explorations of how to employ actors as a modeling construct for cyber-physical systems [25], none of these investigations fully satisfy our data platform requirements, namely storing, managing and processing large-scale data as well as providing for high scalability, real-time computation, data protection, and access control.

In line with the vision of Bernstein et al. [17], we argue that the integration of data management features into actor runtimes can help meet the increasing demand for scalable, low-latency data platforms. Recently, a relational actor programming model has been proposed for in-memory databases and realized in ReactDB [46]. Even though ReactDB shows that the actor model can be used to provide for low latency in databases, we did not consider it as a possible option for our data platform because it is a research prototype and currently not available for production use. Furthermore, in previous work combining actors and databases, there is no systematic review of how to model and structure IoT data platforms, nor discussion of the implementation of such IoT platforms employing an AODB approach. Our work matches the characteristics of an AODB with the requirements and challenges of IoT data platforms, showing how recent research on AODBs can be the basis for a new methodology to model and build IoT data platforms.

8 CONCLUSIONS AND FUTURE WORK

IoT systems require adequate data platforms for handling data storage, management, query and preservation. The modeling and deployment of these platforms remain an open research challenge. In this paper, we presented a generic actor-oriented data platform modeling approach for IoT data platforms, showing how actor-oriented databases can address challenges in the management of IoT data. Our discussion of challenges and their solution was showcased via two distinct case studies, specifically systems for structural health monitoring and beef cattle tracking and tracing. Our contribution covered the detailed modeling of these two real-world case studies and presented the entities and the patterns used to represent their dynamic behavior. This was accompanied by a discussion of modeling challenges, together with our recommendation of technologies and methodologies to address these challenges. As part of this work, we developed a prototype of a structural health monitoring system, which was transitioned to SenMoS. This prototype was validated through experiments demonstrating scalability as more simulated sensors are added as well as low latency in interactive query functions.

We believe that adopting AODBs for IoT systems can help attain the full potential of IoT by extending the reach, scalability, and maintainability of IoT data platforms. As future work, we plan to explore data integration issues in IoT data platforms modeled with the AODB approach, and devise approaches to enforce constraints in AODBs.

ABSTRACT

Demand for real-time stream processing has been increasing and Apache Kafka has become the de-facto streaming data platform in many organizations. Kafka Streams API along with several other open source stream processing systems can be used to process the streaming data in Kafka, however, these systems have very high barrier of entry and require programming in languages such as Java or Scala.

In this paper, we present KSQL, a streaming SQL engine for Apache Kafka. KSQL provides a simple and completely interactive SQL interface for stream processing on Apache Kafka; no need to write code in a programming language such as Java or Python. KSQL is open-source, distributed, scalable, reliable, and real-time. It supports a wide range of powerful stream processing operations including aggregations, joins, windowing, sessionization, and much more. It is extensible using User Defined Functions (UDFs) and User Defined Aggregate Functions (UDAFs). KSQL is implemented on Kafka Streams API which means it provides exactly once delivery guarantee, linear scalability, fault tolerance and can run as a library without requiring a separate cluster.

1 INTRODUCTION

In recent years, the volume of data that is generated in organizations has been growing rapidly. From transaction log data in e-commerce platforms to sensor generated events in IoT systems to network monitoring events in IT infrastructures, capturing large volumes of data reliably and processing them in a timely fashion has become an essential part of every organization. This has resulted in an emerging paradigm where organizations have been moving from batch oriented data processing platforms towards realtime stream processing platforms.

Initially developed at LinkedIn, Apache Kafka is a battle hardened streaming platform that has been used to capture trillions of events per day [2] [16]. Apache Kafka has become the de-facto streaming platform in many organizations where it provides a scalable and reliable platform to capture and store all the produced data from different systems. It also efficiently provides the captured data to all the systems that want to consume it. While capturing and storing streams of generated data is essential, processing and extracting insight from this data in timely fashion has become even more valuable. Kafka Streams API along with other open source stream processing systems have been used to perform such real time stream processing. Such real time stream processing systems have been used to develop applications such as Streaming ETL, anomaly detection, real time monitoring and many more. Many of these stream processing systems require users to write code in complex languages such as Java or Scala and can only be used by users who are fluent in such languages. This is a high barrier of entry that limits the usability of such systems.

Motivated by this challenge, in this paper we present KSQL, a streaming SQL engine for Apache Kafka that offers an easy way to express stream processing transformations[8]. While the existing open source stream processing systems require expression of stream processing in programming languages such as Java, Scala or Python or offer limited SQL support where SQL statements should be embedded in the Java or Scala code, KSQL offers an interactive environment where SQL is the only language that is needed. KSQL also provides powerful stream processing capabilities such as joins, aggregations, event-time windowing, and many more.

KSQL is implemented on top of the Kafka Streams API which means you can run continuous queries with no additional cluster; streams and tables are first-class constructs; and you have access to the rich Kafka ecosystem. Similar to addition of SQL to other systems such as Apache Hive[17] and Apache Phoenix[4], we believe that introduction of SQL for stream processing in Kafka will significantly broaden the users base for stream processing and bring the stream processing to the masses.

The rest of the paper is organized as the following. In the next section we provide a brief overview on Apache Kafka and the Kafka Streams API. Section 3 presents our contribution in design and development of KSQL. We describe data model, basic concepts, query language and the internals of our SQL engine. In Section 4, we present how KSQL can be extended using UDFs and UDAFs. We describe different execution modes for KSQL in Section 5. We present our experimental evaluation results for KSQL in Section 6. Section 7 describes the related work. We present the future work directions and conclude the paper in Section 8.

2 BACKGROUND

KSQL is implemented on top of the Kafka Streams API. In this section we will provide a brief overview on Apache Kafka and the Kafka Streams API.

2.1 Apache Kafka

Apache Kafka is a large-scale distributed publish/subscribe messaging system where data is produced to and consumed from topics [2] [15] [16]. Messages in Kafka include a key and a value. Figure 1 depicts the anatomy of a topic in Kafka. Each topic consists of several partitions where messages are assigned to based on their key. Each partition is an ordered, immutable sequence of records that is continually appended to a structured commit log. To achieve fault tolerance, partitions are replicated across a configurable number of servers, called brokers, in a Kafka cluster. One broker for each partition acts as the leader and zero or more brokers act as followers.

Producers publish data to their desired topics by assigning the messages to the specific partition in the topic based on the message key. To consume the published data to a topic, consumers

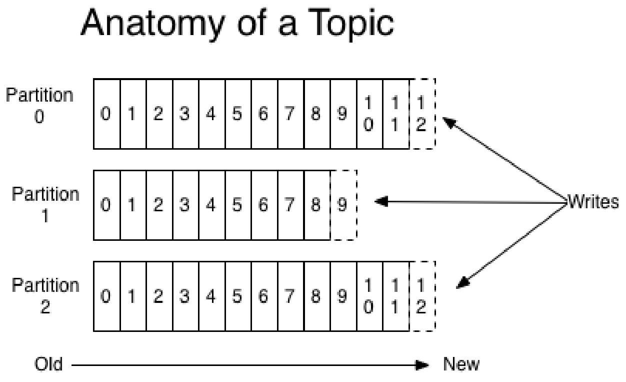

Figure 1: Anatomy of a Kafka topic

form consumer groups where each published message will be delivered to one instance in the consumer group. Figure 2 shows two consumer groups that consume messages from a topic with four partitions in a Kafka cluster with two brokers.

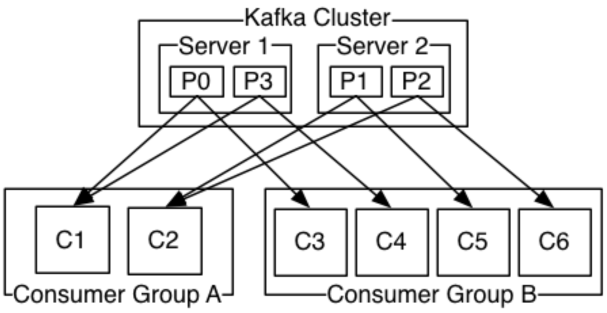

Figure 2: Two consumer groups reading from a topic with four partitions.

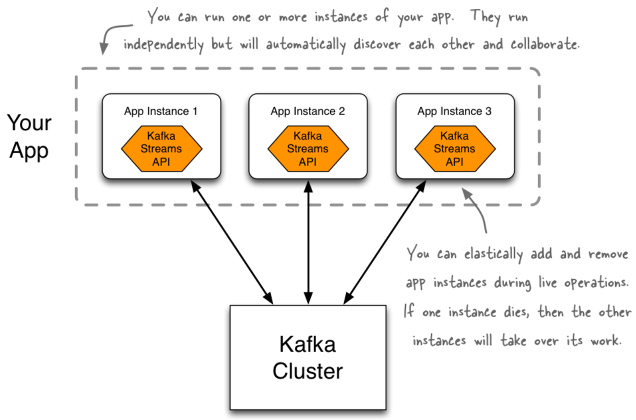
A consumer groups can expand by adding more members to it. It can also shrink when group members fail or are removed explicitly. Whenever, a consumer group changes, Kafka cluster will go through a rebalancing process for the consumer group to guarantee every partition in the topic will be consumed by one instance in the consumer group. This is done by Kafka group management protocol which is one of the fundamental building blocks of the Kafka streams API as we describe below.

2.2 Kafka Streams API

Kafka Streams API is a Java library that enables users to write highly scalable, elastic, distributed and fault-tolerant stream processing applications on top of Apache Kafka [2]. Unlike other stream processing frameworks that need a separate compute cluster to run stream processing jobs, Kafka streams runs as an application. You can write your stream processing application and package it in your desired way, such as an executable jar file, and run instances of it independently. If you need to scale out your application, you just need to bring up more instances of the app and Kafka streams along with Kafka cluster will take care of distributing the load among the instances. The distribution of load in Kafka streams is done with the help of Kafka group management protocol. Figure 3 depicts the architecture of a Kafka streams app.



You can run one or more instances of your app. They run independently but will automatically discover each other and collaborate.
Your App
App Instance 1
Kafka Streams API
App Instance 2
Kafka Streams API
App Instance 3
Kafka Streams API
You can elastically add and remove app instances during live operations. If one instance dies, then the other instances will take over its work.
Kafka Cluster

Figure 3: Two consumer groups reading from a topic with four partitions.

A typical Kafka streams application will read from one or more Kafka topic and process the data and writes the results into one or more Kafka topics. Kafka streams app uses the same data model as Kafka where messages include a key and a value along with a timestamp and offset of the message in its corresponding partition. The processing logic in a Kafka streams app is defined as a processing topology that include source, stream processor and sink nodes. The processing model is one record at a time where an input record from the source is processed by passing through the whole topology before the next recored is processed. Kafka streams provides powerful stream processing capabilities such as joins, aggregations, event-time windowing, sessionization and more. Operations such as join and aggregation are done based on the message key. Kafka streams uses intermediate Kafka topics to perform shuffle for operations such as aggregation and join that need to colocate data based on a key. For instance, if two streams are being joined and the join key is not the same as the message key for both streams, Kafka streams repartitions both stream topics based on the join key and produces new intermediate topics where message key is the same as the join. This will ensure the colocation of the records with the same key that can be joined at the same node.

Kafka streams provides *stateful* stream processing through the so-called *state stores*. The state stores exist in every instance of the streaming application and are used to store the state in operations such as join and aggregation in a distributed fashion. By default Kafka streams uses RocksDB[9] to store application state, however, any in-memory hash map or other data structures can be plugged in.

3 KSQL

In this section we present KSQL, streaming SQL engine for Kafka. As mentioned KSQL uses Kafka streams to run the user queries, therefore, it inherits many properties of Kafka streams.

3.1 Data Model

As mentioned a message in a Kafka topic consists of a key and a value. To keep the messages generic, Kafka does not assume any specific format for the messages and both key and value are treated as array of bytes. In addition to the key and value, a message also includes a timestamp, a partition number that it belongs to and the offset value in the corresponding partition. In order to use SQL on top of Kafka topics we need to impose the relational data model, *schema*, on the value part of messages in Kafka topics. All of the message values in a topic should conform to the associated schema to the topic. The schema defines a message value as a set of columns where each column conforms to the defined data type. Currently, we support the primitive types of BOOLEAN, INTEGER, BIGINT, DOUBLE and VARCHAR along with the complex types of ARRAY, MAP and STRUCT. We plan to add DECIMAL, DATE and TIME types in future. KSQL supports nested column type using the STRUCT type. The fields in a ARRAY, MAP and STRUCT types themselves can be any of the supported types including complex types. As you can see, there is no limit in the level of nesting and users can have as many levels of nesting as they desire. The schema of message values for Kafka topic is used for serialization and deserialization of message values.

3.2 Basic Concepts

KSQL provides streaming SQL for Kafka topics meaning that you can write continuous queries that run indefinitely querying future data. There are two basic concepts in KSQL that users can use in their queries, stream and table. Depending on how we interpret the messages in a Kafka topic we can define streams or tables over Kafka topics in KSQL.

If we consider the messages arriving into a topic as independent and unbounded sequence of structured values, we interpret the topic as a ***stream***. Messages in a stream do not have any relation with each other and will be processed independently.

On the other hand, if we consider the messages arriving into a topic as an evolving set of messages where a new message either updates the previous message in the set with the same key, or adds a new message when there is no message with the same key, then we interpret the topic as a ***table***. Note that a table is an state-full entity since we need to keep track of the latest values for each key. In other words, if we interpret the messages in a topic as a **change log** with a state store that represent the latest state, then we interpret the topic as a table.

As an example consider we store the page view events for a website in a Kafka topic. In this case, we should interpret the topic as a stream since each view is an independent message. On the other hand, consider we are storing user information is a Kafka topic where each message either adds a new user if it is not stored already or updates the user information if we already have stored the user. In this case, we should interpret the topic as a table. Note that at any moment, the table should have the most up to date information for every user.

KSQL also provides *windowed* stream processing where you can group records with the same key to perform stateful processing operations such as aggregations and joins. Currently, KSQL supports three types of windows:

- **Tumbling window** which are time-based, fixed-sized, non-overlapping and gap-less windows
- **Hopping window** which are time-based, fixed-sized and overlapping windows
- **Session window** which are session-based, dynamically-sized, non-overlapping and data-driven windows

Note that the results of windowed aggregations are tables in KSQL where we need to keep the state for each window and aggregation group and update them upon receiving new values.

KSQL also support join operation between two streams, a stream and a table or two tables. The stream-stream join always requires a sliding window since we should prevent the size of the state store growing indefinitely. Every time a new message arrives to either of the streams, the join operation will be triggered and the new message for each matching message from the other stream within the join window will be produced. KSQL supports INNER, LEFT OUTER and FULL OUTER join operations for two streams. The RIGHT OUTER join can be implemented via the LEFT OUTER join by simply change the left and right sides of the join. Joining a stream with a table is a stateless operation where each new message in the stream will be matches with the table resulting in emission of zero or one message. Finally, joining two tables in KSQL is consistent with joining them in relational databases if we materialize both of them. KSQL supports INNER, LEFT OUTER and FULL OUTER joins for two tables.

3.3 Query Language

KSQL query language is a SQL-like language with extensions to support stream processing concepts. Similar to the standard SQL language, we have DDL and DML statements. DDL statements are used to create or drop streams or tables on top of existing Kafka topic. The followings are two DDL statements to create a pageviews stream and a users table:

```
CREATE STREAM pageviews (viewtime BIGINT,
 userid VARCHAR, pageid VARCHAR) WITH
 (KAFKA_TOPIC='pageviews_topic',
 VALUE_FORMAT='JSON');

CREATE TABLE users (registertime BIGINT,
  gender VARCHAR,
  regionid VARCHAR,
  userid VARCHAR,
address STRUCT<
  street VARCHAR, zip INTEGER
>
 ) WITH (
  KAFKA_TOPIC='user_topic',
  VALUE_FORMAT='JSON',
KEY='userid'
 );
```

Note that in addition to defining the schema for the stream or table we need to provide information on the Kafka topic and the data format in the WITH clause. After declaring streams and tables, we can write continuous queries on them.

Unlike standard SQL statements where the queries return finite set of records as the result, in streaming systems we have continuous queries and therefore the results also will be continuous while the query runs. To address this, KSQL provides two types of query statements. If the results of the query are stored as a new stream or table into a new Kafka topic we use **CSAS(CREATE STREAM AS SELECT)** , **CTAS(CREATE TABLE AS SELECT)** or **INSERT INTO** statements depending on the type of the query results. For instance, the following statement enriches the pageviews stream with extra user information by joining it with the users table and only passes the records with regionid = 'region 10'. The result is a new stream that we call enrichedpageviews:

```
CREATE STREAM enrichedpageviews AS
 SELECT * FROM pageviews LEFT JOIN
 users ON pageviews.userid = users.userid
 WHERE regionid = 'region 10';
```

On the other hand, the following CTAS statement creates a table that contains the pageviews for each user in every 1 hour. Here we use an aggregate query with tumbling window with size of 1 hour.

```
CREATE TABLE userviewcount AS
 SELECT userid, count(*)
 FROM pageviews
 WINDOW TUMBLING (SIZE 1 HOUR)
 GROUP BY useid;
```

Note that the results of the above query will be continuous count values for each user and window that will be stored in a Kafka topic. Every time we receive a new record the current count value for the corresponding userid and window will be updated and the new updated value will be written to the topic. As it can be seen the result will be a change log topic.

Depending on the execution model that we will discuss in the later section, KSQL also provides query manipulation statements where user can submit continuous queries, list the currently running continuous queries and terminate the desired ones.

3.4 KSLQ Engine

As mentioned, KSQL uses Kafka streams to run the streaming queries. The main responsibility of the KSQL engine is to compile the KSQL statements into Kafka streams apps that can continuously run and process data streams in Kafka topics. To achieve this KSQL has a metastore component that acts as a system catalog storing information about all the available streams and tables in the system. Currently metastore is an internal component in the KSQL engine. Depending on the execution mode the metastore can be backed by a Kafka topic to provide fault tolerance.

Figure 4 depicts the steps that are taken in the engine to compile KSQL statements into Kafka streams applications to run. As it can be seen, the first step is to parse the statements where the KSQL parser generates an Abstract Syntax Tree (AST). Using the metastore, the generated AST will be analyzed and the unresolved columns references will be resolved. This include detecting the column types along with resolving expression types in the queries along with extracting different components of a query including source, output, projection, filters, join and aggregation. After analyzing each query, we will build a logical plan for it. Logical plan is a tree structure where the nodes are instances of PlanNode class. Currently, we can have the following node types in KSQL logical plan: SourceNode, JoinNode, FilterNode, ProjectNode, AggregateNode and OutputNode. The leaf node(s) are of SourceNode type and the root node is OutputNode type. As it is indicated in Figure 4. rule-based optimization techniques can be applied to the generated logical plan, however, at the moment we do not apply any rule to the logical plan other than pushing down the filters.

The final step is to generate a physical execution plan from the logical plan. The physical plan in KSQL is a Kafka streams topology that runs the stream processing logic. We use the higher level topology structure that is called Kafka streams DSL[2]. Kafka streams defines two fundamental building blocks, **KStream** and **KTable** which are synonymous to stream and table in KSQL. Indeed, A KSQL stream represents a KStream along with a schema. Similarly, a KSQL table represents a KTable along with the associated schema. Kafka streams DSL also provides operations such as map, join, filter, aggregate, etc that convert KStreams/KTables into new KStream/KTables. These operations work on key and value of Kafka messages where there is no assumption on the schema of message value. KSQL defines similar operations on streams and tables, however, in KSQL we impose the proper schema on the message value.

KSQL engine also is responsible for keeping the metastore and queries in the correct state. This includes rejecting statements when they result in incorrect state in the engine. Dropping streams or tables while there are queries that are reading from or writing into them is one of the cases that would result the system to go into an incorrect state. A stream or table can only be dropped if there is no query reading from or writing into it. KSQL engine keeps track of queries that read from or write into a stream or table in the metastore and if it receives a **DROP** statement for s stream or table that is still being used, it will reject the **DROP** statement. Users should make sure that all of the queries that use a stream or table are terminated before they can drop the stream or table.

4 UDFS AND UDAFS

Although standard SQL statements provide a good set of capabilities for data processing, many use cases need to perform more complex and custom operation on data. By using functions in queries SQL systems enhance their data processing capabilities. KSQL also provide an extensive set of built in scalar and aggregate functions that can be use in queries. However, to even make KSQL more extensible, we have added capability of adding custom User Defined Functions (UDFs) and User Defined Aggregate Functions (UDTFs).

4.1 User Defined Functions

UDF functions are scalar functions that take one input row and return one output value. These functions are stateless, meaning there is no state is maintained between different function calls. Currently, KSQL supports UDFs written in Java. Implementing a new UDF is very straightforward using only two annotations. A Java class annotated by *@UdfDescription* annotation will be considered as a UDF containing class. User provide the name of the UDF by setting the *name* parameter of the *@UdfDescription* annotation. Any function in this class that is annotated by *@Udf* annotation will be considered as a UDF that can be used in any query similar to any other built in function. The following is an example UDF that implements multiplication.

```
@UdfDescription(name = "multiply", description =
     "multiplies 2 numbers")
public class Multiply {

  @Udf(description = "multiply two non-nullable INTs.")
  public long multiply(final int v1, final int v2) {
    return v1 * v2;
  }
}
```

After implementing the UDFs, users can package them in a JAR file and upload it to the designated directory in the KSQL engine where the functions will be loaded from when the KSQL engine starts up. The following query shows how the above UDF can be used in a query:

```
CREATE STREAM test AS
 SELECT multiply(col1, 25)
```

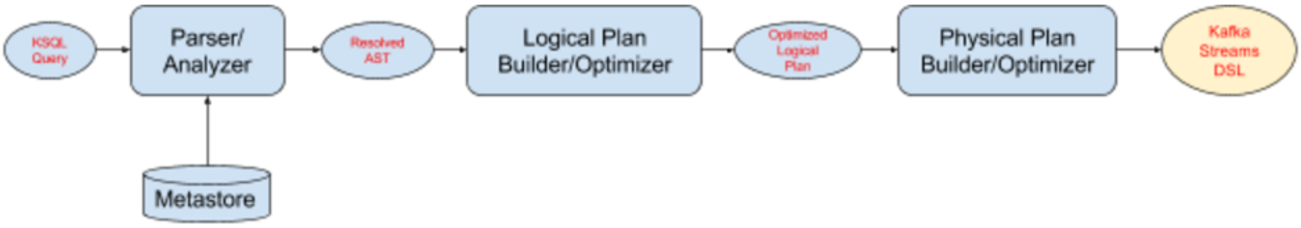


Figure 4: Steps to convert KSQL statements into Kafka streams apps.

```
 FROM inputStream;
```

4.2 User Defined Aggregate Functions

Aggregate functions are applied to a set of rows and compute a single value for them. Similar to the UDFs, KSQL UDAFs are implemented in Java using annotations. To create a new UDAF, users need to create a class that is annotated with *@UdafDescription*. Methods in the class that are used as a factory for creating an aggregation must be *public* and *static*, be annotated with *@UdafFactory*, and must return an instance of *Udaf* class. The instances of a textitUdaf class should implement *initialize*, *aggregate* and *merge* methods. The following is an example UDAF that will perform *sum* operation over double values:

```
@UdafDescription(name = "my_sum", description = "sums")
public class SumUdaf {
@UdafFactory(description = "sums double")
  public static Udaf<Double, Double> createSumDouble() {
    return new Udaf<Double, Double>() {
      @Override
      public Double initialize() {
        return 0.0;
      }

      @Override
      public Double aggregate(final Double aggregate,
           final Double val) {
        return aggregate + val;
      }

      @Override
      public Double merge(final Double aggOne, final
           Double aggTwo) {
        return aggOne + aggTwo;
      }
    };
  }
}
```

Similar to UDFs, UDAFs should be packaged in a JAR file and uploaded to the designated folder in the KSQL engine so the functions can be loaded at the engine start up.

We plan to add support for User Defined Table Functions (UDTFs) in near future.

5 EXECUTION MODES

As discussed above, KSQL engine creates Kafka streams topologies that execute the desired processing logic for Kafka topics. Therefore, running KSQL queries is the same as running Kafka streams topologies. Currently, KSQL provides three different execution modes that we describe here.

5.1 Application Mode

The application mode is very similar to running a Kafka streams app as described earlier. To deploy and run your queries, you need to put them in a query file and pass it as an input parameter to the KSQL executable jar. Depending on the required resources, you determine the number of instances that your application needs and similar to a Kafka streams execution model you will instantiate the instances by running the KSQL jar with the query file as input parameter. The deployment process can be done manually or through third party resource managers such as Mesos[3] or Kubernetes[10]. Note that you don't need any extra processing cluster and the only thing you need is to run your KSQL app by bringing up desired number of instances independently. Everything else will be handled by KSQL and Kafka streams.

5.2 Interactive Mode

KSQL also provides an interactive execution mode where users can interact with a distributed service through a REST API. One way of using the provided REST API is to use KSQL CLI which includes a REST client that sends user requests to the service and receives the response. The building block of the interactive mode is KSQL server that provides a REST end point for users to interact with the service and also KSQL engine to execute the user queries. Figure 5 depicts the architecture of the KSQL service with three servers in the interactive client-server execution mode.

Each KSQL server instance includes two components, the KSQL engine and the REST server. The KSQL service uses a special Kafka topic, **KSQL command topic**, to coordinate among the service instances. When a service instance is started, it first checks the Kafka cluster for the command topic. If the topic does not exists it creates a new command topic with a single partition and a configurable number of replications. All of the service instances then subscribe to the command topic. User interacts with the service by connecting to REST endpoint on one of the instances. The **KSQL command topic** has only one partition to ensure the order of KSQL statements for all server is exactly the same. The **KSQL command topic** can have more than one replicas to prevent loss of KSQL statements in presence of failure. The figure shows the KSQL CLI that connects to either of the instances.

When user submits a new KSQL statement through the REST endpoint, the instance that receives the request will append it to the KSQL command topic. The KSQL engine components in all of the instances will pull the new statement from the command topic and execute the statement concurrently. For instance, consider the following statement is submitted to the service through one of the instances and appended to the command topic.

```
CREATE TABLE userviewcount AS
 SELECT userid, count(*)
 FROM pageviews
```

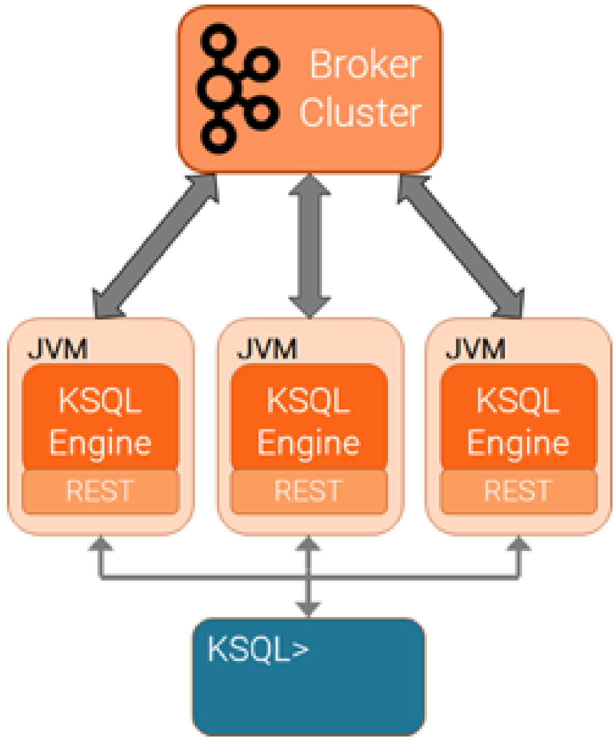

Figure 5: A KSQL interactive service deployment with three server instances.

```
WINDOW TUMBLING (SIZE 1 HOUR)
GROUP BY useid;
```

All of the instances will use the KSQL engine to start the processing of the query and as mentioned above each instance will process portion of the input data from the *pageviews* topic. The service instances continue running the queries until they are explicitly terminated using *TERMINATE* statement.

The KSQL service provides both elasticity and fault tolerance. Service instances can be added or removed independently, depending on the load and performance requirements. When a new instance is started it subscribes to the command topic and fetches all the existing KSQL statements from the command topic and starts executing them. When the new instance starts executing an existing query a rebalance process is triggered and the execution load will be redistributed among the existing instances. Note that the rebalance protocol is handled by the underlying Kafka consumers in the Kafka streams and is transparent for the KSQL service instance. After all of the existing continuous queries start running on the new instance too, it starts listening to the command topic for new queries. Similarly when an instance fails or terminated a rebalance process among the remaining instances of the service happens and the load of the removed instance will be distributed among the remaining instances. Even if all the instances fail and the whole system is restarted, the instances will pick up all the existing KSQL queries from the command topic when they come back online and the whole system will continue processing the queries from the point they were left.

5.3 Embedded Mode

The third execution mode available in KSQL is the embedded mode where we can embed KSQL statements in a Kafka streams application. As mentioned Kafka streams apps are Java programs that use the Kafka streams as library. KSQL provides a **KSQLContext** class with a **sql()** method where KSQL statements can be passed to run in the embedded engine. The following code snippet show a very simple example of using the embedded mode.

```
KSQLContext ksqlContext = new KSQLContext();
ksqlContext.sql("CREATE STREAM pageviews
 (viewtime BIGINT, userid VARCHAR,
  pageid VARCHAR) WITH
  (KAFKA_TOPIC='pageviews_topic',
  VALUE_FORMAT='JSON');");
ksqlContext.sql("CREATE STREAM pageviewfilter
 AS SELECT * FROM pageviews
  WHERE userid LIKE '\%10';");
```

Similar to the Kafka streams apps, in order to execute the queries in the embedded mode, you need to package the application and run instances of it. The deployment can be done through a range of available options such as manually bringing up instances or using more sophisticated tools such as Mesos or Kubernetes.

6 EXPERIMENTAL EVALUATION

6.1 Methodology

We want to evaluate KSQL's ability to handle different types of workloads. To do this, we ran a series of tests with different query types and measured the throughput that a single KSQL server can process. Each test case runs for ten minutes and periodically measures throughput in messages / second and bytes / second.

In practice, users will likely run multiple queries that feed into each other to form a streaming pipeline. We've included a multi-query test to measure performance for this scenario.

Finally, we run multiple queries on a pool of KSQL nodes to see how KSQL scales as servers are added.

6.1.1 Load Generation. To generate load against KSQL we ran a modified version of the "'ksql-datagen"' tool that has had some changes made to improve its performance and to allow it to produce different types of workloads. "'ksql-datagen"' is a tool for generating data into a kafka cluster. The tool generates Kafka records conforming to a specified schema. The schema can be one of a set of pre-defined schemas, or the user can specify their own avro schema for the tool to use. Records are written to Kafka using the Java Kafka producer client. For our tests, we extended "'ksql-datagen"' to support multiple threads, and to support a rate-limit parameter (specified in messages produced per second) implemented using a token-bucket algorithm.

6.1.2 Measuring Throughput. We measured throughput using a counter exported by KSQL that provides the number of messages consumed by a given topic. Throughput for a given time period is computed by sampling the counter at two points in time and dividing the difference in consumed messages by the difference in time. For tests that run multiple queries in a pipeline, consumption is measured against the topic that is the source for the final query in the pipeline. This gives us the throughput of the pipeline as a whole.

6.1.3 Environment. We ran our test in AWS EC2. The test environment consists of a Kafka cluster, a KSQL cluster, and a set of nodes that run the load-generator.

The Kafka cluster consists of 5 Kafka nodes, and 1 node for running ZooKeeper. To run Kafka we chose the i3.xlarge instance type, which has 4 2.3GHz VCPUs, 30.5GB of memory, "up-to-10Gbit" of network, and a 950GB NVME local disk which we'll use to store the Kafka topics. We used fio to benchmark the instance storage, and observed 380MBps write throughput, 950MBps read throughput, 2000016K random write IOPS, and 61000 16K random read IOPS. Finally, we ran some network benchmarks using iperf to get an idea of what network performance to expect, and observed 1.24Gbit of network throughput.

Zookeeper runs on an m3.medium.

The KSQL cluster consists of 1-4 nodes, depending on the test case. We chose i3.xlarge instance for KSQL as well, and use the NVME local disk to store the local state stores.

6.2 Test Data

The test data and workload are derived from a use case for analyzing metrics. Metrics are published by services that comprise a distributed application. The queries consume, transform, aggregate and enrich this metric data. The source stream for the metrics has the following schema:

```
ID VARCHAR,
SOURCE VARCHAR,
INSTANCE LONG,
CLUSTERID VARCHAR,
METRIC STRUCT<
    NAME STRING,
    VALUE INTEGER,
    METADATA1 STRING,
    METADATA4 STRING,
    METADATA5 STRING,
    METADATA6 STRING,
    METADATA7 STRING,
    METADATA8 STRING,
    METADATA9 STRING,
    METADATA10 STRING
>
```

For our tests, we produced test data serialized using AVRO. The average size for test records was 220 bytes. The source topic containing the metrics data has 32 partitions.

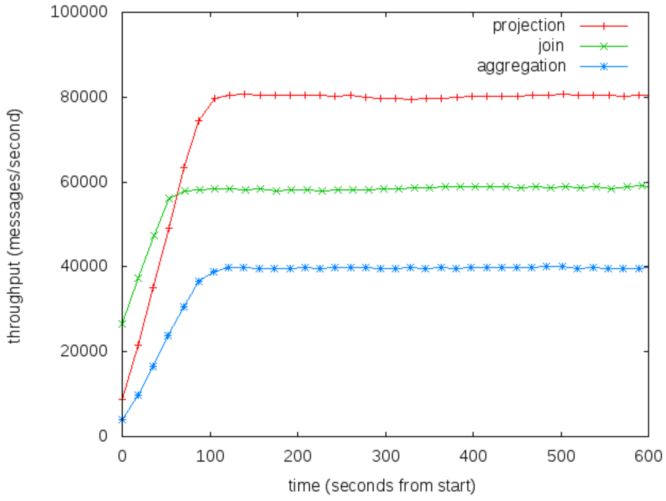

Figure 6: Throughput for Basic Query Types

6.3 Projection

The first type of query we'll evaluate is a basic projection. Users can use similar queries to apply basic stateless transformations and filters to their data. For the test, we'll run the following query:

```
CREATE STREAM SINK
 AS SELECT *
 FROM METRICS_STREAM;
```

Figure 6 depicts the measured throughput over the test run. Throughput starts low, increases as the JVM warms up, and stabilizes just under 90000 messages per second. The main bottleneck for this query type is CPU utilization, which is nearly 100% on the KSQL server during the test run. To discover why, we re-ran the test case while profiling using the YourKit JVM profiler and found the main hot-spots to be deserialization and serialization of the records after reading from, and before writing back to Kafka.

6.4 Aggregation

Next lets look at an aggregation. Aggregations allow the user to group records in a stream or table, and then apply an aggregation function on the grouped records. For this test, we'll run an aggregation to compute the average value of a metric:

```
CREATE TABLE SINK
 AS SELECT
  INSTANCE,
  SUM(METRIC->VALUE) / COUNT(*)
 FROM METRICS_STREAM
 GROUP BY INSTANCE
```

Figure 6 depicts the measured throughput over the test run. Again, the bottleneck is CPU utilization on the KSQL server. In this case, profiling revealed additional overhead from reading from / writing to RocksDB. Each read from RocksDB has to potentially traverse multiple SSTs within the database to find the latest update for the grouping key. The state for aggregations is quite small and fits comfortably within the block cache, so there is no added cost for reading from the kernel cache or decompressing. Writing also adds some cost to write to the memtable and append to the log. The source data for this aggregation is keyed on the grouping column, so there is no additional cost for serializing/deserializing to/from the repartition topic. Aggregations that require a repartition would incur this cost as well.

Space usage on the local disk is quite small, just a few hundred MBs. This makes sense since the state required to compute each aggregation result is small - just the key, sum, and current count, which are all 32-bit or 64-bit integers. Utilization is also quite low - around 50 IOPS and 1MBps. Interestingly, a good portion of the disk usage comes from storing checkpoints for per-task topic offsets rather than from RocksDB itself.

6.5 Windowing

Usually, users want to compute aggregations that correspond to a specific time interval - for example, the average value of a metric over a day or hour. KSQL provides tumbling and hopping windows to allow you to window your aggregation computation using a fixed-size window. A tumbling window computes results for one time interval without any overlap with the previous interval. A hopping window has two arguments: the time interval, and the hop size. Results are returned for windows that are as wide as the interval and advance by the hop size. This lets you approximate a sliding window. In this experiment, we'll compute tumbling and sliding windows and observe the effect on performance:

```
CREATE TABLE SINK
 AS SELECT
  INSTANCE,
  SUM(METRIC->VALUE) / COUNT(*)
 FROM METRICS_STREAM
 WINDOW TUMBLING (
  SIZE 60 SECONDS
 )
 GROUP BY INSTANCE

CREATE TABLE SINK AS SELECT
 INSTANCE,
 SUM(METRIC->VALUE) / COUNT(*)
 FROM METRICS_STREAM
 WINDOW HOPPING(
  SIZE 60 SECONDS,
  ADVANCE BY ? SECONDS
 )
 GROUP BY INSTANCE
```

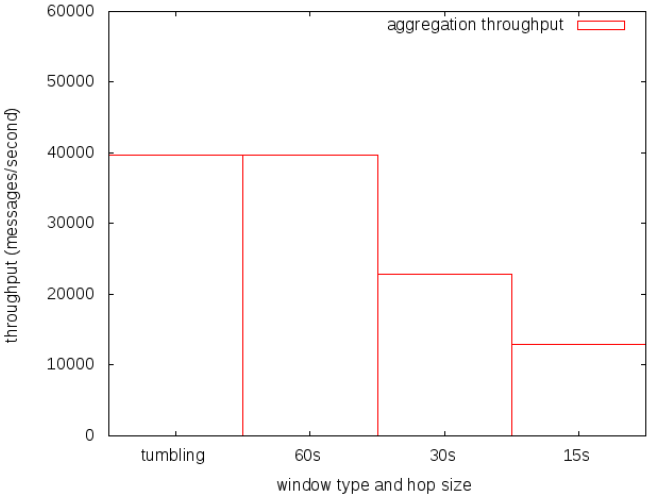

Figure 7: Throughput for Varying Window Sizes

Figure 7 shows that the realized throughput decreases as the number of windows that must be maintained increases. This makes sense - under the hood the aggregation result for each window that a given record maps to is maintained independently. If record arriving in the stream must update 4 windows (as in the ADVANCE BY 15 SECONDS case), then KSQL will do 4 separate reads and write from/to RocksDB. This adds to the CPU cost to process each record.

6.6 Stream Enrichment

Another common use case for KSQL is to enrich a stream of data with a dimension table. In this test, we'll enrich our metric stream by adding information from an instance table to each metric record:

```
CREATE STREAM SINK
 AS SELECT S.*, T.*
 FROM
  METRIC_STREAM S
  LEFT JOIN
  INSTANCE_TABLE S
 ON S.INSTANCE = T.INSTANCE;
```

Figure 6 shows the throughput over time. Again, the primary bottleneck is CPU utilization, which is near 100%. The realized throughput is around 55000 records per second - greater than the aggregation but lower than the projection. This is because to process each record in the stream we must read from RocksDB, but nothing is written back to the state store. Therefore, the CPU utilization per record is lower than that for aggregations, and the realized throughput is higher.

6.7 Multi-Query Application

Usually, KSQL users run multiple queries in a streaming pipeline to form a KSQL "application". To evaluate KSQL in this scenario, we'll build the following test app:

```
CREATE STREAM METRICS_WITH_INSTANCE_INFO
 AS SELECT S.*, T.*
 FROM
  METRIC_STREAM S
  LEFT JOIN
  INSTANCE_TABLE S
 ON S.INSTANCE = T.INSTANCE;

CREATE TABLE AVERAGE_VALUE_BY_PHYSICAL_INSTANCE
 AS SELECT
  T_PHYSICAL_INSTANCE,
  SUM(METRIC->VALUE) / COUNT(*)
 FROM METRICS_WITH_INSTANCE_INFO
 GROUP BY PHYSICAL_INSTANCE;
```

In the app we first enrich the metrics stream with the instance table (as in the previous section), and then compute average metrics grouped by the "physical instance" each instance resides on (which is another field of the instance table schema).

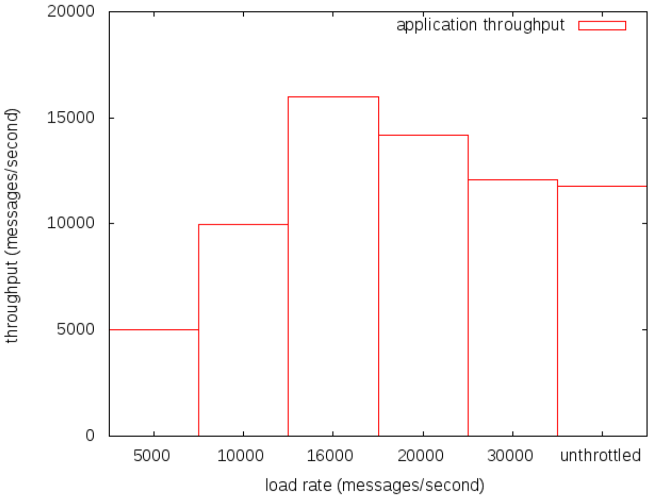

Figure 8: Throughput for Varying Load Rates

To evaluate the possible throughput a KSQL server can process against the app, we generate load at varying rates and measure the consumption rate from METRICS_WITH_INSTANCE_INFO. To understand why its important to rate limit the load generator to determine the maximum possible throughput, lets consider the behavior if load generation was run at a rate that would produce records faster than KSQL could consume them. The "application" presented in Figure 8 consists of 2 queries. The 2 queries have different performance characteristics. Specifically, the join consumes significantly fewer CPU cycles than the aggregation to process the same set of input records. Currently, KSQL does not coordinate execution between separate queries. So, each query would be afforded around half the available CPU time. Ideally, the aggregation should be afforded more CPU than the join. Throttling the input rate gives us a knob to do this indirectly. In practice, a user could accomplish the same thing by scaling out the capacity of their KSQL cluster, or allocating varying numbers of threads to different queries. Figure 8 shows that the maximum throughput a single KSQL server can process running this application is around 16000 records/second.

6.8 Scale-Out

KSQL is designed to scale record throughput as KSQL servers are added. In this section, we'll show that KSQL can process the application we evaluated in the previous section at higher volumes as the cluster grows. We'll evaluate a 2-node and 4-node KSQL cluster. For each configuration, we'll run at 2 times and 4 times the ideal load observed in the previous section, and measure the realized throughput.

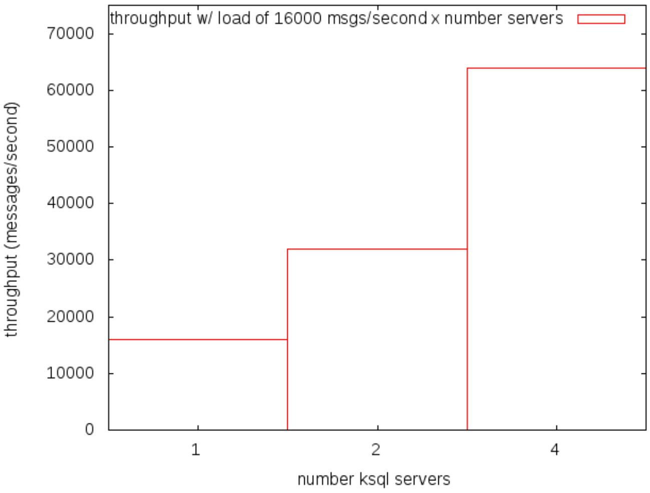

Figure 9: Throughput For Varying Cluster Sizes

Figure 9 shows the results of this experiment. Each bar represents the throughput processed by a KSQL cluster of a given size. Load was generated proportional to the cluster size - 16000 messages per second for the single node cluster, and 32000 messages per second and 64000 messages per second for the 2 and 4 node clusters, respectively. We can see that KSQL is able to process proportionally higher volumes of data as the cluster is grown.

6.9 Future Experiments

The previous sections detailed some initial results of our evaluation of KSQL performance. In the future, we plan to do additional analysis into performance as well as fix some of the issues identified. Latency is a very important metric when evaluating streaming systems that was not measured by our study. After all, one of the primary advantages of stream processing is to be able react to events in real-time. Therefore we plan to measure percentile latency as we invest in evaluating and improving KSQL performance. We also plan to evaluate additional query types. KSQL is a very powerful tool that can perform a wide variety of computations not covered by the evaluation presented here. Some candidate query types for the next round of testing include stream-stream joins and aggregations over session windows.

7 RELATED WORK

Over the past couple of decades stream processing has been one of the main subjects of interest in the data management community. Systems like STREAM [12], Aurora [11] and TelegraphCQ [14] are some of the pioneers in this area.

Increasing demand for scalable streaming engine resulted in development of many systems including open source systems such as Storm [7], Spark [6], Flink [1] and Samza [5]. Although these systems provide a scalable stream processing engine, however, all of them need deployment and management of a complex processing cluster in order to process the streaming jobs. On the other hand, KSQL uses Kafka streams and KSQL queries can be deployed as an application without requiring another complex processing cluster. This significantly simplifies deployment and management of long running streaming jobs in KSQL and provides a wide range of possible deployment options.

SQL language has been the de-facto data management language and many systems support SQL or SQL-like interface. Apache Hive [17] and Apache Spark SQL [13] have shown the effectiveness of using SQL to express computations in batch data processing. They are also great examples of how providing SQL interface can expand the access to scalable data processing systems by eliminating the need to write code in complex programming languages. Some of the open source stream processing frameworks including Apache Spark [6], Apache Flink [1] take this idea to scalable stream processing by providing SQL support. However, the level of SQL support in these system is not at the same level as in KSQL and in order to use SQL for stream processing in these systems users still need to write code in languages such as Java or Scala and embed their SQL statements in their code. On the other hand, in KSQL users describe their processing in KSQL statements and there is no need to write any code in Java or Scala or any other language. This approach significantly simplifies scalable stream processing and makes it available for greater audience.

8 CONCLUSIONS AND FUTURE WORK

In this paper we introduced KSQL, a streaming SQL engine for Apache Kafka. KSQL uses Kafka streams API to run continuous queries and is tightly integrated with Apache Kafka. We showed how a KSQL query is translated into a Kafka streams app in KSQL engine and how we can run KSQL queries in different execution modes. One of the main advantages of KSQL compared to other open source stream processing systems is the elimination of need to code in any other language. KSQL users can use the KSQL CLI and run their streaming queries by expressing them in only KSQL statements. The other main differentiator of KSQL compared to other open source streaming platforms is the query execution model. Unlike other systems that need deployment of a separate processing cluster to handle streaming queries, KSQL queries can run as applications independently without requiring deployment of additional complex cluster. This significantly simplifies deployment and management of streaming queries in KSQL.

We just announced availability of KSQL as an open source streaming SQL engine and released it under Apache license in 2017 Kafka Summit in San Francisco and since then we have witnessed significant interest from the community[8]. We plan to invest heavily in development and expansion of KSQL. Currently we are looking into expanding supported data formats in KSQL along with providing custom functionality through UDF and UDAF in addition to the ones we already have in KSQL. Improving the performance through optimized query planning along with even more simplified deployment and maintenance of KSQL service in the production environment are part of our near future work on KSQL. We believe KSQL along with Apache Kafka provide a full stack stream processing environment that can satisfy the all the real-time stream processing needs in enterprises and will be working towards this goal.

ABSTRACT

This work demonstrates a wide range of applications that use lambda expressions in SQL. Such injected code snippets form a useful technique required by data mining algorithms to overcome the inflexibility of the SQL language, as the language is limited to predefined aggregations only. Following the ’move computation to the data’ paradigm, we extend SQL lambda functions—also known from common programming languages—for machine-learning tasks.

As machine-learning relies mostly on gradient descent and tensor data types, we use lambda expressions for clustering and graph-mining algorithms as well as to formulate loss functions and label data. To underline the flexibility gained in SQL, this work demonstrates a main memory database system with integrated lambda expressions accessible through table functions in SQL. By reusing SQL and performing data mining and machine-learning tasks faster than can dedicated tools, this demonstration aims at convincing data scientists of the capabilities of database systems for computational tasks.

1 INTRODUCTION

Database systems are commonly used for the initial analysis of data, whereas data analysis happens in specialised systems, covering the expensive Export, Transform, Load (ETL) process. In consequence, database systems are often underused as a storage system only, ignoring the advantages coming along with SQL as the declarative query language and the benefits of database systems as providing index structures for fast data retrieval.

Actually, data mining blends well with SQL: Using the same data types, we need only minor adjustments as iterations in SQL or injected code snippets. MADlib [3] proposes a data mining library for extending database systems such as PostgreSQL and Greenplum. The extension uses algorithms that are programmed in Python and can be used as table functions in SQL. Modern main memory database systems try to integrate data mining algorithms in the code generation phase. EmptyHeaded [1] generates and combines code out of special algorithms and relational algebra, whereas HyPer [5] provides specialised operators for data mining tasks. The latter provides flexibility for data mining by so-called SQL lambda functions, which allow for modifications to existing database operators by injecting user-defined code.

Although modern database systems provide data mining algorithms, machine-learning functionalities are still not covered. As machine-learning tasks often rely on tensors and gradient descent, providing an additional tensor data type and flexible loss functions for gradient descent contribute to in-database machine-learning.

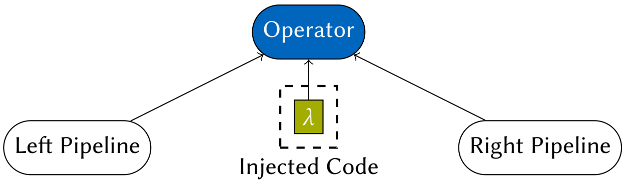

Figure 1: Lambda expression for code injection into an existing operator: The expression can be used inside unary operators to define functions on different tuples of the same relation and inside binary operators to combine tuples of different relations.

Let us shift the boundary between database systems and the specialised tools to save ETL costs and to enjoy the benefits of database systems a bit more throughout the process. We argue that lambda functions can be adapted for machine-learning tasks and extend SQL to a powerful query language for machine-learning. This results in a computational engine, which merits the full benefits of database systems and can be addressed in SQL.

This work demonstrates the first database system to incorporate lambda expressions for minimisation problems. An extended HyPer is presented in detail. The main memory database system developed at the chair of database systems at TU Munich is already familiar with flexible clustering algorithms. It is now extended by flexible PageRank, gradient descent and labelling algorithms for machine-learning. A gradient descent operator and the integrated tensor data type allow supervised machine-learning tasks. As lambda expressions are part of the database system’s core, the query optimiser implicitly performs optimisations, such as predicate push-down, and reduces unnecessary overhead.

The remainder of this paper is structured as follows. First, the paper recaps lambda expressions and shows how they extend database systems to a uniform tool for solving machine-learning tasks. In the evaluation section, we discuss the measurement of the performance of database systems with lambda functions in comparison to dedicated tools to show the competitiveness. Our demonstration scenario allows users to interact with the database system and to create self-defined lambda expressions, for example, to apply gradient descent, to label data or to measure distances in clustering algorithms. The impact of computational

database systems—replacing dedicated machine-learning tools—is summarised in the section on benefits.

2 LAMBDA FUNCTIONS

Lambda functions originate from the lambda calculus invented in 1936 by Alonzo Church [2] and later adapted for programming languages to provide anonymous functions. For use in SQL, the concept of anonymous expressions is adapted to 'inject user-defined code' [4] into analytic operators. Lambda expressions allow a user-friendly way for data scientists—who are already familiar with SQL and lambda functions from other programming languages—to customise algorithms without any modifications of the operators in the database system's core. Another advantage of lambda functions is the implicit deduction of input and output data types from the input tables' attributes without requiring further specification.

Lambda expressions in HyPer have been used in clustering algorithms as distance metrics and in graph-mining algorithms, such as PageRank to specify the edges. As lambda functions allow 'variation points' [6] in inflexible data mining algorithms, their usage can be transferred to machine-learning algorithms to specify loss functions. Lambda expressions are composed as follows:

$$\lambda(< name1 >, < name2 >, \ldots)(< arithmeticexpression >).$$

In the lambda function's header, the arguments name the relations whose table attributes are used in the arithmetic expression itself. The number of expected arguments is hard-coded in the operators as well as in the relations referenced by the arguments. More precisely, in unary operators, all arguments reference one input pipeline, whereas, in binary operators, the references depend on a certain application. Internally, lambda expressions are treated as arithmetic expressions in HyPer like those in the projection operator. Therefore, all known functions supported by the referenced database types can be used inside the expression as long as the expression results in a single value. As HyPer compiles SQL queries, lambda expressions are precompiled to LLVM code and evaluated at runtime.

To demonstrate the use of lambda functions for data mining and machine-learning, we selected two tasks out of each domain where lambda expressions broaden the application area of database operators.

Clustering k-Means as a clustering algorithm assigns points to a predefined number of k centres, which are iteratively adjusted until the summed distance to each centre is minimised. Hereby, the distance function is given as a lambda expression to specify Manhattan (L^1) or Euclidean (L^2) distance.

Graph-mining PageRank is a graph-mining algorithm for gathering the importance of nodes by the number of incoming edges per node weighted by the score of the source node.

Optimisation Machine-learning algorithms rely on optimisation algorithms such as gradient descent. Given a model function parametrised by some weights, one aims to minimise the weights to obtain minimal loss in order to predict the targets/labels of the data and a loss function that measures the deviation from the true labels and their predictions. To allow user-defined loss functions, we adapt the concept of lambda expressions to work as a mathematical function for minimisation on the training set's attributes.

Labelling To label test data, an operator adds the result of a parametrised function to the input relation. Lambda expressions define the loss function to be evaluated on the test data set.

The algorithms for clustering and graph-mining are hard-coded as materialising pipeline breakers in the database system's core, as various iterations are needed to compute the clusters or the PageRank values. The operator for labelling—as part of the pipeline—simply evaluates the lambda expression and adds a new attribute to the input relation. The operator for gradient descent uses a self-developed framework for automatic differentiation based on *placeholders* for the input data and *variables* for the weights and can be designed as either materialising or non-materialising pipeline breaker. All operators define the usage of the lambda functions according to the number of input pipelines. As k-Means and PageRank only need one input pipeline, lambda expressions define the functions between the tuples of one input relation. The lambda expression for the distance metrics in k-Means takes two tuples S, T of the same relation $R\{[x, y]\}$ as argument (L^2 distance, for example):

$$\lambda(S, T)((S.x - T.x)^2 + (S.y - T.y)^2).$$

PageRank—contrary to the other operators—needs **two** lambda expressions to specify the edges: one for the source node and the second one for the destination node of the input relation $R\{[src, dst]\}$:

$$\lambda(R)(R.src), \lambda(R)(R.dst).$$

For gradient descent and labelling, we need data for the placeholders and weights for the variables. Therefore, the lambda expression takes one tuple from each of the two input relations $R\{[a, b]\}$ (initial weights) and $S\{[x, y]\}$ (training data) to formulate the loss function:

$$\lambda(R, S)(R.a * S.x + R.b - S.y)^2.$$

As lambda expressions are part of the database system, they are taken into account by the database's query optimiser. When the data is stored column-wise, only the relevant data for the lambda expression is loaded.

3 EVALUATION

The evaluation section presents the runtimes of the lambda-based operators. The experiments were run on an Intel Xeon E5-2660 v2 (20 cores of 2.20 GHz) server with 256 GB main DDR4 RAM running on Ubuntu 18.04 LTS. The test data was one-month excerpt of the Chicago taxi rides dataset[1] ($> 1.7 * 10^6$ tuples), on which we performed clustering with k-Means and logistic regression by gradient descent, and the LDBC data set with scale factor 10 for graph-mining with PageRank.

Using k-Means, we clustered the taxi dataset geographically by the trip's destination expecting 10 clusters. By logistic regression, we predicted the payment type depending on the distance of a trip and the ages of the customers. We reused the predicted weights to label the data. We take the *person-knows-person*-relationship from the LDBC benchmark to calculate the PageRank values of each person. Each test varied the input sizes to compare the runtime of our extended operators with the lambda functions in HyPer to the runtime of PostgreSQL 9.6.8 with its MADlib v1.13 extension

Figure 2: Runtimes of the operators using lambda functions and of the competitors varying the number of input tuples.

(database system with a plugin), TensorFlow 1.3.0 without GPU support (dedicated machine-learning tool) and R 3.4.2 (statistical tool). The tests were run five times and the average runtimes were taken.

As expected, all the operators scaled linearly in the size of the input dataset and no overhead caused by lambda expressions in SQL was measurable. Figure 2a shows k-Means in comparison to R and TensorFlow (both use predefined library functions). Our database operator with the included lambda function outperformed all dedicated tools by at least a factor of three.

The in-database PageRank function provided by the MADlib library scaled linearly as well but was still four times slower than the integrated operator (see Figure 2b). The lambda expressions did not slow down the runtime of the database system as both operators performed at quite the same time.

The currently introduced gradient descent operator (see Figure 2c) reduced the overhead caused by data extraction and transfer as the data could be processed directly. The results were performance gains of at least five times in comparison to R, the fastest dedicated tool. The hard-coded gradient descent function in PostgreSQL and the equivalent procedure in MariaDB ran out of scope and the MADlib extension for logistic regression performed as fast as our lambda-based operator only for small input relations. Figure 2d shows the labelling of the attributes that performed linearly in the size of the input tuples.

In summary, the lambda expressions broadened the application area of the database systems without performance losses and eliminated the need for dedicated tools.

4 DEMONSTRATION

The demonstration convinces by the simplicity of using SQL for machine-learning: the central part is an extended web interface for HyPer with SQL for the input queries and a tabular output representation (see Figure 3). To facilitate the use of database systems for data scientists, data visualisation—comparable to those of business intelligence tools—enriches the output by simple dragging and dropping the table's attributes on the axes of different sorts of diagrams (pie/bar/line charts). As an additional feature, a box for specifying lambda functions with their input weights allows the plotting of lambda expressions as mathematical functions inside the diagrams.

The database system is fed with an excerpt of the Chicago taxi dataset and the current OpenFlights dataset[2]. The web interface lets users choose between predefined example queries with sample lambda expressions or lets them create their own queries. Our predefined examples cover supervised machine-learning tasks based on gradient descent (see Listing 3), labelling and data mining tasks such as clustering (see Listing 1) and PageRank (see Listing 2).

In our demonstration scenario, the user is encouraged to perform machine-learning tasks, such as the predefined regression to predict, for example, the number of tips given or the kind of payment in dependency of the length of a trip. In addition, the users can specify any kind of loss functions to perform predictions or other methods for the type of gradient descent.

To show the performance of the database systems, two charts—one for the runtime and one for the operator tree—provide informations about optimisations. This feature helps the user to understand how operator reordering and predicate push-down of integrated lambda expressions increase the performance.

5 CONCLUSION

In this demonstration, we presented SQL lambda functions for in-database machine-learning and data mining with an interactive web interface devoted to its use by data scientists.

We proposed extending already known lambda expressions for use in machine-learning, especially to specify loss functions for gradient descent. By this extension, we used database systems with SQL as a universal computational engine, eliminated the need for dedicated machine-learning tools and reduced the time needed for data communication. To tackle the acceptance of SQL with lambda functions, we created a web interface that interactively combines SQL with data visualisation and provides informations about the optimised query plans.

This work aimed at adding lambda functions in standardised SQL to allow changing the database system as an underlying machine-learning tool. Lambda functions are essential for providing a higher-order machine-learning language to be used by data scientists. For that purpose, a declarative language is needed to further increase the acceptance of database systems and should be designed to be compiled to SQL or an executable to call the application interfaces of current dedicated tools.

MINARET: A Recommendation Framework for Scientific Reviewers

Mohamed R. Moawad, Mohamed Maher, Ahmed Awad, Sherif Sakr
University of Tartu, Estonia
{mohamed.ragab,mohamed.abdelrahman,ahmed.awad,sherif.sakr}@ut.ee

ABSTRACT

We are witnessing a continuous growth in the size of scientific communities and the number of scientific publications. This phenomenon requires a continuous effort for ensuring the quality of publications and a healthy scientific evaluation process. Peer reviewing is the de facto mechanism to assess the quality of scientific work. For journal editors, managing an efficient and effective manuscript peer review process is not a straightforward task. In particular, a main component in the journal editors' role is, for each submitted manuscript, to ensure selecting adequate reviewers who need to be: 1) *Matching* on their research interests with the topic of the submission, 2) *Fair* in their evaluation of the submission, i.e., no conflict of interest with the authors, 3) *Qualified* in terms of various aspects including scientific impact, previous review/authorship experience for the journal, quality of the reviews, etc. Thus, manually selecting and assessing the adequate reviewers is becoming tedious and time consuming task.

We demonstrate MINARET, a recommendation framework for selecting scientific reviewers. The framework facilitates the job of journal editors for conducting an efficient and effective scientific review process. The framework exploits the valuable information available on the modern scholarly Websites (e.g., Google Scholar, ACM DL, DBLP, Publons) for identifying candidate reviewers relevant to the topic of the manuscript, filtering them (e.g. excluding those with potential conflict of interest), and ranking them based on several metrics configured by the editor (user). The framework extracts the required information for the recommendation process from the online resources *on-the-fly* which ensures the output recommendations to be dynamic and based on up-to-date information.

1 INTRODUCTION

The world is witnessing a continuous growth in the size of scientific communities and the number of scientific publications. With the current rates, it is expected that the global scientific output doubles every nine years[1]. For example, Figure 1 shows the statistics of the popular DBLP indexing services for computer science publications[2]. In particular, the DBLP library is currently indexing over 3.8M publications. Out of these publications, the number of journal articles published in 2018 is about 120K articles. In 2017, Elsevier journals received 3919 submissions, out of which 530 were accepted with acceptance rate of 14%[3]. This situation raises a crucial need for continuous efforts to ensure and improve the quality of the scientific publication process.

In general, peer reviewing is a widely accepted practice to assess the quality of scientific publications [5, 9]. In this process, the *selection* of appropriate reviewers for evaluating the submitted manuscript is a significant step. For example, selecting reviewers without adequate knowledge in the topic of the submissions or selecting inexperienced reviewers would lead to poor reviews that harm the quality of the publishing venue, the scientific community, and the authors of the manuscript [3]. In addition, it is crucial to avoid any reviewers with potential conflict of interest [10]. In practice, assigning reviewers for a conference submission is less challenging than assigning a reviewer for a journal submission. In particular, the universe of reviewers is *closed* where it is limited to the program committee (PC) members who are commonly selected based on their experience and reputation in the scientific field of the conference. In addition, accepting the membership for the PC of a scientific conference indicates explicit commitment for the assigned review workload of the conference within the defined review deadline. Moreover, conference management systems provide a bidding process where each PC member should select the submissions that he/she would like to review. Thus, with this setup and conditions, it is possible to automate the paper-reviewer assignment task [2, 3, 8].

The manuscript review process for a journal submission is different. In particular, the universe of reviewers is *open* with various aspects of *uncertainty*. Thus, it depends much on the editor's experience, effort and professional network to select the adequate reviewers for a submitted manuscript. For example, there is no pre-defined agreement or arrangement between the journal and a set of committed reviewers. In particular, the manuscript review is a totally voluntary work with the only incentive of having a mutual benefit when the volunteering reviewer is an author of another manuscript submission that needs to be reviewed in the same or other journals. In addition, reviews' deadlines are soft constraints that are not obligatory for the reviewer. Thus, in order to achieve efficient and effective review process, it is the role of the editor to choose the reviewers that should at least cover the following main criteria: 1) Have matching research interests with the topic of the submitted manuscript, 2) Fair in their evaluation of the manuscript with no potential conflict of interest, 3) Have a good rank according to the editor's preferences in various criteria [4]. In practice, the first point can be managed by the editors' experience with the scholars of the scientific community of the journal and by browsing the profiles for candidate

[3] source:https://journalinsights.elsevier.com/journals/0142-9612/acceptance_rate

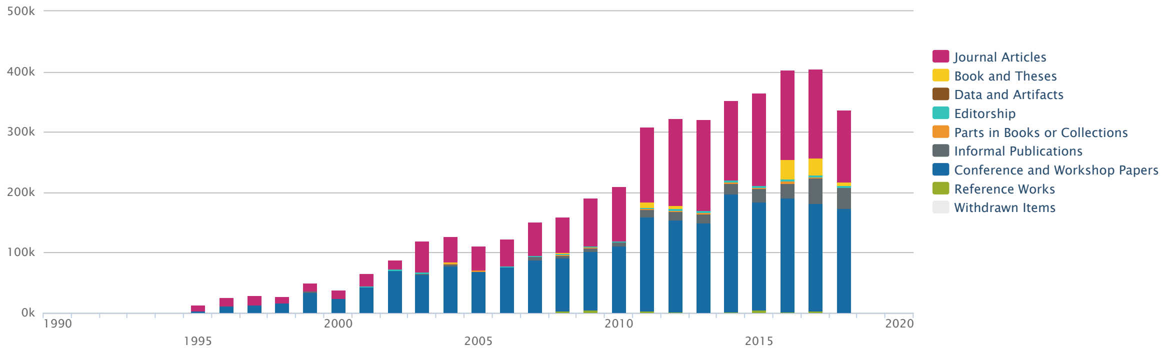

Figure 1: Statistics of DBLP library content

reviewers. However, the second point would require investigating the track record for both the authors and reviewers for discovering any potential for conflict of interest (e.g., co-authorship, having current/previous similar affiliations, ..., etc). Manually exploring and investigating this information would be a tedious and time-consuming task for the editors. The third point involves various aspects that need to be considered. For example, inviting a high-profile reviewer who happens to be quite busy will do nothing but delaying the review process as she might not reply to the invitation in a timely manner, simply reject it or accepting the invite and sending the review very late. Such selections may increase the turnaround time for making the decision on the submitted manuscript. Another aspect that can be considered is the history of review activities of the candidate reviewers and the quality of their reviews. Thus, it is crucially required that the reviewer selection process strikes a balance between these criteria and aspects.

Recently, we have been witnessing a continuous increase in the number of Websites and services that provide comprehensive scholary information. For example, DBLP provides the list of publications for a given author, Google scholar provides information about important metrics for the scientific impact (e.g., citation count, H-index, i10-index), Publons[4] provides information about the reviewing activities that have been conducted by a scholar. In this demonstration, we present MINARET, a recommendation framework for choosing scientific reviewers of a given manuscript information. The framework facilitates the job of journal editors for conducting an efficient and effective scientific review process by dynamically exploiting and integrating the available information on scholarly Websites *on-the-fly*. Within the search process, keywords representing the submission are semantically expanded to provide a wider range of related reviewers as candidates. Extracted information about the candidate reviewers are used to automatically exclude those with potential conflict of interests with the authors of the manuscript. Finally, the list of reviewers is ranked based on various criteria including the experience of the reviewer, recency of his familiarity with the topic of the submission, likelihood to accept and timely return his review, h-index, etc. The weight of these criteria is flexible to be configured by the users of the framework (editors).

2 REVIEWER RECOMMENDATION

Figure 2 shows the workflow of our recommendation framework. Using the basic information of the submitted manuscript (e.g., keywords, authors list and their current affiliation), the recommendation workflow goes through three main phases: *information extraction*, *filtration*, and *ranking* of the candidate reviewer list.

2.1 Information Extraction

The information extraction phase consists of the following main steps:

- *Verification of authors' identities*: This step is concerned with the disambiguation of authors' names [1, 6, 7]. For example, in the far east, many scholars may share one of the popular names[5]. The identification of the correct author profile is crucial as it influences the accuracy of the collected information. We use various services (e.g., DBLP, Google Scholar, ACM) to gather the information about the author list. In case of multiple matches, the user has to manually identify the correct profiles for the author list among the returned matches.
- *Extracting the track records of the author list*: This step focuses on extracting information about the publications list and affiliation history of the author list using multiple services (e.g., DBLP, Google Scholar, ACM, Publons). Extracting the authors' track record is particulary important to allow discovering any potential for conflict of interest.
- *Retrieval of candidate reviewers' profiles*: The main driver for candidate reviewers search is the list of keywords supplied as part of the manuscript details. Usually, this list contains three to five keywords defined by the authors to describe the research topic of their submission. To widen the search space of candidate reviwers, we employ a semantic keyword expansion. For this purpose, as our demonstration is focusing on the computer science community, we rely on an ontology of computer science topics[6]. Each relevant expanded keyword is assigned a similarity score $sc \in \left[0, 1\right]$ that defines the relevance between the returned keyword from the ontology and the original keyword. For example, if one of the manuscript's keywords is "RDF", the expansion module

[4] https://publons.com/

[5] https://dblp.uni-trier.de/pers/hd/z/Zhou:Lei

[6] https://cso.kmi.open.ac.uk/downloads

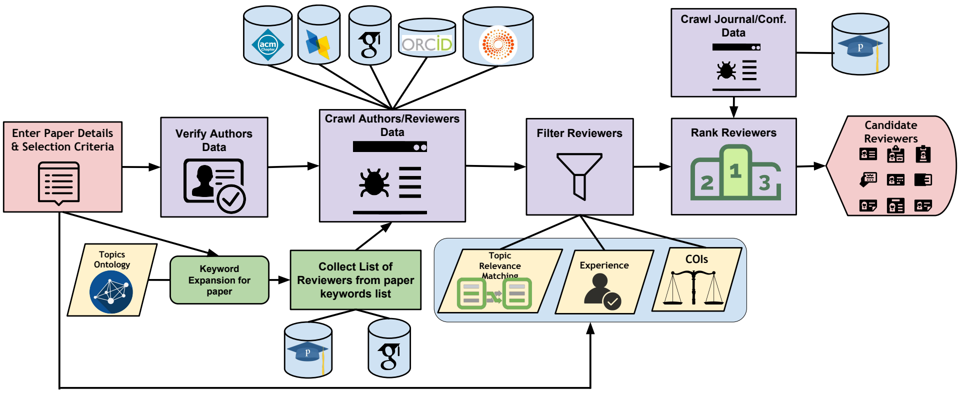

Figure 2: `MINARET` workflow

would return "Semantic Web", "Linked Open Data", and "SPARQL" as semantically related keywords among its results. Using the expanded keywords list, we retrieve the scholars who are registering these keywords as research interests by querying multiple services (e.g., Google Scholar and Publons).

`MINARET` is currently implemented to extract the information from six main sources: `Google Scholar`, `DBLP`, `Publons`, `ACM DL`, `ORCID` and `ResearcherID`. However, the framework is flexibly designed to include any further information from any additional scholary resource.

2.2 Filtering

In this phase, the list of candidate reviewers which is returned from the expanded keyword-based reviewer search gets filtered using the following conditions:

- *Conflict of interest*: COI is determined by checking the extracted profile information for both of the author list and candidate reviewers and based on the existence of a previous co-authorship between the candidate reviewer and one of author list or the existence of any shared affiliations on the level of the university or country, as configured by the editor.
- *Keyword matching score*: The editor can specify a threshold on the similarity score between the expanded keywords and those attached to the reviewers' profiles. Candidate reviewers with matching score below the defined threshold are filtered out.
- *A set of expertise constraints defined by the editor*: The user/editor can specify filtering out some of the candidate reviewers based on various user-defined filtering criteria (e.g., the range of number of citations / H-index, the number of previous review activities)

2.3 Ranking

The last phase of our workflow is ranking the candidate reviewers. `MINARET` ranks the list of reviewers by means of a score which is computed as a weighted sum that fuses the following components:

- *Topic coverage*: Represents the reviewer's coverage score for the keywords of the submitted manuscripts. For example, if the paper keywords were "Semantic Web" and "Big Data" and we have two recommended reviewers with fields of interest as "Semantic Web, Ontologies, RDF"and "Semantic Web, Big Data", respectively. `MINARET` gives the second reviewer a higher rank than the first, because the second reviewer covers more topics/keywords of the paper and therefore is more related to the paper.
- *Scientific impact*: This component is based on the number of citations/H-index of the reviewer, as configured by the user. Clearly, the higher the number of citations/H-index, the higher the rank.
- *Recency*: Reviewers who have recently authored papers in the topic of the reviewed manuscript are ranked higher than others with less recent publications in the topic [5].
- *Experience with manuscript reviewing*: This component is based on the total number of manuscript reviews that is previously conducted by the candidate reviewer. This information is obtained from the `Publons` profile of the candidate reviewer.
- *Familiarity/Activity with the target outlet*: The reviewer's familiarity score is calculated based on two sub-components. The first is the number of previous reviewers that are conducted by the candidate reviewer for the target outlet. The second subcomponent is how many times this reviewer has published papers in this journal.

`MINARET` allows the user to configure the weights of the different components for computing the final ranking score for the candidate reviewers.

3 DEMO SCENARIO

`MINARET` is available both as a Web application[7] as well as RESTful APIs[8]. In this demonstration[9], we will present to the audience the workflow and the phases of the `MINARET` framewrok (Figure 2). We start by introducing to the audience the challenges we tackle, the main goal and the functionalities of our framework. Then, we take the audience through the reviewers recommendation process for sample manuscripts. We start by completing the manuscript details form (Figure 3) with the basic information including authors' names,

authors' current affiliations, submission topics/keywords, target journal in addition to any user-defined filters for the target reviewers (e.g, citation range, H-index range). Next, we will show how MINARETchecks and verifies authors names (Figure 4). After this, we will show how MINARET queries the different scholary sites for extracting the required information (Section 2) for candidate reviewers. Next, we will continue with the stage of reviewers' filtration and ranking till returning the final results (Figure 5) where the computed score of each reviewer is shown. By clicking on the total score, score details for each ranking component will be displayed.

While MINARET is designed for tackling the more challenging case of recommending reviewer for journal submissions. It can be also integrated with conference management systems to automate the paper-reviewer assignment. In that case, the list of programme committee members can be used as a further filter. Thus, only candidate reviewers who belong to the programme committee are retained.

SCube: A Tool for Segregation Discovery

Alessandro Baroni

baroni@di.unipi.it

Salvatore Ruggieri
University of Pisa, Italy
ruggieri@di.unipi.it

ABSTRACT

Segregation is the separation of social groups in the physical or in the online world. Segregation discovery consists of finding contexts of segregation. In the modern digital society, discovering segregation is challenging, due to the large amount and the variety of social data. We present a tool in support of segregation discovery from relational and graph data. The SCube system builds on attributed graph clustering and frequent itemset mining. It offers to the analyst a multi-dimensional segregation data cube for exploratory data analysis. The demonstration first guides the audience through the relevant social science concepts. Then, it focuses on scenarios around case studies of gender occupational segregation. Two real and large datasets about the boards of directors of Italian and Estonian companies will be explored in search of segregation contexts. The architecture of the SCube system and its computational efficiency challenges and solutions are discussed.

1 SOCIAL SEGREGATION

Ethical issues in data and knowledge management are gaining momentum in the last few years. In addition to the traditional field of privacy, techniques for data analysis are being designed or enhanced to take into account moral values such as fairness, transparency, accountability, and diversity[1]. We have recentely developed a novel data-driven technique for addressing segregation of social groups through multi-dimensional data analysis [4]. The approach is implemented in the SCube system, which we propose to demonstrate using real case studies.

Social segregation refers to the "separation of socially defined groups" [11]. People are partitioned into two or more groups on the grounds of personal or cultural traits that can foster discrimination, such as gender, age, ethnicity, income, skin color, language, religion, political opinion, membership to a national minority, etc. Contact, communication, or interaction among groups are limited by their physical, working or socio-economic distance. This can be observed when dissecting society in organizational units (neighborhoods, schools, job types). Due to the ubiquitous presence and pervasiveness of ICT, segregation is shifting from ancient forms of well explored spatial segregation[2] to novel forms of digital segregation. For instance, it has been warned that the filter bubble generated by personalization of online social networks may foster idelogical segregation [6], opinion polarization [10], and informational segregation. A data-driven technology that enables the assessment of the extent, nature, and trends of social segregation in the offline or online world, is of extreme interest for a wide audience: social scientistics, public policy makers, regulation and control authorities, professional associations, civil rights societies, and investigative journalists. Business decision makers should also care of business practices, particularly automated decision making, that segregate customers and products through stereotypes, because this limits diversity and reduces opportunities of cross-selling. Finally, data scientists and professionals should be aware of the unintended consequences of their models (recommender systems, link suggestion systems, classifiers) on the cohesion of society at large.

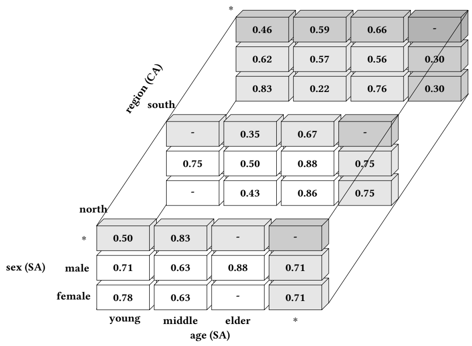

Figure 1: A segregation data cube with dissimilarity index.

2 SEGREGATION DISCOVERY

From a data analysis perspective, the key problem of assessing social segregation has been investigated so far by hypothesis testing, i.e., by formulating one or more possible contexts of segregation against a certain social group, and then in empirically testing such hypotheses. Such an approach is currently supported by statistical tools, such as the R packages *OasisR*[3] and *seg*[4] [9], or by GIS tools such as the *Geo-Segregation Analyzer*[5] [2]. The formulation of an hypothesis, however, is not straightforward, and it is potentially biased by the expectations of the data analyst of finding segregation in a certain context. In addition, exploration of multiple hypothesis can be time consuming, since data have to be processed multiple times. Finally, this approach is subject to erroneous conclusions if data is considered at wrong granularity – an instance of the Simpson's paradox.

Multi-dimensional segregation data cube. Our approach consists of providing the analysts with a multi-dimensional data cube that can be explored in search of candidate contexts of segregation. An example segregation data cube is shown in Fig.1. Dimensions of the data cube include two types of attributes:

- *segregation attributes* (SA), such as `sex`, `age`, and `ethnicity`, which denote (minority/protected) groups potentially exposed to segregation;
- *context attributes* (CA), such as `region` and `job type`, which denote contexts where segregation may appear.

Metrics of the data cube are chosen among the social science indexes proposed for measuring the degree of segregation of social groups within a society [12]. Here, we recall only one such index, but the SCube system is parametric to the indexes

and it computes 6 of them: dissimilarity, Gini, Information index, Isolation, Interaction, Atkinson. Also, we restrict to binary groups (minority/majority). Let T be the size of the total population under consideration, $0 < M < T$ be the size of a minority group, $T - M$ the size of the rest of society (or majority group) and $P = M/T$ be the overall fraction of the minority group. Assume that there are n organizational units (or simply, units – such as schools, neighboorhoods, job types, etc.), and that for $i \in [1, n]$, t_i is the size of the population in unit i, and m_i is the size of the minority group in unit i. The *dissimilarity index* D measures the absolute distance between the fractions of minority and majority groups over the units:

$$D = \frac{1}{2} \sum_{i=1}^{n} \left| \frac{m_i}{M} - \frac{t_i - m_i}{T - M} \right|$$

D ranges over $[0, 1]$, with higher values denoting higher segregation. Dissimilarity is minimum when for all $i \in [1, n]$, $m_i/t_i = M/T$, namely the distribution of the minority group is uniform over units. It is maximum when for all $i \in [1, n]$, either $m_i = t_i$ or $m_i = 0$, namely every unit includes members of only one group (complete segregation). Dissimilarity and other segregation indexes can be interpreted as metrics in a cell of a multidimensional cube as follows: set the total population as those individuals that satisfy the CA coordinates of the cell; and, set the minority population as those individuals that satisfy the SA coordinates. For instance, the cube cell in Fig.1 with SA coordinates `sex=female, age=young` and CA coordinates `region=north` contains the dissimilarity index for the population living in the north region and for the minority group of young women. Notice that the number n of organizational units here have to be determined *a-priori*, while the total population and minority groups in each unit depend on the values of cell coordinates. As in standard multi-dimensional modelling [7], the special value "$\star$" allows for considering different granularities of analysis.

Segregation analysis of tabular data. We assume in input a relational table with a tuple for every individual in the population, including SA and CA attributes, and with a further attribute `unitID` which denotes the unit an individual belongs to. Unfortunately, segregation indexes are not additive metrics (see [4]). This gives rise to the problem of efficiently computing a data cube for segregation analysis. Our approach is more specialized than generic holistic aggregate computation in datacubes [13]. We resort to frequent closed itemset mining [8]. Data cube coordinates are encoded into itemsets of the form **A**, **B**, where **A** denotes a minority subgroup and **B** denotes a context. Recalling the previous example, **A** =`sex=female, age=young` defines the SA coordinates, and **B** =`region=north` defines the CA coordinates. The *SegregationDataCubeBuilder* algorithm described in [4] fills data cube cells with the value of a segregation index by scanning frequent closed itemsets of the form above. Since relational data is transformed into transaction database for itemset mining, we obtain for free that CA or SA attributes can be multi-valued, e.g., to denote that an individual owns both a house and a car we admit a relation tuple σ such that $\sigma[\texttt{owns}] = \{\texttt{house}, \texttt{car}\}$.

Segregation analysis of graph data. While transaction databases are able to cover typical analysis from traditional social science, they are not enough powerful to deal with social network data. We formalize such a case using attributed graphs, where nodes are assigned values on a specified set of attributes. However, in this scenario, there is no *a-priori* defined notion of organizational unit, i.e., the `unitID` attribute assumed in input so far. Some forms of community discovery using graph clustering become necessary in order to determine the organizational units. Clustering attributed graphs consists of partitioning them into disjoint communities of nodes that are both well connected and similar with respect to their attributes [5]. In summary, attributed graph clustering can be used first to partition a social network into communities. At this stage, every node/individual in a community is described by its attributes and the community id, which will be our `unitID` attribute. We have thus reduced the problem to the analysis of relational data, for which the *SegregationDataCubeBuilder* algorithm can be applied.

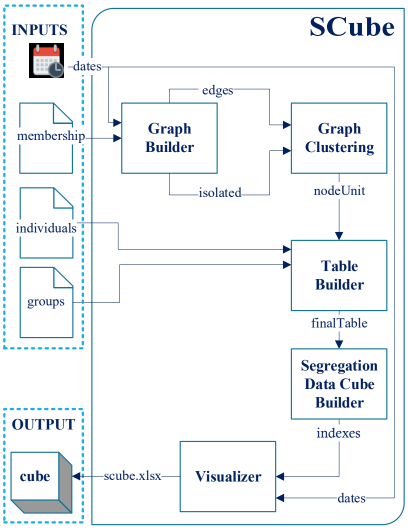

Figure 2: SCube architecture.

Segregation analysis of bipartite graphs. An even more complex scenario is when individuals are not connected among them, e.g., because they are friends, but through a connection with another entity, e.g., because they work in the same company. Here, a form of projection on unipartite graph is needed to reduce to the previous case. For instance, in [4], we adopt a bipartite projection of the bipartite graph of directors and companies to obtain a graph of companies connected by shared directors. Using projection, we have reduced the problem to the previous case, where attributed graph clustering can be adopted to find communities of companies, which then represent the organizational units for segregation analysis.

3 SCUBE ARCHITECTURE

The architecture of SCube is shown in Fig. 2. The system is developed in Java, and it relies on a few state-of-the-art libraries[6].

Inputs. The user has to provide features for two entities: *individuals* and *groups*. In the reference case studies, individuals are directors and groups are companies. The input `individuals` (a CSV file or a JDBC query) provides for each individual an ID and a number of attribute values, distinguished into segregation attributes (e.g., `gender`, `age`, `birthplace`) and context attributes (e.g., `residence`). A second input `groups` provides for each group an ID and a number of context attributes values (e.g., industrial `sector` of a company and its headquarter `location`). Notice that individuals are subjects to possible segregation, while groups are

...	...	...	...	...	...

Figure 3: The process of segregation discovery supported by SCube (left, top), input to SegregationDataCubeBuilder (left, bottom), and an output report on dissimilarity segregation index of the Italian provinces (right).

not. For this reasons, groups have no SA feature. A third input is `membership`, which includes the edges of the bipartite graph of individuals and groups, i.e., all pairs (`individualID`, `groupID`) for which the individual is related to the group. In our case studies, directors are related to companies they sit in the board of. We also admit that the pairs are labeled with a time interval of validity, thus allowing for temporal analysis of segregation. We have such an information for the Estonian dataset. A fourth input is a list of snapshot dates at which to consider snapshots of the membership relation.

Modules. SCube consists of five software modules. *GraphBuilder* projects the bipartite graph of individuals and groups into an unipartite attributed graph, where nodes are groups and an edge connect two groups if they are related by at least one shared individual. In the case studies, nodes are companies, and edges connect companies that share at least one director in their boards. Edges are weighted by the number of shared directors. *GraphBuilder* outputs edges of the projection (`edges`), and nodes that have zero degree (`isolated`). The *GraphClustering* module computes then a clustering of nodes into organizational units (output file `nodeUnit`). Methods for clustering available in SCube include: extraction of connected components (Breadth-First Search), removal of edges from the giant component with weight below a threshold and then extraction of connected components (designed in [4]), and an attributed graph clustering method for very large graphs (SToC algorithm [3]). In our case studies, the result of *GraphClustering* is a partitioning of companies into clusters based on connections among companies determined by shared directors – which can be readily considered a signal of relationships (business, personal, or other) between companies. Clusters represent the organizational units needed for computing segregation indexes. *TableBuilder* joins features of individuals with features of the companies in an organizational unit. This yields a `finalTable` with a row per individual and organizational unit she belongs to. An example is shown in Fig. 3 (left, bottom). This is the input for the *SegregationDataCube* builder module, implementing the algorithm of [4]. Notice that if the data under analysis contains already the assignment of individuals to units, i.e., it is already in the form of `finalTable`, the pre-processing steps of bipartite projection and graph clustering do not need to be performed. The *Visualizer* module transforms the extended datacube in output of SegregationDataCube into a standard OOXML format that can be opened by Microsoft Excel, Libre Office, and other office productivity tools (see Fig. 5). Segregation data cube exploration can be easily interfaced with visualization tools, as in the map overlay in Fig. 3 (right).

Process, Wizard, and GUI. The whole process of segregation discovery supported by SCube is shown in Fig. 3 (left, top). To facilitate the adoption of SCube by non-technical users, we have developed two interfaces (see Fig. 4). The first one is a standalone wizard that guides the user throughout all the steps of the process, asking for inputs and parameters when appropriate, and finish launching Microsoft Excel or Libre Office on the output file. Using popular desktop tools as GUI's makes the learning curve of approaching and effectively using SCube more manageable. The second one is a cloud service offered by the SoBigDataLab freely accessible research infrastructure (www.sobigdata.eu/access/virtual), a web front-end comprising a catalogue of data, services, and virtual research environments for big data and social mining research.

4 DEMONSTRATION SCENARIO

The demonstration starts with a brief introduction on concepts and methods of segregation measurement [12] and segregation discovery [4]. This provides the audience with the basic definitions for understanding the SCube functionalities. The architecture of SCube is presented next. For interested participants, computational efficiency, algorithmic solutions, and source code internal aspects are discussed. Then, two running case studies in the context of occupational segregation in the boards of company directors [1] are introduced. They are based on a 2012 snaphost of Italian companies (3.6M directors, 2.15M companies), and on a 20-year long dataset of Estonian companies (440K directors, 340K companies). Such anonymized datasets are the largest ever considered in the literature of segregation analysis. We summarize the data pre-processing activities to produce the inputs for SCube.

The demonstration then proceeds by presenting three analysis scenarios based on input data of increasing complexity. In all scenarios, `gender`, `age`, and `birthplace` are used as segregation attributes. The first scenario considers tabular data, where company sector is used as organizational `unitID`, and it is intended

to answer questions such as: how much are women segregated in company sectors? The second scenario considers attributed graph data, where nodes are directors, and edges connect two directors if they belong to a same company board. Here, the organizational units are determined through clustering over attributed graphs. This scenario can answer questions such as: how much are women segregated in communities of connected directors? Finally, the third scenario considers a bipartite attributed graph of directors and companies, as presented throughout the paper. An example of question it can answer is: how much are women segregated in communities of connected companies? For each scenario, the output of SCube is interactively explored using pivot tables and charts. The audience is guided to the discovery of a few actual cases of *a-priori* unknown segregation contexts and to the understanding of which attributes contribute the most to segregation. Moreover, a cross-comparison of the Italian vs Estonian segregation findings will be discussed.

5 CONCLUSION

This demonstration illustrates the SCube tool for interactive exploration of social segregation indexes in large and complex data. The audience is made aware of social exclusion issues that can be hidden in data and of the indexes that measure segregation. Real case studies on scenarios of increasing complexity are discussed and explored. Efficiency issues and algorithmic solutions adopted for scaling to large datasets and graphs are detailed.

SparkTune: tuning Spark SQL through query cost modeling

ABSTRACT

We demonstrate SparkTune, a tool that supports the evaluation and tuning of Spark SQL workloads from multiple perspectives. Unlike Spark SQL's optimizer, which mainly relies on a rule-based model, SparkTune adopts a cost-based model for SQL queries; this enables the accurate estimation of execution times and the identification of cost and complexity factors in a user-defined workload. The estimate is based on the cluster configuration, the database statistics (both automatically retrieved by the tool) and the resources allocated to the workload. Thus, for any given cluster, database and workload, SparkTune is able to identify the best cluster configuration to run the workload, to estimate the price to run it on a cloud platform while evaluating the performance/price trade-off, and more. SparkTune turns the cluster tuning efforts from manual and qualitative to automatic, optimized and quantitative.

1 INTRODUCTION

Over the past years, Apache Hadoop has become the most popular framework for Big Data handling and analysis. On top of it, *SQL-on-Hadoop* solutions have been introduced to provide a relational abstraction layer to the data. Among them, one of the most popular is Apache Spark, whose SQL-based sub-system (i.e., Spark SQL [1]) enables SQL queries to be rewritten in terms of Spark commands and to be executed in parallel on a cluster[1].

Although these systems are largely adopted and quickly becoming more solid and mature, they are still limited in terms of cost modeling features. For instance, the module in charge of translating SQL queries to Spark commands (i.e., Catalyst [1]) mainly relies on a rule-based optimizer. The cost model introduced to Catalyst in its 2.3.0 release is still very simple (e.g., as concerns join ordering, the cost function estimates a logical cost in terms of number of returned rows). The need for robust cost-based models is increasing, since the possibility to evaluate a priori the execution cost of a workload is still lacking. Very little work has been done on this aspect: some optimizers propose cost-based features, but they evaluate only portions of a query [8].

Our system, *SparkTune*, is an application that builds on a cost model [3] for Spark SQL to support the user understanding the cost of a workload and gaining the required knowledge to properly optimize the execution. From a high-level perspective, SparkTune allows to: i) evaluate the duration of a workload; ii) see the cluster's size and potential first-hand, so as to properly optimize the allocation of resources; iii) evaluate the trade-off between the execution time and the price to execute it on a cloud platform. The latter point is achieved by extending the cost model with the pricing information of major cloud providers, which enables the translation of resource consumption into actual money. On a more technical side, SparkTune also: iv) enables the prior identification of stragglers (i.e., tasks that performs more poorly than similar ones due to insufficient assigned resources); v) if adopted by Spark SQL, it would enable the creation of a full cost-based optimizer, both static and dynamic.

In Section 2 we summarize the core aspects of the cost model (full details have been published in [3]), while Section 3 discusses the features of SparkTune; the demonstration proposal is finally given in Section 4.

2 COST MODEL OVERVIEW

The Spark architecture consists of a *driver* and a set of *executors*. The driver negotiates resources with the cluster resource manager (e.g. YARN) and distributes the computation across the executors, which are in charge of carrying out the operations on data. Data are organized in *Resilient Distributed Datasets* (RDDs), i.e., collections of immutable and distributed elements *partitions* that can be processed in parallel. Partitions can either come from a storage (e.g. HDFS) or be the result of a previous operation (i.e., held in memory). At the highest level of abstraction, a Spark computation is organized in *jobs*, which are composed of simpler logical units of execution called *stages*. The physical unit of work used to carry out a stage on each RDD partition is called *task*. Tasks are distributed over the cluster and executed in parallel.

In Spark SQL, a declarative SQL query is translated in a set of jobs by its optimizer, Catalyst, which carries out the typical optimization steps: analysis and validation, logical optimization, physical optimization, and code generation. Physical optimization creates one or more *physical plans* and then it selects the best one. At the time of writing, this phase is mainly rule-based: it exploits a simple cost function only for choosing among the available join algorithms [1].

Our cost model [3] computes the query execution time given the physical plan provided by Catalyst. We remark that it is *not* a cost-based optimizer, as the latter implements query plan transformations to optimize the original plan, and it does so without necessarily computing the whole cost of the query.

The cost model covers a wide class of queries that composes three basic SQL operators: selection, join and generalized projection. The combination of these three operators determine GPSJ (Generalized Projection / Selection / Join) queries, which were first studied in [5] and which are the most common class of queries in OLAP applications. Each Spark physical plan modeling a GPSJ query can be represented as a tree whose nodes represent tasks; each task applies operations to one or more input tables, either physical or resulting from the operations carried out in its sub-tree. Our cost model relies on a limited number of *task types* (listed in Table 1) that, properly composed, form a GPSJ query. In particular, a feasible tree properly composes the following task types: *table scan* SC(), *table scan and broadcast* SB(), *shuffle join* SJ(), *broadcast join* BJ() and *group by* GB(). SC() and SB() are always leaf nodes of the execution tree since they deal with the

[1] Spark is not necessarily tied to Hadoop, although this is its most used architecture.

physical storage where the relational tables lie. SJ() and BJ() are inner nodes of the trees and can be composed to create left-deep execution trees; finally GB(), if present, is the latest task to be carried out.

The execution time is obtained by summing up the time needed to execute the tasks of the tree coding the physical plan of a query. In particular, the cost model is based on the disk access time and on the network time spent to transmit the data across the cluster nodes; CPU times for data serialization/deserialization and compression are implicitly counted by the disk throughput. This is consistent with [9], which clearly explains that *one-pass* workloads on Spark (e.g., SQL queries) are either network-bound or disk-bound, whereas CPU can become a bottleneck limitedly to serialization and compression costs. Also, the cost model assumes that data always fits the executors memory, so that data is never spilled to local disks.

Depending on its type, each task involves one or more basic operations (such as reading, writing, and shuffling) which we refer to as *basic bricks*; the cost of a task is calculated as the sum of the cost of the involved bricks (see 1 for the usage of bricks by the task types). In particular, each brick models the execution of an operation on a single RDD partition and considers the resource contentions given by parallel execution. Bricks are SQL-agnostic and require some parameters about Spark (e.g., network and disk read/write throughput) and about the cluster (e.g., number of executors per rack and number of cores per executor) to be known. As explained in Section 3, most of these parameters are automatically retrieved by SparkTune. In the following, we briefly discuss the nature of each basic brick.

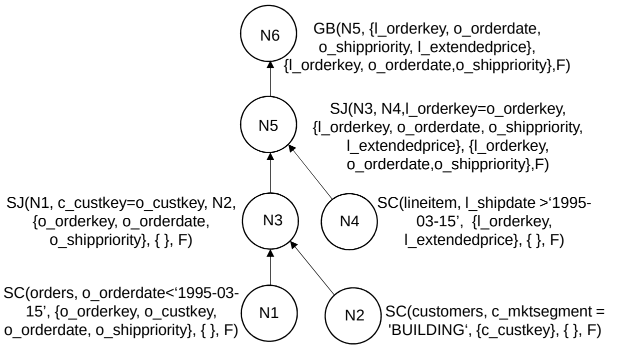
- Read: consists in reading an RDD partition from disk. If the data does not reside on the executor's node, it must be read from another one, according to the locality principle. The cost model exploits the known cluster configuration to estimate the probability of such a case. When reading from another node, both the time to transfer the data over the network must be considered in addition to the time to read the data from disk. Since Spark enables in-memory pipelining of subsequent transformations that do not require shuffling (according to the Volcano model [4]), the overall time is computed as the maximum for disk reading and data transmission.
- Write: consists in writing an RDD partition to the local disk; no network data transfer is necessary.
- Shuffle read: consists in reading an RDD partition from disk and shuffling it through the network. Similarly to the Read brick, the overall time is computed as the maximum for disk reading and data transmission; in this case, however, disk reading only happens on the local disk.
- Broadcast: consists in loading the whole RDD on the application driver and in sending it to every executor. Since the two operations cannot be pipelined, the overall cost is determined as the sum of the two. The broadcast brick does not involve disk reading or writing, thus the cost only depends on network time.

Ultimately, we remark that – thanks to the known cluster configuration – the cost model is able to probabilistically estimate the amount of data to be read and/or transferred through the network for each brick.

Example 2.1. The following GPSJ query is taken from the TPC-H benchmark [7]; it computes the total income collected in a given period and for a specific market segment grouped by single orders and priority of shipping.

Table 1: Task types characterization

Task Type	Addittional params	Basic bricks
SC()	pred, cols, groups	Read, Write
SJ()	pred, cols, groups	Shuffle Read, Write
SB()	pred, cols	Read, Broadcast
BJ()	pred, cols, groups	Write
GB()	pred, cols, groups	Shuffle Read, Write



N6
GB(N5, {l_orderkey, o_orderdate, o_shippriority, l_extendedprice}, {l_orderkey, o_orderdate,o_shippriority},F)
N5
SJ(N3, N4,l_orderkey=o_orderkey, {l_orderkey, o_orderdate, o_shippriority, l_extendedprice}, {l_orderkey, o_orderdate,o_shippriority},F)
SJ(N1, c_custkey=o_custkey, N2, {o_orderkey, o_orderdate, o_shippriority}, { }, F)
N3

GROUP BY l_orderkey, o_orderdate, o_shippriority
```

A graphical representation of the Spark physical plan chosen by Catalyst is reported in Figure 1.

3 THE SYSTEM

SparkTune is implemented as a web application on a classic WAMP stack (Windows, Apache, MySQL, PHP) and it is publicly available at http://semantic.csr.unibo.it/sparktune. We plan to release SparkTune as a standalone application in the near future. The architecture of the system is sketched in Figure 2, where the flow of data is also indicated.

3.1 Environment setup

The system enables registered user to setup their own environment in order to define custom scenarios and run user-specific analyses. The setup of the environment can be done either manually or in an automatic fashion. The information required by the system is the following:

- Cluster configuration, such as the number of nodes and racks, the number of cores per node, HDFS's replication factor, hardware statistics. Automatic retrieval of these data is enabled by providing credentials for an SSH connection to one of the cluster's nodes. Most parameters are obtained through calls to the Hadoop's APIs, while Spark jobs are run to infer the read and write throughput of the disk, as well as the intra-rack and inter-rack network throughput. Both throughput values are inferred as a function of the number of concurrent processes that require disk access and network data transfer.
- Database statistics. Automatic retrieval of these data is enabled by providing credentials to access the Hive Metastore. For any of the available database, the user can trigger the retrieval of the name, size, and statistics for every table and attribute.
- One or more workloads, meant as sequences SQL queries to be manually provided by the user; then, the system automatically retrieves from Spark the physical plan.

These data are stored in the Metadata repository. Each user can setup multiple clusters, databases, and workloads. The versions of Spark currently supported are 1.5 and 2.2.

3.2 Analyses

The system provides four kinds of analysis and simulation. Each of them requires to define a specific environment (i.e., to select a cluster, a database, and workload among the ones provided in the setup), possibly requests additional parameters (e.g., the number of executors to be allocated for each node), and outputs a detailed report depending on the kind of analysis. Figure 3 shows examples of such reports, which are fully discussed in the following.

Workload analysis. The goal is to provide an in-depth analysis of the complexity and cost of executing the workload on a cluster with a specific configuration (i.e., the number of executors and the number of cores per executor must be defined by the user). First of all, SparkTune runs each query's physical plan in the workload on the cost model to estimate the total execution time of the workload. Secondly, it provides full details about every task of every query (including the amount of data read/written, the time to read/write data from disk or to transfer it across the network). On the one hand, this greatly helps the identification of stragglers: Figure 3.1 shows the report of a single query, which presents the tasks in the execution tree colored on a red gradient (the harder the red, the higher the percentage of time required by the task w.r.t. to the query). On the other hand, it helps understanding which factors mainly impact on the cost of each task/query: below the execution plan in Figure 3.1, the total estimated time of the query is split among disk read time, disk write time, and network time; then, by clicking on a task in the tree, a pop-up as the one in Figure 3.2 shows the same data for each task — together with other detailed information (e.g., the amount of data read/written/transferred, the cardinality of the involved table(s), etc.).

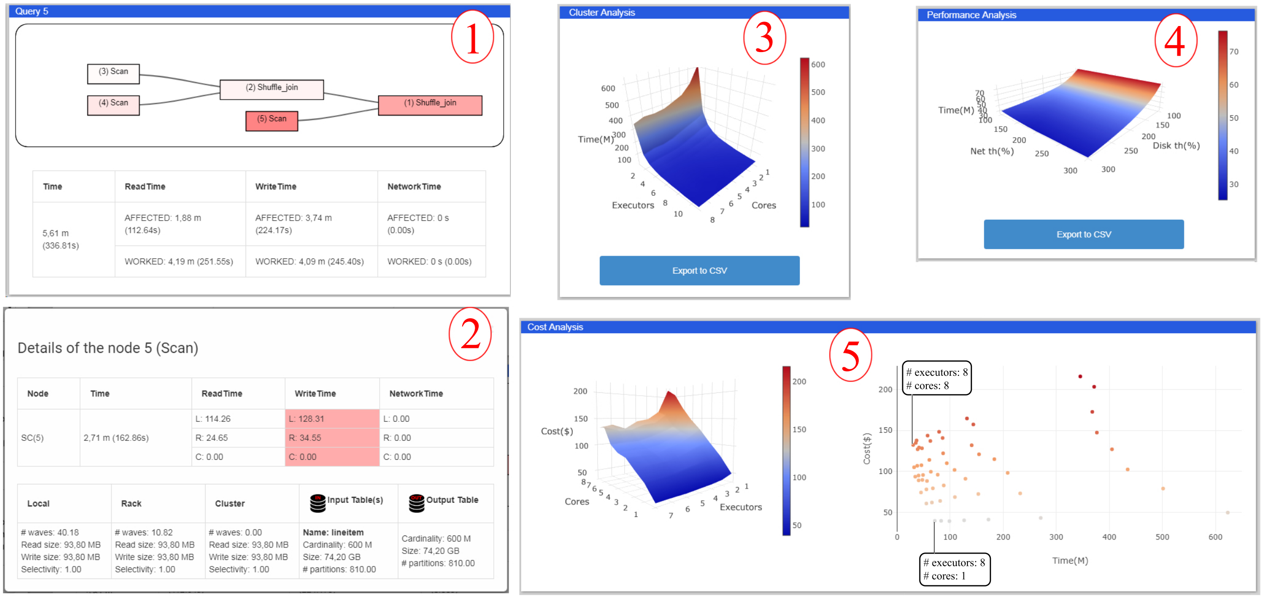
Cluster analysis. The goal is to optimize the allocation of resources by understanding the impact of the configuration parameters on the performance. The total execution time of the workload is calculated for every configuration potentially available within the boundaries set in the cluster setup[2]. The results are presented in a 3D surface graph (Figure 3.3), showing the execution time by the number of executors and the number of cores. This graph emphasizes how the increase of executors and cores progressively reduces the execution time; more specifically, it shows which of the two factors has the greatest impact in the time reduction for the given workload.

Performance analysis. The goal is to provide a what-if analysis that shows the potential impact of enhancing the performance of the cluster (in terms of disk throughput and network throughput) on the execution time of a workload. Given a specific cluster and its configuration, the system estimates the execution time by progressively improving the disk and/or network throughput in steps of 20% (i.e., 120% w.r.t. to the current throughput, 140%, etc.). The results are presented in a 3D surface graph (Figure 3.4), which helps understanding which factor (disk or network) is most critical in determining the execution time. Noticeably, the increase in disk throughput is assumed in the same measure for both reading and writing.

Cost analysis. The goal is to evaluate the price of executing a workload on a cloud infrastructure. To make such an estimate, we extended our cost model with the pricing information obtained from cloud providers Amazon AWS (http://aws.amazon.com) and Google Cloud (http://cloud.google.com); this enables the translation of the time usage estimates of every core and every executor to the amount of USD (United States Dollars) to be paid to the provider for the execution of the workload. Similarly to the Cluster analysis, the system exhaustively calculates the total execution time of the workload in every possible configuration (within the upper bounds set in the cluster setup), but it is eventually translated to USD. Ultimately, two results are presented. The first one (left-hand side of Figure 3.5) is a mere cost analysis, showing the price obtained with the different cluster configurations by means of a 3D surface graph; this enables the identification of the cheapest cluster configuration, as well as the understanding of which factor (i.e., number of executors or number of costs) is the most expensive. The second one (right-hand side of Figure 3.5) is an evaluation of the trade-off between execution time and price; it is shown as a 2D chart, pinpointing each cluster configuration in the 2D surface represented by the execution time and the price. This chart allows an immediate identification of the ideal cluster configurations, which minimize both the time spent and the money to be paid. For the sake of completeness, we note that the price estimate only considers the consumption of the cluster's resources for the estimated time; it does not consider the price of the disk, which is required to store the database.

Example 3.1. The reports in Figure 3 pertain to a workload of 8 queries from the TPC-H benchmark on our 11-node cluster. Workload analysis. Figure 3.1 represents the execution tree of the query in Example 2.1 and shows that the overall time (5.61 min) is mostly due to two tasks (nodes 1 and 5). Given Spark's in-memory pipelining, the "affected time" voice indicates the portion of the time spent reading/writing/transferring data (i.e.,

[2] We adopt this naive approach for the purpose of showing a full report to the user. A cost-based optimizer that only looks for an optimal configuration could apply some heuristics to avoid an extensive research [2].



Time	Read Time	Write Time	Network Time
5,61 m (336.81s)	AFFECTED: 1,88 m (112.64s)	AFFECTED: 3,74 m (224.17s)	AFFECTED: 0 s (0.00s)
	WORKED: 4,19 m (251.55s)	WORKED: 4,09 m (245.40s)	WORKED: 0 s (0.00s)

# waves: 40.18 Read size: 93,80 MB Write size: 93,80 MB Selectivity: 1.00	# waves: 10.82 Read size: 93,80 MB Write size: 93,80 MB Selectivity: 1.00	# waves: 0.00 Read size: 93,80 MB Write size: 93,80 MB Selectivity: 1.00	**Name: lineitem** Cardinality: 600 M Size: 74,20 GB # partitions: 810.00	Cardinality: 600 M Size: 74,20 GB # partitions: 810.00

Figure 3: Screenshots of the various functionalities of SparkTune, discussed in Section 3

"worked time") that actually contributed to determining the overall query time. Figure 3.2 shows the details of node 5 in Figure 3.1; it is the scan of the Lineitem table and it shows that the task is mostly disk-bound. Cluster analysis. Figure 3.3 clearly shows that, for the given workload, the performance gain due to increasing the number of executors is superior to the one due to increasing the number of cores per executor. Performance analysis. Figure 3.4 further confirms that the workload is disk-bound; indeed, improving the network throughput would have little to no impact on the execution time, as opposed to the adoption of more performing disks. Cost analysis. The prices shown in Figure 3.5 refer to to Amazon AWS; interestingly, the left chart shows that the cheapest configurations are those with a low number of cores. This indicates that the higher core-power would not be adequately put to use, as it does not correspond to a significant reduction in time (as the Cluster analysis also anticipated). Ultimately, this is confirmed by the right chart, which shows a high disproportion between the price required to reduce the execution time of the cheapest configured and the time actually saved.

4 DEMO PROPOSAL

In the demonstration we will show how cluster tuning can be automatized and optimized adopting a cost-based approach. First, we will demonstrate the automatic retrieval of data for the environment setup, either on our own cluster or on a cluster owned by someone in the audience (provided their willingness to grant its access). Then, we will develop with the audience an experience to showcase the various functionalities of the system and to understand their value from the perspective of different professional figures. In particular, two distinct scenarios will be simulated for data scientists (which will be interested in analyzing workloads from a more technical angle) and data architects (which will be interested in an analyzing the same workloads from a different, higher-level perspective). With data scientists we will mainly focus on SparkTune's Workload and Cluster analyses to answers several questions, such as: *"What are the reasons for the poor performance of this workload?"*, or *"How can I reallocate the resources to speed up the execution of the workload without exceeding my budget?"*. Differently, with data architects we will mainly focus on SparkTune's Cost and Performance analyses to address issues related to the design and deployment of the infrastructure; in particular, we will answer questions such as *"Which cloud provider will let me run this workload at the lowest price and at a reasonable performance?"*, or *"What kind of scale-up or scale-out improvements can I bring to the cluster to improve its performance?"*. The demo will put the audience in the shoes of one of these figures and we will develop a simulation aimed at answering the aforementioned questions.

Our real cluster that we use as a reference consists of 11 nodes with 8 cores per node. SparkTune will be configured with different benchmark databases, including the well-known TPC-H [7] and the Big Data Benchmark [6]. We will define different workloads on each database, in order to present scenarios that require the exploitation of the different features of SparkTune.

ABSTRACT

We present HOTMapper, a tool that maps tables of Open Data with historical information into unified data sources. The tool couples data exchange and integration techniques implemented into two main components: 1) a CLI script with commands to create and update tables, and to insert and update the data, using 2) a simple mapping definition file, interpreted by the CLI script, to store the schema and data mappings throughout different years. The tool is implemented using Python and MonetDb. This demo will show the creation of the mapping definition and the execution flow of the CLI script for creating a unified data source from scratch and then updating an existing one. It will unify real world data sources, with millions of records, containing information about the Brazilian educational system.

1 INTRODUCTION

The availability of large Open Data sources raises several opportunities for researchers from different domains to extract and process the data. Governments from different countries are releasing vast amounts of governmental data, i.e. regarding public services and expenditures. However, in order to effectively use the data, some difficult problems must be addressed: open data sources are often heterogeneous, with different representation formats, data models, schemas (if any), data quality, and others. Such problems can be categorized into Data Exchange, Data Integration and Table Stitching issues. Data Exchange is the problem of transforming data from one source, which has a source schema, into a target schema [10]. Data Integration is defined as the problem of uniformly accessing different source schemes through an integrated source [10]. Finally, Table Stitching is defined as the problem of unifying many tables with identical schemes into a single table identifying extra attributes for it [7].

Open Data is often de-normalized (e.g. in large CSV (Comma Separated Values) files) and represents a small period of time (i.e. a semester or a year). New data is periodically released, with several files that need to be integrated. In addition, from one release to another, data and schema changes often occur. While each periodic instance could be handled separately, having a unified view of the data allows to do historical analysis and comparisons. Thus, it is important to develop methods and tools that are able to create a unified view of the data, to translate each periodic source into the unified view, to perform transformations on the data sources and to update them periodically. This means it is necessary to provide simple ways to maintain schema and data mappings from several input schemes and data sources into a unified one, keeping data compatibility.

There are different solutions/tools partially covering these issues. The Clio tool [5] is one of the best known, being developed before the advent of Open Data and a precursor to many others. More recently the *Polystore*-like approaches, such as *BigDawg*[3], ESTOCADA [1] or MISO[6] focus on the data integration issues, as does the Data Civilizer system[2]. *Ling at al.* [7] handled the problem of table stitching: new columns in the data source need to be identified and stitched into unified tables. The approach from [8] presents a brief history on data integration solutions and the current issues when having multiple Open Data sources. Their solution for creating union-able tables [9] could be valuable for a mapping framework, though they do not focus on maintenance and updates of the data. As a drawback, the solutions completeness and adaptability to several kinds of queries and data sources makes it hard to be used in specialized scenarios, such as the historical Open Data mapping presented in this paper.

The **HOTMapper tool** [1] (Historical Open Data Table Mapper) was developed as a domain specific data mapping/integration solution, targeted to de-normalized Open data sources, spread into several input files, where the mappings are simple and need to be stored and modified periodically. The implementation couples different aspects of data integration, data exchange and table stitching. It consists of a Command Line Interface (CLI) tool for historical data and schema mapping, translated from CSVs into the *MonetDb*[2] column store.

The tool receives as input the CSV files and a mapping definition file with information on how to unify the data. The mappings are defined in CSV as well, relating all desired input data with the corresponding target columns. The mapping definition file has information to guide the following actions: 1) creation of the target unified schema; 2) source-to-target data transformations, which are maintained for each given period; 3) creation of new derived data 4) update of an existing source with new columns and mappings; and 5) full reconstruction of the unified source based on the input sources and mappings. More actions could be added if needed.

This demonstration will present the execution flow of the tool:

- development of the periodical data and schema mappings;
- creation of a new data source;
- insertion of the corresponding data into the unified model;
- update with a new data source;
- update in the columns and data transformations.

We will execute the tool in a real world scenario, processing information about the Brazilian educational system. The data includes the enrollments and related information (schools, courses or teachers) in schools and Universities, with hundreds of columns. The mappings and commands can be modified on

the fly following the audience interactions, showing how fast and simple the tool is.

The unified data produced by the tool is currently being used and can be visualized in an open web portal [4] [3]. The amount of data already processed by the tool is summarized in Table 1. It was extracted from Open Data sources produced by INEP (Instituto Nacional de Pesquisa Educacionais Anísio Teixeira)[4].

Table 1: Summary of data from the INEP Open Data Source processed by HOTMapper

Year	Tables	Records
2017	13	102.176.661
2016	20	116.009.013
2015	18	116.946.948
2014	17	121.115.913
2013	18	112.645.020
2012	11	36.029.271
2011	7	12.025.035
2010	7	8.768.490

The paper is organized as follows: section 2 presents a motivating example of HOTMapper; section 3 explains HOTMapper's design and working principle and Section 4 describe the steps of the tool demonstration.

2 MOTIVATING EXAMPLE

Consider the necessity of extracting a metric (or indicator) regarding the number of enrolled students in all Brazilian schools from 2013 to 2017. The information about enrollments is available at an Open Data source produced by INEP. While this is a particular metric, the idea can be generalized as "extracting indicators from public Open Data sources". The input data is de-normalized in a set of large CSV files, with approx. 100 different fields each. The choice for publishing de-normalized data is common in open data sources, because it decreases the number of files that need to be managed in the long run.

The metric/indicator must be correctly extracted from this source and can be aggregated in different dimensions, i.e, location dimensions such as country, state or city; enrollments on public vs. private schools, enrollments on scientific courses, among others. The metric also needs to support yearly updates, because a new set of files is released every year, raising three main issues:

1. **Integrated source creation**: a first set of tables needs to be created to be able to execute queries considering the historical data. In this case, the input data has 87 columns for the 2013 and 2014 years, and 96 columns in 2015-2017.
2. **Schema evolution**: every year, the data sources definition changes, so it is necessary to provide schema mappings:
   (a) direct mappings:
   ```
   NATIONALITY <- [2013-2017] NATIONALITY
   SPECIAL_NECESSITY <- [2013-2014] HAS_NECESSITY
   SPECIAL_NECESSITY <- [2015-2017] SPECIAL_NECESSITY
   ```
   (b) new mapping (when a column is added):
   ```
   REGION <- [2013-2015] not-available
   REGION <- [2016-2017] REGION
   ```
3. **Data evolution**: data has to be transformed and kept compatible along all years, requiring instance mappings:
   (a) mapping creation: a new dimension is generated from existing data
   ```
   PROFESSIONAL_STUDIES<-[2013-2014]
   WHEN STUDIES_KIND between 30 and 40 THEN 1
   WHEN STUDIES_KIND between 41 and 50 THEN 2
   PROFESSIONAL_STUDIES<-PROFESSIONAL_STUDIES[2015-2017]
   ```
   (b) mapping update: the data mapping from the data sources may change (dimension or metric), which means the previous mappings, for all previous years, has to be updated
   ```
   GENDER <- [2013-2014]
             WHEN M THEN 1
             WHEN F THEN 2
   GENDER <- [2015-2017] GENDER
   ```

This motivating example considered just one indicator and illustrative examples, with intersections of data exchange, integration and table stitching. This kind of mapping is commonly applied to more or less 90 columns of annual data. In addition, INEP publishes at least four main raw data sets: Students, Teachers, Schools and Sessions, containing more than one hundred columns. There are other sources released on a similar basis, replicating this scenario for every new indicator produced, presenting a challenging setting for the extraction and maintenance of Open Data sources.

3 HOTMAPPER

In this section we present the HOTMapper tool, addressing the maintenance of data and mappings of Open Data sets.

3.1 Tool description

HOTMapper's architecture is shown in Figure 1. It consists of a CLI (Command Line Interface) manager interacting with three kinds of input and/or output, on which six predefined actions can be performed. With a flexible implementation using Python and SQL programming languages, the tool allows for an easy extension by adding more actions.

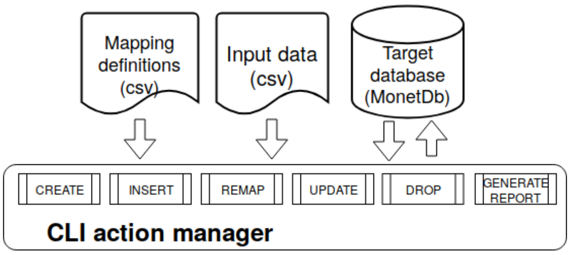

Figure 1: HOTMapper overview

The **mapping definition** files are in CSV format. There is one file for each table in the target RDBMS. It describes the columns that are created and the mappings, per year, of each input column.

The **input data** is the set of CSV files that are included in the target database, one file per metric (or set of metrics), and per year. For instance, the *enrollments* metric has five input files, from 2013 to 2017. The files are de-normalized, which means they have a high number of columns.

The **target database** has the set of tables that contain the integrated information produced by the tool. We use the *MonetDb* column store and keep the included data as similar as possible to the input data, i.e., we do not normalize the target data. This has some advantages: the definition and maintenance of mappings remains relatively simple; the data model does not need to be

[3] http://dadoseducacionais.c3sl.ufpr.br
[4] http://portal.inep.gov.br/microdados

constantly adapted for every new release; the queries are fast, because joins are minimized; and bulk insertion operations are fast. It is important to emphasize that the target database is only updated by new releases of the input data, without OLTP operations.

The actions currently handled by HOTMapper are: **table maintenance** actions (1) `CREATE` and (2) `DROP`; **data and table manipulation** actions (3) `INSERT`, (4) `REMAP` and (5) `UPDATE`; and a **reporting** action (6) `GENERATE REPORT`:

1. `CREATE` action takes as input the table definition and executes the DML (Data Manipulation Language) commands;
2. `DROP` action deletes the table passed as parameter and any related data. The tool executes standard DML commands, so that it can be used in different RDBMS's;
3. `INSERT` action executes a bulk insert of the input CSV files into a temporary table in the target database. Then, it reads the mapping definition to transfer the data into the target table. The creation of a temporary table is important to facilitate the manipulation of the input data, avoiding direct operations on the CSV file;
4. `REMAP` action modifies the initial table definition;
5. `UPDATE` action updates a table after a change in the mappings; and
6. `GENERATE REPORT` action produces a report with column equivalences between the input table and the current database. It is not necessary for inserting or updating data, but eases the creation of the mapping definition file.

Figure 2 illustrates a mapping definition and two input CSV files, with information about the universities in Brazil.

Figure 2: Illustration of a mapping definition and two input CSV data files

File `OpenData-Mapper.csv` contains the mapping definition, composed of eight columns: `[Lab.Var]` is an identifier for each mapping; `[Standard Label]` has the name of the mapped columns; `[New Label]` has the description of the column; `[Temp Column]` defines whether the column is temporary (used when pre-calculations are necessary); `[DB name]` is the name of the column in the target database; `[Data type]` has the data type of the column defined by `[DB name]`; and columns `[2010]`,`[2011]` have the yearly mappings of each input column into the corresponding target column. Every time a new release is available, a new year column is added, with its corresponding mappings. The periodicity can be different, depending of the characteristics of the input data.

HOTMapper also supports source-to-target mappings. For a given line in the CSV file, the `[DB name]` column points to the target column in the database. Then, for each year, it is possible to define two kinds of mappings: 1) simple equivalence mappings, by indicating the name of the source column; 2) data transformation mappings, defined by `CASE` statements in SQL. The `CASE` statements are injected in the code responsible for the transformation. The context of each statement is the current cursor of the SQL execution.

Consider the first equivalence mapping from the motivating example, i.e., for `NATIONALITY`. Five columns, from 2013 to 2017, have the value of the input column `NATIONALITY`. The same is valid for `SPECIAL_NECESSITY`, though it will have different names depending on the year. Non-existent mappings are just left blank. All other data transformations are written using `CASE`, one per year, independently from each other.

Considering the `PROFESSIONAL_STUDIES` column, following code is written to process years 2013 and 2014:

```
CASE
  WHEN (STUDIES_KIND >= 30 AND STUDIES_KIND <= 40) THEN 1
  WHEN (STUDIES_KIND > 40 AND STUDIES_KIND <= 50) THEN 2
END
```

Simple join operations are also supported. For instance, the following expression (`~ SCHOOL.REGION_ID`) written in the mappings of the `ENROLLMENTS` table causes a join with the `SCHOOL` table and returns the `REGION_ID` column.

The mapping definition is kept as simple as possible, yet rich enough to express data translations. The choice of a sub-set of SQL enables fast SELECT + INSERT executions, which would demand handcrafted loops over millions of records with an imperative programming language. The complexity of the translation depends on the `CASE` expression written. They support 1-to-1 and N:1 mappings, and simple joins with other tables. This choice for simplicity is crucial for the continuous maintenance of the mappings.

4 HOTMAPPER DEMONSTRATION

The demonstration will show how to create a mapping definition file, how to use it to create and update tables and its corresponding data. The process will be interactive, so the mapping can be modified if necessary and the tool can be re-executed, to show its efficiency and ease of use.

4.1 Requirements

HOTMapper has following software requirements:

- A Python environment
- The MonetDB[5] database
- The Open Data files in CSV[6]
- A connection configuration file[6]
- The HOTMapper code[6]

After the installation, it is necessary to set up the configurations in the file `settings.py`. It contains the database configurations (login, host, database name) and the path to the CSV files. The utilization of the CLI interface is straightforward:

```
./manage.py create|insert|remap|drop|remap|generate_report
            INPUT_TABLE_NAME PARAMETERS
```

All the options process a mapping definition file with the same name of the input table name, except for the period indication. The development of this file is a central part of the tool usage.

4.2 Using the HOTMapper

This demonstration will show two scenarios, illustrating two workflows: 1) the creation and insertion of an open data source from scratch, and 2) the update of mappings and data of an existing table. In both scenarios the audience will be able to

[5] https://www.monetdb.org/

[6] https://gitlab.c3sl.ufpr.br/tools/hotmapper

propose modifications in the mapping definitions and check the results on the fly.

In the **first scenario**, we will map a table containing information about the undergraduate institutions in Brazil, from 2010 to 2016 (`localoferta_ens_superior`). It is a relatively small table, with approximately 200K records per year, and for its creation the mapping definition file must contain the necessary columns. We execute the command:

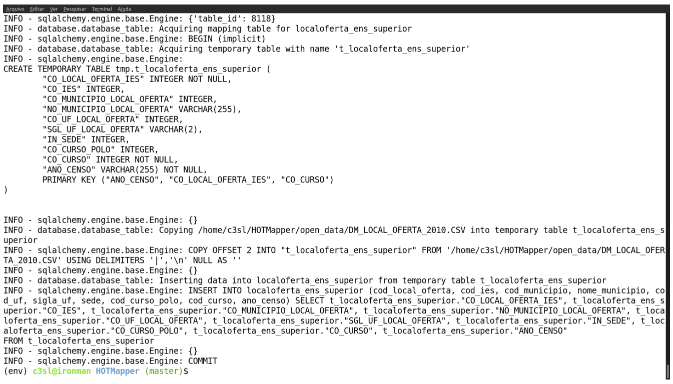
```
./manage.py create localoferta_ens_superior
```

In addition, HOTMapper creates an auxiliary table to store the mapping definitions, called `mapping_localoferta_ens_superior`. These mappings can be used for any subsequent modifications, enabling a faster processing and generation of SQL commands. A final commit is done after the tables are created. Then, we execute the command below to insert the data into the target table.

```
./manage.py insert /FILEPATH/DM_LOCAL_OFERTA_2010.CSV
            localoferta_ens_superior 2010 --sep="|"
```

The process is repeated for data files from each year, i.e., from 2010 to 2016, using the corresponding mapping definitions for each year. An excerpt of the mapping is shown in the three items below: (1) the labels of the mapping file; (2) a complete 1-to-1 mapping with the institution code; (3) a mapping with the institution start date. In this case, we do not have data for every year, leaving the corresponding column blank.

(1) `Label,Std.Label,New Label,DB Name,Type, 2010,2011,2012,2013,2014,2015,2016`
(2) `LOCAL-OFERTA,CO_IES,Institution code,cod_ies,INTEGER, CO_IES,CO_IES,CO_IES,CO_IES,CO_IES,CO_IES,CO_IES`
(3) `LOCAL-OFERTA,DT_INICIO_FUNCIONAMENTO,Start date, data_incio_funcionamento,VARCHAR(255),,,, DT_INICIO_FUNCIONAMENTO,DT_INICIO_FUNCIONAMENTO, DT_INICIO_FUNCIONAMENTO,DT_INICIO_FUNCIONAMENTO`



```

INFO - sqlalchemy.engine.base.Engine: COMMIT
(env) c3sl@ironman HOTMapper (master)$
```

Figure 3: Screenshot of the insertion execution flow

The screen shot of the execution log is shown in Figure 3. The command first inserts the table into a temporary table, with the same structure as the input CSV, in a bulk insert action. Then, it inserts the data into a final table applying the mapping definitions. If this insertion is successful, the tool commits all changes to the MonetDb database. Once a first insertion is done, we will execute the drop command (`./manage.py drop localoferta_ens_superior`), and the audience can propose alterations to the mapping definition file to see different outcomes.

In the **second scenario**, we start from an already existing table, with more complex mappings and records. We use the table from the motivating example in Section 2, with the enrollments of all students from 2013 to 2017. As already stated, it has about 90 columns and millions of records per year. We execute the *remap* and *update* actions for 2013 as follows:

```
./manage.py remap matricula
./manage.py update_from_file /FILEPATH/MATRICULA_2013.csv
   matricula 2013 --columns="profissionalizante" --sep="|"
```

The actions check if there is a difference between the current table specification (`matricula`) and the new mapping definition provided. It updates the table and the data. The mappings have, in addition to simple definitions as the ones from the *scenario 1*, expressions requiring data conversions using `CASE` statements. We will edit the `PROFESSIONAL_STUDIES` mapping, whose excerpt is shown below:

```
IN_PROFISSIONALIZANTE,Educação Profissional,0,
                                          profissionalizante,BOOLEAN,
~CASE
WHEN ("FK_COD_MOD_ENSINO"=1 OR "FK_COD_MOD_ENSINO"=2
OR "FK_COD_MOD_ENSINO"=3) THEN CASE WHEN null THEN null
WHEN ("FK_COD_ETAPA_ENSINO">=30 AND "FK_COD_ETAPA\_ENSINO"<=40)
OR ("FK_COD_ETAPA_ENSINO">=59 AND "FK_COD_ETAPA_ENSINO"<=65)
OR ("FK_COD_ETAPA_ENSINO">=67 AND "FK_COD_ETAPA_ENSINO"<=68)
OR ("FK_COD_ETAPA_ENSINO">=73 AND "FK_COD_ETAPA_ENSINO"<=74)
OR "FK_COD_ETAPA_ENSINO"=57
THEN 1 ELSE 0 END
END
```

The last column is the mapping for year 2013, also repeated for 2014. The remaining years already have the desired information. During the demonstration, this and other mappings can be changed following audience interactions.

To summarize, the HOTMapper demo will show how to write, store and manage mappings and data, from Open Data sources with historical information into an integrated database. The simple definition format and rapid bulk insertions enables efficient management of several Open Data sources over time.

Acknowledgments: this work was partially funded by CAPES, Sistema de Monitoramento de Políticas de Promoção da Igualdade Racial (SNPPIR), Simulador de Custo-Aluno-Qualidade (SASE/MEC).

Demonstration

SmartML: A Meta Learning-Based Framework for Automated Selection and Hyperparameter Tuning for Machine Learning Algorithms

Mohamed Maher, Sherif Sakr
University of Tartu, Estonia
{mohamed.abdelrahman,sherif.sakr}@ut.ee

ABSTRACT

Due to the increasing success of machine learning techniques, nowadays, thay have been widely utilized in almost every domain such as financial applications, marketing, recommender systems and user behavior analytics, just to name a few. In practice, the machine learning model creation process is a highly iterative exploratory process. In particular, an effective machine learning modeling process requires solid knowledge and understanding of the different types of machine learning algorithms. In addition, all machine learning algorithms require user-defined inputs to achieve a balance between accuracy and generalizability. This task is referred to as *Hyperparameter Tuning*. Thus, in practice, data scientists work hard to find the best model or algorithm that meets the specifications of their problem. Such iterative and explorative nature of the modeling process is commonly tedious and time-consuming.

We demonstrate `SmartML`, a meta learning-based framework for automated selection and hyperparameter tuning for machine learning algorithms. Being meta learning-based, the framework is able to simulate the role of the machine learning expert. In particular, the framework is equipped with a continuously updated knowledge base that stores information about the meta-features of all processed datasets along with the associated performance of the different classifiers and their tuned parameters. Thus, for any new dataset, `SmartML` automatically extracts its meta features and searches its knowledge base for the best performing algorithm to start its optimization process. In addition, `SmartML` makes use of the new runs to continuously enrich its knowledge base to improve its performance and robustness for future runs. We will show how our approach outperforms the-state-of-the-art techniques in the domain of automated machine learning frameworks.

1 INTRODUCTION

Machine learning is the field of computer science that focuses on building algorithms that can automatically learn from data and automatically improve its performance without end-user instructions, influence or interference. In general, the effectiveness of machine learning techniques mainly rests on the availability of massive datasets, of that there can be no doubt. The more data that is available, the richer and the more robust the insights and the results that machine learning techniques can produce. Nowadays, we are witnessing a continuous growth in the size and availability of data in almost every aspects of our daily life. Thus, recently, we have been witnessing many leaps achieved by machine learning in wide range of fields [1, 9]. Consequently, there are growing demand to have increasing number of data scientists with strong knowledge and good experience with the various machine learning algorithms in order to be able to build models that can achieve the target performance and to keep up with exponential growing amounts of data which is produced daily.

In practice, the machine learning modeling process is a highly iterative exploratory process. In particular, there is no one-model-fits-all solution, i.e, there is no single model or algorithm which is well-known to achieve the highest accuracy for all data set varieties in a certain application domain. Hence, trying many machine learning algorithms with different parameter configurations is commonly considered an inefficient, tedious, and time consuming process. Therefore, there has been growing interest to automate the machine learning modeling process as it has been acknowledged that *data scientists do not scale*[1]. Therefore, recently, several frameworks have been designed to support automating the machine learning modeling process. For example `Auto-Weka` [8] is an automation framework for algorithm selection and hyper-parameter optimization which is based on Bayesian optimization using sequential model-based algorithm configuration (SMAC) and tree-structured parzen estimator (TPE). `Auto-Sklearn` [3] is a framework that has been implemented on top of the popular python `scikit-learn` machine learning package that automatically considers the past performance on similar datasets for its automation decision. Other tools include `Google Vizier` which is based on grid or random search [5] and `TPOT` which is based on genetic programming [10].

In this demonstration, we present `SmartML`, a meta learning-based framework for automated selection and hyperparameter tuning for machine learning algorithms (using 15 classifiers). In our framework, the meta-learning feature is emulating the role of the domain expert in the field of machine learning [4, 11]. In particular, we exploit the knowledge and experience from previous runs by storing a set of data meta-features along with their performance. In addition, our knowledge base is continuously updated after running each task over `SmartML` which contributes to improving framework performance over the time. Our meta-learning mechanism is mainly used for the algorithm selection process in order to reduce the parameter-tuning search space which is conducted using SMAC Bayesian optimization [7]. This is different from other tools [3, 8] which

Table 1: Comparison between State-of-the-art Automated Machine Learning Frameworks

deal with algorithm selection as one of the parameters to be tuned.

`SmartML` can be used as a package in `R language`, one of the most popular languages in the data science domain, or as a Web application[2]. It is also designed to be programming language agnostic so that it can be embedded in any programming language using its available REST APIs. Table 1 shows a feature comparison between our framework and other state-of-the-art frameworks. In our demonstration, we will show that `SmartML` can outperform other tools especially at small running time budgets by reaching better parameter configurations faster. In addition, `SmartML` has the advantage that its performance can be continuously improved over time by running more tasks which makes `SmartML` *smarter* by getting more experience based on the growing knowledge base.

2 SMARTML ARCHITECTURE

Figure 1 illustrates the framework architecture of `SmartML`. In the *input definition* phase, the user uploads the dataset, choose the required options for features selection and preprocessing, specify which features of the dataset should be included in the modeling process, specify the target column which represents the classes of labels of the instances in the dataset and specify the `time budget` constraint for the framework for conducting the hyper-parameter tuning process. `SmartML` accepts `csv` and `arff` (attribute relation file format developed with the Weka machine learning software) file formats.

In the *preprocessing* phase, `SmartML` starts by performing the feature preprocessing operations specified by the selected features. Table 2 lists the feature preprocessing operations supported by the `SmartML` framework. In this phase, the dataset is randomly split into *training* and *validation* partitions where the former is used in algorithm selection and hyper-parameter tuning while the later is used for evaluating the selected configurations during parameter tuning. In addition, a list of 25 meta-features are extracted from the training split describing the dataset characteristics. Examples of these features include *number of instances*, *number of classes*, *skewness* and *kurtosis of numerical features*, and *symbols of categorical features.*

Currently, `SmartML` supports 15 different classifiers (Table 3). In the *algorithm selection* phase, the meta features of the input dataset at hand, which is extracted during the *preprocessing* phase, are compared with the meta features of the datasets that are stored in the knowledge base in order to identify the *similar* datasets, using a nearest neighbor approach. The dataset similarity detection process follows a weighted mechanism between two different factors. The first factors is the *Euclidean distance* between the meta-features of the dataset at hand and meta-features of all datasets stored in the knowledge base. The second factor is the magnitude of the best performing algorithms on the similar dataset. For example, it may be better to select the top n top performing algorithms on a single very similar dataset than selecting the first outperforming algorithm for n similar datasets. We use the retrieved results of the best performing algorithms on similar dataset(s) to nominate the candidate algorithms for the dataset at hand.

In the *hyper-parameter tuning* phase, `SmartML` attempts to tune the selected classifiers hyper-parameters for achieving the best performance. In particular, the knowledge base contains information about the best parameter configurations for each algorithm on each dataset. The configurations of the nominated best performing algorithms are used to initialize the hyper-parameter tuning process for the selected algorithms. The time budget constraint specified by the end user represents the time used in hyper parameter tuning of the selected classifiers. In particular, this budget is divided among all the selected algorithms according to the number of hyper-parameters to tune in each algorithm (Table 3). `SmartML` applies the SMAC technique for hyper-parameter optimization [7]. In particular, SMAC attempts to draw the relation between the algorithm performance and a given set of hyper-parameters by estimating the predictive mean and variance of their performance along the trees of the random forest model. The main advantage of using SMAC is its robustness by having the ability to discard low performance parameter configurations quickly after the evaluation on low number of folds of the dataset [7].

Finally, the results obtained from the hyper-parameter tuning process of the different nominated algorithms are compared with each other to recommend the best performing algorithm to the end user. In addition, a weighted ensembling [2] output of the top performing algorithms can be recommended to the end user based on their choice. In addition, we have integrated the `Interpretable Machine Learning (iml)` package[3] in order to explain for the user the most important features that have been used by the

3 DEMO SCENARIO

`SmartML` is available both as a Web application as well as RESTful APIs[5]. In this demonstration[6], we will present to the audience the workflow of the `SmartML` framework (Figure 1). In particular, we will show that how our approach can help non-expert machine learning users to effectively identify the machine learning algorithms and their associated hyperparameter settings that can achieve optimal or near-optimal accuracy for their datasets with little effort.

We start by introducing to the audience the challenges we tackle, the main goal and the functionalities of our framework. Then, we take the audience through the automated algorithm selection and hyper-parameter tuning process for sample datasets. We start by showing different features which is provided for the end-user (Figure 2). For example, the user can upload either a dataset file or a direct URL for the dataset. In addition, the user can choose either to perform both algorithm selection and hyper-parameter

tuning or only algorithm selection. In the later case, it is possible to upload only the dataset meta-features file instead of the whole dataset. The user will be also able to configure different options such as whether any kind of feature preprocessing is needed or not, whether model interpretability is needed or not and specify the time budget for hyper-parameter tuning. Then, we will take the audience through the different phases of the framework until returning the final results (Figure 1).

Table 4 shows the performance comparison between SmartML and Auto-Weka[7] using 10 datasets where a *time budget* of 10 minutes has been allocated for each dataset in each framework. In our experiments, we have bootstrapped the knowledge base of SmartML using 50 datasets from various sources including OpenMl[8], UCI repository[9] and Kaggle[10]. The results show that, using this relatively very small knowledge base, the accuracy results of SmartML outperform the results of Auto-Weka for all the datasets. As a part of our demonstration, we will provide the audience with the live chance to compare the performance of SmartML with Auto-Weka and other related frameworks using various datasets.

ABSTRACT

User-defined functions (UDFs) facilitate the execution of analytics pipelines inside the database. They provide many advantages over traditional methods, such as close-to-data execution and automatic parallelization. However, the standard workflow for developing and debugging UDFs does not allow developers to use their regular toolchains and Integrated Development Environments (IDEs). As a result, writing functional UDFs is challenging. In this demo, we present the devUDF, a plugin to the PyCharm IDE that allows developers to develop and debug their MonetDB/Python UDFs directly from within the IDE.

1 INTRODUCTION

To perform data analysis, data scientists frequently use scripting languages, such as R and Python. These languages have a huge ecosystem of existing machine-learning and classification libraries (e.g., TensorFlow [1] or Sci-Kit Learn [6]). Using these languages in conjunction with a relational database management system (RDBMS) has many advantages, as the RDBMS can offer robust storage of data and handle common data wrangling operations. The traditional method of combining a RDBMS with these scripting languages is to connect to a RDBMS using a client protocol. The data is then transferred from the database to the analytical tool. However, this is not efficient when a large amount of data needs to be retrieved [8].

This issue can be solved by in-database analytics. By performing the analytics inside the database, the data transfer overhead is mitigated [7]. The primary way of performing in-database analytics is through the use of UDFs. To facilitate this, most RDBMS vendors support UDFs in at least one scripting language frequently used for analysis [3].

The development workflow for UDFs differs depending on the DBMS that is used. Certain databases provide their own custom tools for developing UDFs, such as pgAdmin [9] for Postgres and ODS [4] for DB2 and Oracle. However, these tools have a number of limitations. They are not database agnostic, only work for developing UDFs written in PL/SQL and require developers to learn how to use complex tools designed for DBAs.

The generic workflow for developing a UDF is to write a function using a simplistic text editor. The function can then be created inside the RDBMS through a SQL command, and used by calling it within a SQL query. If there are bugs or problems within the UDF, the function has to be recreated and the SQL query has to be rerun. This process has to be repeated until the problem is fixed.

This workflow is problematic when developing complex UDFs, as advanced IDE features and modern debugging techniques cannot be used. Using these IDE features is not easily doable because the developer has to manually perform code transformations to convert the Python code to a SQL command that creates the UDF. As seen in Table 1 [2], IDEs are heavily preferred for development over simplistic text editors due to their development features. Therefore, we argue that offering support for the usage of these features in the development workflow of UDFs will make developing UDFs more attractive, faster and easier for many developers.

Name	Market Share	Type
`Eclipse`	25.2%	**IDE**
`Visual Studio`	19.5%	**IDE**
`Android Studio`	9.5%	**IDE**
`Vim`	7.9%	Text Editor
`XCode`	5.2%	**IDE**
`IntelliJ`	4.8%	**IDE**
`NetBeans`	4.0%	**IDE**
`Xamarin`	3.8%	**IDE**
`Komodo`	3.4%	**IDE**
`Sublime Text`	3.3%	Text Editor
`Visual Studio Code`	3.3%	Text Editor
`PyCharm`	2.3%	**IDE**

Table 1: Most Popular Development Environments.

IDEs are also attractive because they facilitate the usage of sophisticated interactive debugging techniques, such as stepping through the code line by line and pausing code execution. However, these techniques cannot be used in conjunction with UDFs because the RDBMS must be in control of the code flow while the UDF is being executed. Instead, developers have to resort to inefficient debugging strategies (e.g., print debugging) to make their code work [3].

Another issue with the standard UDF workflow is that UDFs are stored within the database server. As a result, version control systems (VCSs) such as Git [5] cannot be easily integrated to keep track of changes to UDFs. Without a VCS, cooperative development is challenging and the development history is not stored.

In this demo we showcase devUDF, a plugin for the popular IDE PyCharm that facilitates developing and debugging MonetDB/Python UDFs [7] directly from within the IDE. Using our plugin, advanced debugging features can be used while refining and refactoring UDFs.

2 THE DEVUDF PLUGIN

The devUDF plugin is developed for the PyCharm IDE that facilitates the usage of advanced IDE features for development of MonetDB/Python UDFs. It allows developers to create, modify and test UDFs without leaving their IDE environment. All

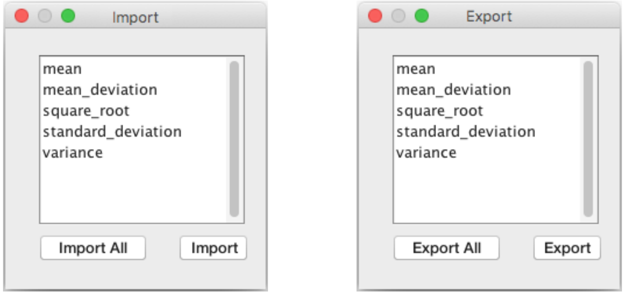
2.1 Usage

The devUDF plugin can be accessed through the main menu of the IDE (See Figure 1). In this menu, a submenu labeled "UDF Development" contains the three main aspects of the plugin.

Initially, devUDF must be configured so it can connect to an existing database server. This can be done through the settings window shown in Figure 2. The parameters required are the usual database client connection parameters (i.e., host, port, database, user and password).

After the devUDF plugin has been configured to connect to a running database server, the development process begins by importing the existing UDFs within the server into the development environment. This is done through the "Import UDFs" window, shown in Figure 3(a). The developer has the option to select the functions that he wishes to import, or he can choose to import all functions stored within the database server.

After the UDFs are imported, the code of the UDFs is exported from the database and imported into the IDE as a set of files in the current project. The developer can then modify the code of the UDFs in these files, use version control to keep track of changes to the UDFs and export the UDFs back to the database server for execution through the "Export UDFs" window (see Figure 3(b)).



(a) Import

(b) Export

Figure 3: Importing and Exporting UDFs from the Database.

The developer can also run any of the imported UDFs with the IDEs interactive debugger by running the project as they would run a normal PyCharm project (using the "Debug" command). Since a UDF is never executed in isolation, but always within the context of a SQL query, the user must provide a SQL query which executes the to-be-debugged UDF. This SQL query must be specified in the Settings menu (see Figure 2).

Running the UDF in the interactive debugger will execute the function locally on the developers' machine instead of remotely inside the database server. As the UDF requires data from the database (as its input parameters), the data must be transferred from the database server to the developers machine. For this data transfer, the developer can configure another set of options. As the data can be large, we offer a method of compressing the data during the transfer, leading to faster transfer times. In addition, the developer can choose to execute the UDF using a uniform random sample of the input data instead of the full set of input data. This will alleviate the data transfer overhead.

Since the data contained inside the database server might be sensitive, and it must be exported for debugging purposes, we also offer an optional encryption feature that can be used to safely transfer the sensitive data.

2.2 Implementation

The devUDF plugin works by connecting to the database using a JDBC connection. It then extracts the source code of the UDF together with its input parameters from the database by querying the databases' meta tables. An example of how MonetDB stores the source code of a Python function is shown in Listing 1. In order to be able to execute the UDF locally a set of code transformations has to be applied to this code, as the database only contains the function body. We need to create the header of the function using the function name and its parameters. To then run the created function, we need to obtain the input data from the database. In the generated code, we load the input data from a binary blob using the pickle library and pass it as a parameter to the function. The final transformed code is shown in Listing 2. When the user wants to export the UDF back to the database, these transformations are reversed and only the function body is committed.

When the user wants to debug the UDF locally using the interactive debugger, the input data of the function has to be extracted from the database. To obtain the input data, we take the user-submitted SQL query containing the call to the UDF, and we replace the call to the UDF with a predefined extract function that transfers the input data back to the client instead of executing the UDF inside the server. We then run the transformed SQL query inside the database server to obtain the input data, store it on the developers machine and run the code of the transformed UDF.

The extract function used changes depending on the data transfer options selected by the user. If encryption is requested, the data is encrypted by the extract function before being transferred using the password of the database user as a key. The client then reverses the encryption to obtain the actual input data. The compression option works in a similar fashion. If the sample option is enabled, a uniform random sample of a size specified by the user is taken before extracting the data from the database server.

+----------------+-----------------------------------+
```

Listing 1: MonetDB UDF Example.

2.3 Nested UDFs

Loopback queries inside UDFs are supported by MonetDB/Python. They allow users to query the database directly from within the UDF. The results of the query are converted to the host language of the UDFs. In MonetDB/Python UDFs, loopback queries can be can issued through the _conn object that is passed to every UDF. They are useful because they can bypass cardinality restrictions of the relational querying model.

The loopback queries can also contain UDFs themselves. An example of a nested UDF is shown in Listing 3. This UDF calls the function depicted in Listing 2 with a set of different parameters in order to find the best classifier and its parameters. In order to provide support for extracting and debugging these nested UDFs, we must execute the same transformation steps on the nested UDFs as we did for the main UDF being executed. With an additional transformation rule on the _conn object to the correct function call. After being transformed, we can execute the nested UDFs locally by transferring their input data in conjunction with the main UDF data, Finally they can be executed from within the IDE.

```
import pickle

def train_rnforest(data, classes, n_estimators):
    import pickle
    from sklearn.ensemble
        import RandomForestClassifier
    clf = RandomForestClassifier(n_estimators)
    clf.fit(data, classes)
    dict = {'classifier': pickle.dumps(clf),
            'estimators':n_estimators }
    return dict;

input_parameters =
        pickle.load(open('./input.bin','rb'))

train_rnforest(input_parameters['data'],
        input_parameters['classes'],
        input_parameters['n_estimators'])
```

Listing 2: Exported UDF Code Example.

```
CREATE FUNCTION find_best_classifier(esttest INT)
RETURNS DOUBLE LANGUAGE PYTHON {
import pickle
(tdata, tlabels) = _conn.execute("""SELECT data,
    labels FROM testingset""");
best_classifier = None
best_classifier_answers = -1
best_estimator = -1
for estimator in esttest:
    res = _conn.execute
        ("""
    SELECT *
    FROM train_rnforest(
        (SELECT data, labels
        FROM trainingset), %d);
    """ % estimator)
    classifier = pickle.loads(res['clf'])
    predictions = classifier.predict(tdata)
    correct_pred = predictions == tlabels
    correct_ans = numpy.sum(correct_predictions)
    if correct_ans > best_classifier_answers:
        best_classifier = classifier
        best_classifier_answers = correct_ans
        best_estimator = estimator
return {'clf': best_classifier,
        'n_estimators': best_estimator}
};
```

Listing 3: Nested UDF Example.

2.4 Extensions

Extending to Other Databases. Our solution is implemented for MonetDB. However, our plugin can be easily extended to work with other RDBMSes, as the same implementation strategy can be used. However, the processing model of the respective database needs to be taken into consideration. MonetDB uses the operator-at-a-time processing model, which means the UDFs are only called once with the entire columns as input. Row-store databases (e.g., Postgres or MySQL) use the tuple-at-a-time processing model, under which the UDFs are called many times with only individual rows as input. As this changes the way UDFs are called, the execution of the UDF must be adapted to these differing processing models. The tuple-at-a-time execution method can be simulated by issuing a loop over the input tuples.

Extending to Other UDF Languages. Our solution is implemented for Python/PyCharm. However the plugin is fully developed in Java and compatible with all the other JetBrains IDEs. In order to extend our plugin for other UDF languages, the code transformations for the new language must be added into the plugin. Additional care must be taken when dealing with compiled languages. Our model assumes that the RDBMS stores the source code of the UDF. If the database stores only a compiled blob of the UDF, the code transformations cannot be applied and an alternate solution must be used. In addition, when dealing with compiled languages some additional work must be performed on compiling and linking the code prior to execution.

2.5 Demo Outline

In the general outline for our interactive demo, we will introduce the typical setup for UDF Development. The general presentation for all the scenarios is as follows:

(1) We introduce the typical setup for UDF Development: Developers write code in their text editor of choice, insert the UDF into the database through a SQL command, repeating this process if the UDF has any bugs.
(2) We show common pitfalls in developing a UDF. Foremost, we focus on issues related to debugging.
(3) We show how bugs can be located using simplistic debugging strategies like print debugging.
(4) Finally, we repeat the same process but using devUDF to facilitate the development workflow. Showcasing how easy, fast and secure it is to use in the UDF development workflow.

In our demonstration we will ingest several CSV files, located in one directory, with one column of integers, our final goal is to create a UDF that calculates the mean deviation of said column, as a reference we compare the results with a correct version of the function. As common pitfalls, we will showcase the following scenarios:

Scenario A. In this scenario we present a UDF that calculates the median of a column with a bug, depicted in Listing 4. In line 9, the regular difference is calculated instead of the absolute difference which produces a semantic error, that is syntactically correct but logically incorrect.

Scenario B. Now, we use a correct version of the *mean_deviation* function. However, we introduce a bug in our data loader. Creating a data dependent error depicted in listing 5. In line 5 we introduce the bug that skips one of the CSV files in a given directory because it considers that *range* is right side inclusive.

3 SUMMARY

When it comes to assessing the potential impact of devUDF, we point out two current trends: First, the use of UDFs to perform In-Database Analytics is gaining popularity with support of many languages in major DBMSs. Especially in data science environments when the data is already stored inside a DBMS. Second, IDEs like Eclipse, IntelliJ and PyCharm have been gaining popularity over more simplistic text editors. Looking at both trends, we see a growing market for tools like devUDF, especially considering the void it fills in UDF development workflow.

```
1  CREATE FUNCTION mean_deviation(column INTEGER)
2  RETURNS DOUBLE LANGUAGE PYTHON {
3    mean = 0
4    for i in range (0, len(column)):
5        mean += column[i]
6    mean = mean / len(column)
7    distance = 0
8    for i in range (0, len(column)):
9        distance += column[i] - mean
10   deviation = distance/len(column)
11   return deviation;
12 };
```

Listing 4: Wrong mean deviation.

```
1  CREATE FUNCTION loadNumbers(path STRING)
2  RETURNS TABLE(i INTEGER)
3  LANGUAGE PYTHON {
4  files = os.listdir(path)
5  result = []
6  for i in range (0,len(files)-1):
7      file = open(files[i],"r")
8      for line in file:
9          result.append(int(line))
10 return result
11 };
```

ABSTRACT

This demonstration presents a machine learning language *MLearn* that allows declarative programming of machine learning tasks similarly to SQL. Our demonstrated machine learning language is independent of the underlying platform and can be translated into SQL and Python as target platforms. As modern hardware allows database systems to perform more computational intense tasks than just retrieving data, we introduce the *ML2SQL* compiler to translate machine learning tasks into stored procedures intended to run inside database servers running PostgreSQL or HyPer. We therefore extend both database systems by a gradient descent optimiser and tensor algebra.

In our evaluation section, we illustrate the claim of running machine learning tasks independently of the target platform by comparing the run-time of three in *MLearn* specified tasks on two different database systems as well as in Python. We infer potentials for database systems on optimising tensor data types, whereas database systems show competitive performance when performing gradient descent.

1 INTRODUCTION

Database systems provide with SQL a declarative language that allows data manipulation and data retrieving without caring about optimisation details. With increasing hardware performance, database systems will not fully exploit the servers' hardware potentials as long as they are used for data retrieval only. To shift computation to the data stored in database systems, algorithms can be specified in SQL—as it has been Turing complete since providing recursive tables—or as user-defined functions. The latter allow injecting code as stored procedures to be executed inside the database system and make an additional data manipulation layer on top obsolete. Even though the run-time would decrease, user-defined functions are not fully established as they form a mixture of declarative and procedural language and are inconvenient to express for data scientists.

When dealing with data and minimisation problems, dedicated tools as TensorFlow [1] or Pytorch form the status quo for performing machine learning tasks with tensors and gradient descent. Another approach of formulating machine learning tasks is using a declarative language as MLog [7], that compiles to code using TensorFlow, but, so far, it lacks support for use together with database systems. For computations inside of database systems, the support of linear algebra together with matrices or tensors is essential. Different studies focus on the integration of linear algebra [8] and matrices inside of database systems [5]. Going one step further, so called array database systems replace relations by arrays as the native way of storing attributes. To support machine learning, TensorDB [6] aims at providing tensor calculus on top of array database systems. One study even provide an own declarative language (BUDS) [2] on top of a prototyped database system that supports matrix data types. Comparable domain specific languages are Weld[1] for data driven workloads and IBM SystemML[2] for creating flexible algorithms, but both cannot be used inside of database systems. The intermediate language Ferry [3] allows to translate from various code (i.e. Ruby or Haskell) into SQL but is not designed for use with array datatypes.

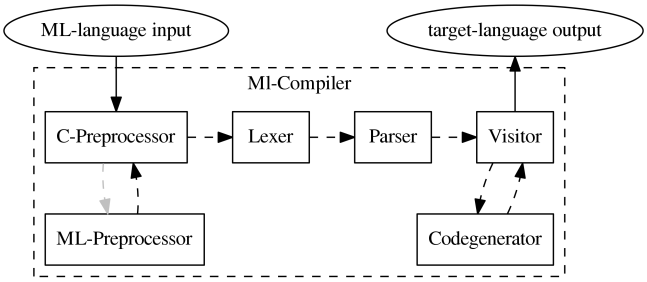

Figure 1: The compilation process: the *MLearn* language first gets preprocessed twice for handling includes, then the language gets tokenised and parsed. For each target platform, a generator allows to translate the abstract syntax tree into the target language.

However, while linear algebra in database systems have been integrated and declarative language concepts have been proposed, there is no successful study on bringing a declarative language, tensor calculus and gradient descent in database systems together. We therefore develop a declarative machine learning language aimed at optimising models for supervised machine learning and data analysis. Our *MLearn language* allows specifying tasks independently of the target language, changing the underlying engine and makes it easy to compare run-times and results of different underlying frameworks. This demonstration presents the *ML2SQL* compiler in particular, which compiles code written in *MLearn* to SQL (for PostgreSQL or HyPer [4]) or to Python using the frameworks NumPy and TensorFlow (see Fig. 1).

This demonstration paper is structured as follows: First, we introduce the *MLearn* language specifications and the details of the corresponding compiler. We evaluate the run-time of the generated code on the target platforms using the Chicaco taxi

dataset as input data and linear regression as optimisation model (optimised by gradient descent or as closed form solution). At the end, we introduce the demonstration concept including our web interface for online testing and conclude by improvements that might increase database systems' computation performance.

2 MLEARN AND THE ML2SQL COMPILER

The *MLearn* language is designed to define machine learning tasks in a declarative manner to be compiled to SQL or Python. We begin by introducing the language specification needed for enjoying the demonstration as a visitor. We precede by listing the prerequisites of the target platforms in order to run the introduced tasks. Finally, we will give examples on how to use the *MLearn* language during the demonstration later on.

2.1 Language Specification

All operations work on integers, floating point numbers, Boolean values or strings as basic types, which can be composed to tensors. On these types, *MLearn* provides the following features (s. Lst. 5):

- **Reading CSV files** as the fundamental operation to store the data in variables or relations of the database system.
- **Mathematical expressions** as provided by NumPy or SQL (as part of the projection operator).
- **Tensors** form the main part in our computations. Beside mathematical operations we support accessing, slicing, concatenation and transposition.
- **Functions** allow to structure the code and to reduce code duplication. Also external functions imported from other files or of a target language are allowed.
- **Control blocks.** In addition to our declarative statements, we allow conditional expressions and loops.
- **Distributions** are used for data sampling when initializing tensors with random values.
- **Preprocessor statements** as known from C can be used to include files and to allow the abstraction of different functions to different files.
- **k-fold cross validation** as a predefined building block splits up a data set into training and test sets to find the best—so-called—hyper parameters.
- **Gradient descent** as a separate building block optimises the weights for a given loss function on input data.

2.2 Target Language

We designed our machine learning language to compile to Python code with the libraries that data scientists would use. To work with SQL we picked out the disk-based database system PostgreSQL and its main-memory counterpart, HyPer. We assume for both systems an underlying script language, PL/pgSQL in PostgreSQL and HyPerScript in HyPer, that combines declarative SQL statements with procedural control blocks. The tensor operations in Python are performed using NumPy library calls. HyPer has already implemented all basic tensor operations including addition, (scalar) multiplication, power (including inverse for matrices on negative exponents), transposition, initializing an identity matrix and filling a matrix by a predefined value. As those operations do not exist in PostgreSQL, we have implemented these operations as C library function calls, also supporting parallelism. Furthermore, we make use of predefined array operations as slicing and concatenation to divide the input dataset into training and testing one. Also, we wrap a PostgreSQL library extension around our already presented gradient descent [9] library to allow in-database gradient descent in PostgreSQL.

2.3 Example

Fig. 2 shows the exemplary usage of the *MLearn* language where we specify linear regression as closed form solution:

$$\vec{w} = (X'^T X')^{-1} X'^T \vec{y}.$$

The example code (see Lst. 1) splits a tensor (A) into features (X, the first three attributes) and labels (y). Then a tensor out of the value 1 as bias is prepended in front of the features. Afterwards, the optimal weights (w) are computed out of tensor algebra. The compiled code to Python can be seen in Lst. 2, the one for PostgreSQL in Lst. 4 and the one for HyPer in Lst. 3. We can see that the code written in our declarative language is much more compressed.

3 EVALUATION

For evaluation (s. Fig. 3), we specify linear regression as closed form or using gradient descent in our machine learning language and let the tasks run on the following target platforms: PostgreSQL version 10.5, Python 2.7.15 with NumPy 1.13.3 and TensorFlow 1.3.0 and the current HyPer system. We used an Ubuntu 18.04.01 LTS server with two sockets and twenty cores of Intel Xeon E5-2660 v2 processors in total (supporting hyper-threading). The server has 256 GiB of main memory and uses 1 TiB of SSD as background storage. As test data served 85 mio. tuples of the Chicaco taxi rides dataset[3].

We tested the run-time of loading data from CSV (s. Fig. 3a), the run-time of linear regression in closed form (s. Fig. 3b) and by using gradient descent (s. Fig. 3c). For gradient descent, we used a learning rate of 0.0000005 and varied the number of iterations from 1 to 10^4, but we used a constant input size (the whole dataset). The time measurements consider only the run-time needed for the specific operations, the time for data loading and array creation is measured separately.

The results show that data loading took in all three systems about the same time, no system seems to dominate one another. For the matrix operations used for closed form linear regression, Python using NumPy still dominates the other systems (even PostgreSQL does not support two dimensional array creation for more than 10^7 tuples). Hence, the integration of matrix calculus in database systems still has to be improved. Whereas using gradient descent, both database systems show competitive performance. Even some performance benefits originate from the used gradient descent optimiser, the results underline the possibility of analyzing data where it is stored.

In summary, the evaluation underlines the claim that the *ML2SQL* compiler makes it easy to compare different systems and that database systems show competitive performance on certain tasks.

4 DEMONSTRATION

For our demonstration scenario, we have created an interactive web interface (see Fig. 4) that allows formulating tasks in *MLearn*, compiling to the choosable target language and executing the tasks. Switching between the different target platforms (Python, HyPer, PostgreSQL) makes it possible to compare the results and the run-times of each target language. Behind the web interface,

we run a PostgreSQL and an HyPer database server fed with an excerpt of the Chicago taxi dataset. The demonstration visitors are invited to try out the introduced types of tensor algebra as well as minimising arbitrary loss functions as, for example, linear or logistic regression.

5 CONCLUSION

This demonstration presented the first declarative machine learning language *MLearn*, which allows describing machine learning tasks independently of the target engine and whose compiler allows running the code in the core of database systems. This paper first introduced comparable approaches before it presented the language specifications for performing linear regression and gradient descent using any possible loss function. Then, we evaluated the run-time of the tasks on the different target platforms PostgreSQL, HyPer and Python using NumPy and TensorFlow. The results showed, that it was indeed feasible to run the tasks as stored procedures inside of database systems showing comparable run-time especially during matrix creation.

Overall we have shown the potential of a declarative machine learning language of expressing tasks compactly and being independent of the underlying engine. As future work—to boost the capabilities of database systems for array data—remains the development of efficient array data types and the standardised integration of optimisation methods such as gradient descent inside of database systems.

ABSTRACT

Realizing the full potential of Linked Open Data sharing and reuse is currently limited by the difficulty users have when trying to understand the data modeled within an RDF graph, in order to determine whether or not it may be useful for their need.

We demonstrate our **RDFQuotient** tool, which builds compact summaries of heterogeneous RDF graphs for the purpose of first-sight visualizations. An RDFQuotient summary provides an overview of the complete structure of an RDF graph, while being typically many orders of magnitude smaller, thus can be easily grasped by new users. Our summarization algorithms are time linear in the size of the input graph and incremental: they incrementally update a summary upon addition of new data.

For the demo, we plan to show the visualizations of our summaries obtained from well-known synthetic and real data sets. Further, attendees will be able to add data to the summarized RDF graphs and visually witness the incurred changes.

1 INTRODUCTION

Semantic Web graphs are nowadays being published and shared at a massive scale, e.g., Linked Open Data (LOD) Cloud (https://lod-cloud.net) lists 1.200 graphs, while the LOD Atlas portal (http://lodatlas.lri.fr) references more than 20.000 graphs. Some of these graphs are *domain-oriented*, that is, they reflect a certain application domain, e.g., education, medical etc. On the contrary, a few RDF graphs are *encyclopedic*, e.g., DBpedia (https://wiki.dbpedia.org) and YAGO [7], covering many different topics; often, these are unions of many domain-specific ones, e.g., DBpedia is available for download as a set of domain-oriented "datasets". An overwhelming majority of the RDF graphs found in portals such as LOD Cloud or LODAtlas, https://data.gov.uk, https://data.gov etc. are domain-oriented.

Currently, a large obstacle toward exploiting this wealth of data is the difficulty for human users to make sense of a newly encountered RDF graph. The motivation for our work is to help users learn *at first sight*, without any prior knowledge about the graph and without having to set any parameter, the *(ideally complete) structure of a domain-specific RDF graph*. Given that RDF graphs can be very large, while the human information absorption capacity is relatively limited, *RDF graph summaries* have been used as intermediaries: from a given graph G a summary is extracted, then the summary is shown to the users in order to convey information about the structure and/or content of G.

We demonstrate **RDFQuotient**, a tool for constructing a complete summary of the structure of an RDF graph which does not require any user input. The particular advantage of RDFQuotient is its *tolerance to heterogeneity*, which enables it to build *compact, easy-to-visualize summaries* even from very large graphs, while preserving many of the important structural features of the graph. RDFQuotient summaries can be built efficiently, in linear time in the size of the graph. Further, they can be *incrementally updated*: upon addition of a triple t to a graph G, the summary of $G \cup \{t\}$ can be efficiently computed out of the current summary of G and t, without re-traversing the G triples.

Motivating example Figure 1 illustrates a possible visualization of an RDFQuotient summary of a BSBM [1] benchmark graph of $\mathbf{10^8}$ triples. This visualization reflects the *complete* structure of the graph, using only **5 nodes and 11 edges**, comparable to a simple small Entity-Relationship diagram. This summary reads as follows: (*i*) Non-leaf graph nodes belong to one of five disjoint classes, each represented by a summary node (boxes labeled $N1$ to $N5$ in Figure 1). The number of graph nodes in each class appears in parenthesis after the label Ni of their representative; (*ii*) Graph nodes from a class may have types. Each such type appears under the summary node label, together with its number of occurrences among graph nodes of that class, e.g., 5919 nodes represented by $N3$ are of type Producer, while 3050 are of type Vendor; (*iii*) Graph nodes from a class may have outgoing properties whose values are *leaf* nodes in the graph; the set of all such properties appears in the corresponding summary node, one property per line. For each property, e.g. country for $N3$, the summary node specifies how many graph nodes represented by this summary node have it (8969 in this case), and how many distinct leaf nodes are target of these edges (10 in this case); (*iv*) Graph nodes from a class may have outgoing properties whose values are *non-leaf* nodes in the graph. For each graph edge $n_1 \xrightarrow{a} n_2$, where n_1, n_2 are non-leaf graph nodes and a is the property (edge label), an a-labeled edge in the summary goes from the representative of n_1 to that of n_2. Next to a, this summary edge is also labeled with the number of graph edges to which it corresponds; (*v*) Properties from a small, fixed vocabulary are considered *metadata* (as opposed to *data*) and therefore they are not used to group nodes in classes, e.g., *rdf-schema#-comment* and *rdf-schema#-label* in Figure 1. More such visualizations can be found online[1]; below, we also work out an example leading from an RDF graph to its summary and then such a visualization.

We propose to *demonstrate the incremental construction of four* related (but different) *summaries*, i.e., show how summaries quickly adjust when triples are added to the summarized RDF graphs. Our summaries can be built from graphs where none, some or all nodes have one or more types; this is important because in many synthetic and real-life RDF graphs we studied, a large share of nodes is untyped [3]. Two of our summaries give preeminence to types (when available) to build the summary; nodes are first grouped by types and then by the relationships to other nodes. By contrast, the two other (including the one in Figure 1) give preeminence to node relationships; nodes are first grouped according to their relationships with others, then, each group is typed with the types of the graph nodes it represents within the summary (this is how each type has been attached to a summary node in our figure). In the total absence of types, each

Figure 1: Visualization built from an RDFQuotient summary.

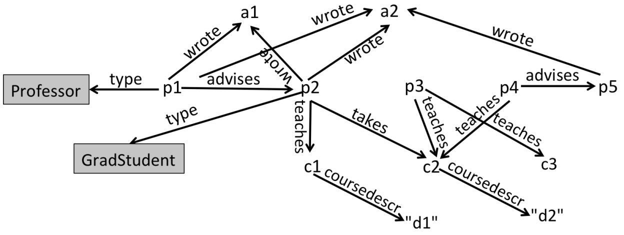

Figure 2: Sample RDF graph.

type-first summary coincides with a type-ignorant one (thus, our four summaries collapse into two).

Below, we define our summaries (Section 2) and summarization algorithms (Section 3). Then, we present the demonstration scenario based on summary visualizations (Section 5). Finally, we compare them with related work and we conclude (Section 6).

2 RDFQUOTIENT SUMMARIES

Let U be a set of URIs, L be a set of literals and B be a set of blank nodes as per the RDF specification. An RDF graph $\mathtt{G}$ is a set of *triples* of the form (s, p, o) where $s \in U \cup B \cup L$, $p \in U$ and $o \in U \cup B \cup L$. The special URI *type*, part of the RDF standard, is used to attach types to nodes. An RDF graph may contain *ontology (schema)* triples; while there are interesting interactions between summarization and ontologies [3], below we only focus on summarizing the non-schema triples, which make up the vast majority of all RDF graphs we encountered. Thus, we consider $\mathtt{G}$ consists exclusively of *type* triples and/or *data* triples (all those whose property is not *type*; we call these *data properties*).

An *RDF equivalence relation* denoted $\equiv$ is a binary relation over the nodes of an RDF graph that is reflexive, symmetric and transitive. Given an equivalence relation $\equiv$, an *RDF graph quotient* is an RDF graph having (i) one node for each equivalence class of nodes; (ii) for each edge $n_1 \xrightarrow{a} n_2$, a summary edge $n_1^{\equiv} \xrightarrow{a} n_2^{\equiv}$, where $n_i^{\equiv}$, $i \in \{1, 2\}$, is the summary node corresponding to the equivalence class of n_i, also called *representative of* n_i. The literature comprises many quotient graph summaries (see Section 6), which differ by their equivalence relations.

The equivalence relations we use are based on the concept of *property cliques*, which encodes a *transitive* relation of *edge co-occurrence on graph nodes.* Given an RDF graph $\mathtt{G}$, two data properties p_1, p_2 are in the same **source clique** iff: (i) there exists a $\mathtt{G}$ node n which is the source of p_1 and p_2 (i.e., $(n, p_1, x) \in \mathtt{G}$ and $(n, p_2, y) \in \mathtt{G}$ for some x and y), or (ii) there exists a data property p_3 such that p_3 is in the same source clique as p_1, and p_3 is in the same source clique as p_2. Symetrically, p_1 and p_2 are in the same **target clique** if there exists a G node which is the target of p_1 and p_2, or a data property p_3 which is in the same target clique as p_1 and p_2. In Figure 2, the properties *advises* and *teaches* are in the same source clique due to p_4. The same holds for *advises* and *wrote* due to p_1; consequently, *advises* and *wrote* are also in the same source clique. Further, the graduate student p_2 teaches a course and takes another, thus *teaches*, *advises*, *wrote* and *takes* are all part of the same source clique. In this example, p_1, p_2, p_3, p_4, p_5 have the source clique $SC_1 = \{advises, takes, teaches, wrote\}$, c_1, c_2, c_3 have the source clique $SC_2 = \{coursedescr\}$ and a_1, a_2 have the empty source clique $SC_3 = \emptyset$. Similarly, the target cliques are, respectively; $TC_1 = \{advises\}$ for p_2, p_5, $TC_2 = \{teaches, takes\}$ for c_1, c_2, c_3, $TC_3 = \{coursedescr\}$ for d_1, d_2, $TC_4 = \{wrote\}$ for a_1, a_2 and $TC_5 = \emptyset$ for p_1, p_3, p_4.

It is easy to see that the set of non-empty source (or target) cliques is a *partition over the data properties of an RDF graph* $\mathtt{G}$. Further, if a $\mathtt{G}$ node n is source of some data properties, they are all in the same source clique; similarly, all the properties of which n is a target are in the same target clique. Based on these cliques, for any nodes n_1, n_2 of $\mathtt{G}$, we define:

- n_1 is **weakly equivalent** to n_2, denoted $n_1 \equiv_{\mathtt{W}} n_2$, iff n_1, n_2 have the same source clique *or* the same target clique;

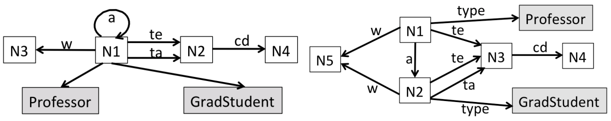

Figure 3: Weak (left) and strong (right) graph summary.

- n_1 is **strongly equivalent** to n_2, denoted $n_1 \equiv_{\mathtt{S}} n_2$, iff n_1, n_2 have the same source clique *and* the same target clique.

Further, we decide that in any RDF equivalence relation, *any class node*, i.e., a URI c appearing in a triple of the form $(n, type, c)$, is (*i*) only equivalent to itself and (*ii*) represented by itself in any RDFQuotient summary. This ensures that RDF types (classes), which (when present) denote an important information that data producers added to help understand their RDF graphs, are preserved in the summary.

The equivalence relations $\equiv_{\mathtt{W}}$ and $\equiv_{\mathtt{S}}$ lead to the **weak**, respectively **strong** summaries, defined as *quotients of* $\mathtt{G}$ *through* $\equiv_{\mathtt{W}}$, denoted $\mathtt{G}_{/\equiv_{\mathtt{W}}}$, respectively, *through* $\equiv_{\mathtt{S}}$, denoted $\mathtt{G}_{/\equiv_{\mathtt{S}}}$. Figure 3 illustrates these on the sample graph in Figure 2. For brevity, in Figure 3 and from now on, we use a, w, te, ta, cd to denote respectively the properties *advises*, *writes*, *teaches*, *takes*, and *coursedescr*.

In $\mathtt{G}_{/\equiv_{\mathtt{W}}}$, N_1 represents all the people (p_1 to p_5), N_2 represents the courses, N_3 the articles and N_4 the course descriptions. Note the self-loop from N_1 to itself; it denotes that *some* nodes represented by N_1 advise *some* nodes represented by N_1. This summary has only 4 nodes and 5 edges. It conveys the essential information that some nodes advise, write, also they teach and take something that has course descriptions. The Professor and GradStudent types of nodes p_1, respectively p_2, are attached to their common representative N_1.

$\mathtt{G}_{/\equiv_{\mathtt{S}}}$ differs from $\mathtt{G}_{/\equiv_{\mathtt{W}}}$ by representing the person nodes in two separate groups: those represented by N_1 advise those represented by N_2. This is because the target clique of p_1, p_3 and p_4 is empty, while the target clique of p_2 and p_5 is $\{advises\}$. This example illustrates the fact (visible from the summary definitions) that $\mathtt{G}_{/\equiv_{\mathtt{S}}}$ summarizes *at finer granularity* than $\mathtt{G}_{/\equiv_{\mathtt{W}}}$ (or, equivalently, $\equiv_{\mathtt{S}}$ entails $\equiv_{\mathtt{W}}$, but the opposite does not hold).

Clique-based structural summarization leads to **compact summaries** even in graphs with **heterogeneous structure**. This is because of the *transitive* aspect of the property cliques. For example, p_1 and p_3 have the same source clique, even though their property sets are disjoint: $\{a, w\}$ for p_1, $\{te\}$ for p_3; they are in the same source clique e.g. due to p_4, which has both a and te. In contrast, previously studied quotient summaries, in particular those aimed for indexing and query optimization, would not accept p_1 and p_3 as equivalent; in general, such summaries lead to more equivalence classes (summary nodes), thus also summary edges, making summaries hard to understand visually.

Type-first summarization The weak and strong summary group nodes according to their incoming/outgoing data triples and then just "carry" their types to the summary. A different choice is to group nodes first by their *set of types* (if any)[2], and use the data triples to group the nodes without types. We define:

- n_1 is **typed-weak equivalent** to n_2, noted $n_1 \equiv_{\mathtt{TW}} n_2$, iff (*i*) n_1, n_2 have the same non-empty set of types *or* (*ii*) both n_1, n_2 are untyped, and $n_1 \equiv_{\mathtt{W}} n_2$;

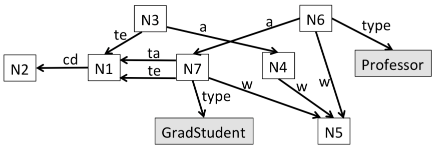

Figure 4: Typed weak graph summary.

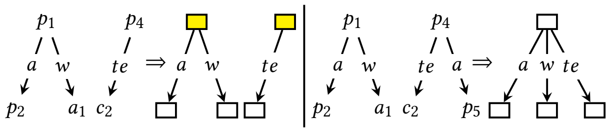
- n_1 is **typed-strong equivalent** to n_2, noted $n_1 \equiv_{\mathtt{TS}} n_2$, iff (*i*) n_1, n_2 have the same non-empty set of types *or* (*ii*) both n_1, n_2 are untyped, and $n_1 \equiv_{\mathtt{S}} n_2$.

These relations lead to the **typed weak** ($\mathtt{G}_{/\equiv_{\mathtt{TW}}}$), respectively, to the **typed strong** ($\mathtt{G}_{/\equiv_{\mathtt{TS}}}$) RDFQuotient summaries. Figure 4 illustrates typed weak summarization on our sample graph; on this simple example, $\mathtt{G}_{/\equiv_{\mathtt{TS}}}$ is identical (in general, it may differ).

3 BUILDING RDFQUOTIENT SUMMARIES

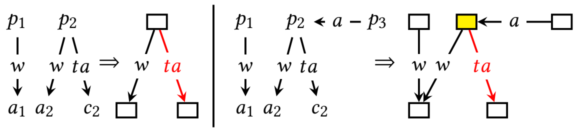
We have devised algorithms which build $\mathtt{G}_{/\equiv_{\mathtt{W}}}$, $\mathtt{G}_{/\equiv_{\mathtt{S}}}$, $\mathtt{G}_{/\equiv_{\mathtt{TW}}}$ and $\mathtt{G}_{/\equiv_{\mathtt{TS}}}$ through a single traversal of an RDF graph $\mathtt{G}$, in two flavors: (*i*) *global*: traverse $\mathtt{G}$, compute all the cliques, then traverse it again and represent nodes according to their cliques and/or types; (*ii*) *incremental*: in a single traversal of $\mathtt{G}$, *gradually build each source and target clique* based on the triples traversed *up to that point* and *simultaneously* represent $\mathtt{G}$ nodes in a summary that is continuously updated; after traversing the last triple of $\mathtt{G}$, each incremental summarization algorithm ends up with the respective summary of the full $\mathtt{G}$. The algorithms are detailed and their correctness is proved in [3]; below, we illustrate their interesting points on minimal examples.



First, let us see on an example how $\equiv_{\mathtt{W}}$ can grow during *incremental weak summarization*. Suppose the graph $\mathtt{G}$ in Figure 2 is traversed and summarized starting with: (p_1 *advises* p_2), then (p_1 *wrote* a_1), then (p_4 *teaches* c_2) (see the figure above). When we summarize this third triple, we do not know yet that p_1 is equivalent to p_4, because no common source of *teaches* and *advises* (e.g., p_3 or p_4) has been seen so far. Thus, p_4 is so far not equivalent to any other node, and represented separately from p_1. Now, assume the fourth triple traversed is (p_4 *advises* p_5): at this point, we know that *advises*, *wrote* and *teaches* are in the same source clique, thus $p_1 \equiv_{\mathtt{W}} p_4$, and their representatives (highlighted in yellow) must be **fused** in the summary. More generally, it can be shown that $\equiv_{\mathtt{W}}$ **only grows** as more triples are visited (i.e., is monotonic), in other words: if in a subset $\mathtt{G}'$ of $\mathtt{G}$'s triples, two nodes n_1, n_2 are weakly equivalent, then this holds in any $\mathtt{G}''$ with $\mathtt{G}' \subseteq \mathtt{G}'' \subseteq \mathtt{G}$.

Incremental strong summarization is even more complex because unlike $\equiv_{\mathtt{W}}$, $\equiv_{\mathtt{S}}$ **may grow and shrink** during summarization (i.e., is non-monotonic). For instance, assume the summarization of the graph in Figure 2 starts with (p_1 *wrote* a_1), (p_2 *wrote* a_2), (p_2 *takes* c_2) (see the figure below). After these, we know $p_1 \equiv_{\mathtt{S}} p_2$; their source clique is $\{wrote, takes\}$ and their target clique is $\emptyset$. Assume the next triple traversed is (p_3 *advises* p_2): at this point, p_1 is *not* $\equiv_{\mathtt{S}}$ *to* p_2 *any more*, because p_2's target clique is now $\{advises\}$ instead of $\emptyset$. Thus, p_2 **splits** from p_1, that is, it needs to be represented by a new summary node (shown in yellow below), distinct from the representative of p_1.

[2] We use *set of types* and not just "type" on purpose, because an RDF node may have more than one type. If we classified a node according to *each* of its types, as in e.g. [2], a node with many types would have more than one representative, which is incompatible with quotient summarization.



Further, note that the representative of p_1 and p_2 (at left above) had one *takes* edge (highlighted in red) which was *solely due to p_2's outgoing takes edge*. By definition of a quotient summary, that edge *moves* from the old to the new representative of p_2 (the yellow node). If, above at left, p_1 had also had an outgoing edge labeled *takes*, at right, both nodes in the top row would have had an outgoing *takes* edge. It can be shown that *splits only occur in such cases*, i.e., a node whose target clique becomes non-empty (respectively whose source clique becomes non-empty) and the node was previously represented together with other nodes; if it was represented alone, the respective clique of its representative is just updated.

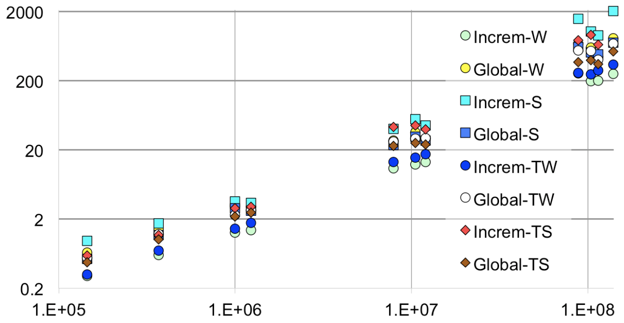


Figure 5: Summarization time (s) vs. graph sizes |G|.

The **amortized complexity** of our summarization algorithms is linear in the number of triples of G. Figure 5 illustrate this empirically on a variety of benchmark (LUBM and BSBM) and real-life (DBLP, Springer conference etc.) datasets ranging from a few hundred thousands to more than 100 million triples; note that both axes are in log-scale. The implementation is made in Java 1.8; RDF graphs are stored in Postgres 9.6 and traversed from there. Increm-W is the fastest overall; it traverses G only once, thus it is faster than global-W which performs one extra pass to compute the cliques. S, TW and TS, in this order, are more expensive, and finally incremental S, which pays an extra performance overhead for growing and shrinking the equivalence relation.

4 FROM SUMMARIES TO VIZUALIZATIONS

The core of our work is on defining and efficiently building summaries; here we present one possible way of rendering them through a vizualization like the one illustrated in Figure 1.

On our four summaries we apply **leaf and type inlining**, as follows. We remove type edges; instead, each type attached to a node in the summary is shown in the box corresponding to the node, after the node ID. Similarly, for each edge $n \xrightarrow{a} m$ where m is a leaf, we include a as an "attribute" of n, and do not render m (we say it has been "inlined" within n). A sizable part of an RDF graph's nodes are leaves; as we will show, inlining them into their parent nodes greatly simplifies the visualization.

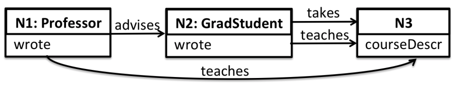

Figure 6: Leaf and type inlining on the sample strong summary from Figure 3 (right).

Figure 6 illustrates inlining for the S summary of our sample graph. This summary is extremely compact, yet rich with information; professors, students, and courses are visible at a glance. Articles have been inlined within their authors as they were leaves in $G_{/\equiv_{TS}}$ (Figure 3). This simplification can also be seen as a small loss of information: Figure 6 does not immediately suggest that Professors may have written articles together with GradStudents. However, (*i*) only leaf nodes are folded and (*ii*) after a first glance, users may pursue exploration by other means (e.g., queries to check for such joint articles).

5 DEMONSTRATION SCENARIO

Demonstration attendees will be able to pick an RDF graph from a list of well-known synthetic and real data sets, visualize their summaries, and compare with other close competitor summaries, such as those mentioned in Section 6; some of these vizualizations can be seen online (https://team.inria.fr/cedar/projects/rdfquotient/). Attendees will also be able to add new triples to an RDF graph, to figure out through our summary visualization how changes in the original data are rapidly reflected into the summary thanks to incremental summarization. To make it entertaining, we plan to use RDF data on the conference attendees, from DBLP, other public sources, and made-up triples to get interesting summary changes.

6 RELATED WORK & CONCLUSION

The literature comprises many RDF summarization techniques, more than a hundred of which we covered in a recent co-authored survey [4]. RDFQuotient summarizes *the structure of the data triples*, which form a vast majority of RDF graphs; complementary proposals summarize the ontology, the values, find the most frequent property groups etc. Closest to us are quotient summaries which group nodes by *the set of their outgoing data properties* ("characteristic sets" [6]) and possibly also by *by the set of their incoming data properties* (forward and backward bisimulation [5]). Our clique-based summarization differs from these by the *transitive* aspect of the cliques which leads to *heterogeneity-tolerant summarization*. Indeed, as we plan to show during our demonstrations, more strict summaries such as [5, 6] support query optimization and indexing well, but have too many nodes and edges, even after inlining, for a comfortable vizualization. In exchange, our summaries are not generally appropriate for indexing, as they do not give e.g. access to "all the resources having properties a and b": the graph nodes whose source clique is $\{a, b\}$ may have one or another or both.

ABSTRACT

Most of the trajectory datasets only record the spatio-temporal position of the moving object, thus lacking semantics and this is due to the fact that this information mainly depends on the domain expert labeling, a time-consuming and complex process. This paper is a contribution in facilitating and supporting the manual annotation of trajectory data thanks to a visual-analytics-based platform named VISTA. VISTA is designed to assist the user in the trajectory annotation process in a multi-role user environment. A session manager creates a tagging session selecting the trajectory data and the semantic contextual information. The VISTA platform also supports the creation of several features that will assist the tagging users in identifying the trajectory segments that will be annotated. A distinctive feature of VISTA is the visual analytics functionalities that support the users in exploring and processing the trajectory data, the associated features and the semantic information for a proper comprehension of how to properly label trajectories.

1 INTRODUCTION

The increasing access to positioning devices technologies such as smart-phones, GPS-enabled cameras and sensors, resulted in vast volumes of mobility data collected, stored and available for analysis. Such mobility data are typically modeled as streams of spatio-temporal points, called trajectories. There is a growing research interest in analysis methods for semantically enriched trajectories [7, 8]. However, only a few datasets containing semantically labeled trajectory data are available. This is primarily because the semantic labels tend to indicate a specific behavior whose identification depends on the humans' interpretation: in fact, the understanding of the moving object behavior depends on multiple factors and, in most of the cases, it cannot be automatically inferred. The process of manual annotation may be, therefore, complex and time-consuming, even by domain experts who might be uncertain in the correct data interpretation or they might disagree. Indeed, the labeling process is complex due to a number of factors: (1) the annotator user needs to have an immediate view and understanding, not only of the spatio-temporal trajectory details and the numerical features deriving from them but also of the contextual semantic information; (2) different annotators might have different roles and interpretations on how to label trajectories (e.g., "is the ship fishing or not?"); (3) not only the whole trajectory might express a single behavior, very often the parts of a trajectory have to be individually labeled since different behavior may co-exist during the same journey (e.g., a vessel is first fishing then traveling to harbor). How to correctly identify the switch points from one behavior to the other is another critical issue to be solved. We believe that these issues might be alleviated by a proper trajectory annotation platform that effectively assists the user in coping with all these aspects during the semantic labeling process.

A promising approach is to build a platform supporting the annotation by exploiting concepts from Visual Analytics. The idea of Visual Analytics is to create systems that enable analytical reasoning about complex problems with the goal of making the data processing and the inferred information clear and evident for the analysis [5]. This is accomplished by integrating data processing methods with visualizations designed to assist users in making efficient decisions. We can observe that the human mind generally conveys information more effectively through visualization than only relying on textual and numerical data. Combining visualization with user interactions enables a system to explore the data from different perspectives, thus linking and combining distinct information pieces to derive new insights from the data.

Pioneering works on semantic trajectories annotations [6, 10] used a predefined set of rules established by domain experts to automatically assign the semantic labels to the whole trajectories or to segments of trajectories. Although these methods work well for many scenarios, they are not suitable in case there are no clear criteria for identifying the object behavior and/or the segment to be labeled. In this case, we need the human intervention to establish the most appropriate label for each trajectory (or trajectory segment) based on both numerical and semantic features. Recently, some works proposed methods to simplify the manual annotation task like in [9] where a web interface has been proposed to upload personal trajectories and annotate each segment with the activity performed by the user. However, in this case, all trajectory segments need to be annotated directly by the traveling user, and this becomes unfeasible when the number of trajectory segments is very high and/or the annotator does not represent the entity which performed the movement like in the case of vehicles, vessels or animals. To cope with this problem, other methods propose machine learning approaches (e.g. semi-supervised or active learning) to automatically classify trajectories into semantic labels by starting from a small set of manually annotated traces [3, 4]. All these approaches must rely on an accurately labeled dataset to reach a good classification accuracy. Therefore, there is a strong need for supporting the

Series ISSN: 2367-2005 10.5441/002/edbt.2019.58

manual annotation process which can lead to good quality annotated datasets and therefore reliable analysis findings. To the best of our knowledge, no approach combines visual analytics with trajectory processing functions to assist the user in the process of manually tagging trajectory data.

The challenge of a visual analytics trajectory annotation system is to provide efficient and effective support for the user interaction, helping the user in focussing on each specific annotation task, highlighting the features values for each trajectory point or segment and properly visually combine contextual knowledge. Specifically, the annotators need to use their domain knowledge for thinking, creating associations, and generating insights from the trajectory data. On the other hand, the system also needs capabilities for processing and aggregating trajectory data. Deciding where to set the segmentation point in a trajectory is very challenging because it will directly affect the values of the segments' features and therefore the overall labeling of the trajectory dataset. We propose VISTA as an interactive visual user interface integrating spatio-temporal processing capabilities to play an essential role in semantic trajectory annotation. With VISTA, we provide full support to the manual trajectory annotation by tailoring a visual analytics platform that guides the user in this process. We strongly believe that VISTA can significantly contribute to the scientific community in supporting the domain experts in the annotation process and produce more reliable semantically labeled trajectory datasets available for analysis.

2 SYSTEM ARCHITECTURE

The architecture of VISTA has been designed to provide solutions to the three issues introduced in the previous section, namely the immediate understanding, the different users' role and the support for the segment switch points identification.

A distinctive feature of VISTA is the possibility to handle a multi-user annotation process where the users might have different roles. VISTA supports both the creation of an annotation session (e.g., upload trajectories, contextual information, feature creation, etc) by the *session manager* and the annotation process itself by the *annotator* (e.g., user analyses a trajectory, provide partitioning positions, compare the segments, annotates a trajectory, etc).

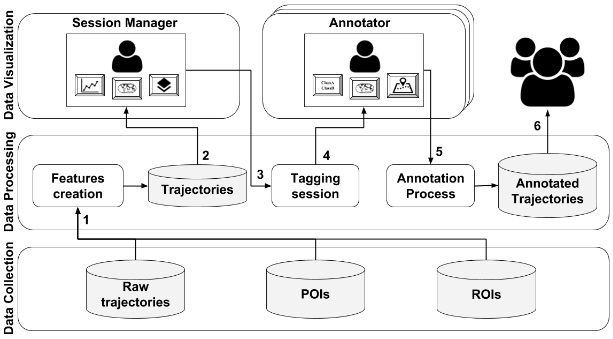

Figure 1: VISTA architecture and workflow.

The architecture and workflow overview is illustrated in Figure 1. As we can see, it is organized into three main components: (i) the data collection to handle raw trajectory and contextual geographical information like Point of Interests (POI) and Region Of Interests (ROI), (ii) the Data Processing that deal with trajectory and annotation data, and (iii) the Data Visualization to interact with the users in the processes of both creating a tagging session, detect the switch points and annotating trajectories. The workflow of VISTA to perform trajectory annotation includes six steps depicted as the numbers of the arrows of Figure 1. In the first step, the session manager is requested to set the stage for the annotation process, namely upload raw trajectories and the POIs and ROIs that are relevant to the studied domain. In the following step (Step 2), the data processing engine automatically creates numerical features related to each trajectory point, called *point features* like the distance traveled, the estimated speed, the bearing, the bearing rate, and the acceleration. The engine also calculates the shortest distances to a POIs, and detects when the trajectory points intersect with ROIs. The shapely library[1] was used to calculate the shortest distance and intersections. At this point, each trajectory uploaded by the user is stored as a document in a MongoDB[2] collection. In step 3, VISTA displays the trajectories associated to these new features to the session manager whose tasks are: (1) the data exploration for the selection of the features that are relevant for the tagging session, (2) the creation of the annotation classes (i.e. labels) that must be used in a tagging session, and (3) the invitation to the annotator users to participate in a tagging session. With a tagging session created, it is now possible for the invited annotators to start the tagging process of trajectory data. In step 4, the annotators explore the trajectory data and create the trajectory segments that must reflect the annotation classes available for tagging. Several visualization functionalities are available for the process of tagging and are detailed in Section 3. After going through all trajectories and tagging their segments with the labels (Step 5), a dataset with annotated trajectories will be available for all the users to download (Step 6).

As we discussed above, a crucial step in annotating trajectory data is to determine the parts of the trajectory where the moving object's behavior changes. Detecting such switches in the object movement behavior is challenging for an annotating user since there is a need to explore a possibly high number of features to precisely determine where and when the object behavior changed. This is done through a process usually called *segmentation*. Segmenting a trajectory means to find the partitioning points that are used to create trajectory segments, or sub-trajectories, characterized by the fact that each segment has uniform behavior respect to some criteria [2]. Once these segments have been identified, additional numerical features like average, median, standard deviations, and percentiles may be created to better characterize the behavior of the moving object in that segment (the so-called *segment features*).

3 DEMONSTRATION

The objective of our demonstration is to involve the user in the VISTA tagging experience by providing a trajectory dataset to be annotated together with semantic contextual information. We have selected two datasets: (1) 10 trajectories of vessels that should be annotated as "fishing" and "not "fishing" activity; (2) 20 trajectories of people that should be annotated with transportation means as "walking", "bike", "train", "bus", and "car". During the demo the authors will guide attendees through the whole process where the user will experience both roles, the *session manager* and the *annotator*, whose tasks and relative interfaces are detailed in the next sections.

3.1 Session Manager

The role of this user is setting the stage for the actual annotation process. This is done through four screens. In the first screen, the user is requested to create and give a name to a new tagging session or select a session that was previously created. In the second screen, the user is requested to upload raw trajectories in delimited separated file format (e.g., CSV, TSV, etc) and map the file fields to the columns representing the raw trajectory data: *trajectory_id, time, latitude, longitude*. In the third screen, the user is asked to upload POIs and/or ROIs that are relevant to the domain. Then, VISTA executes a process in the background to create the following point features for each raw trajectory point: time difference from the previous point, distance traveled from the previous point, speed, acceleration, bearing, jerk, bearing rate, and rate of bearing rate. The relative computation formulas and details can be found in [1]. The platform also will create other two point features using POIs and ROIs: (1) for every POIs layer, the platform will calculate the shortest distance to a POI on the particular layer; (2) for ROIs layers, the platform will verify if a trajectory point intersects a ROI in the specific layer. Finally, in the fourth screen, the user will create the labels that must be used by annotators and invite annotators in the trajectory tagging session by providing their emails. This sequence of actions represents steps 1, 2 and 3 of Figure 1. After this step, the annotators will receive a notification with the invitation to enter the tagging session.

3.2 Annotator

When a user receives an invitation for a tagging session, he/she can start to tag trajectories. The process of annotating trajectories is iterative and interactive, where a single trajectory is presented to the user and further explored in each iteration with the system. We recall that the two-fold objective of a tagging session is (1) to identify the segments of the trajectory with a uniform behavior, or, in other words, identify the change points and (2) actually tag the segment with the appropriate label. In VISTA, the annotator has access a dashboard providing tools to understand the behavior of the moving object, depicted in Figure 2. We observe that the main screen is divided into two interactive panels: (i) a map on the left and (ii) summary statistics on the right. The map panel visualization needs to be effective in showing the actual movement of the trajectory with point and trajectory features. For this reason, we implemented two visualization solutions to support the annotator in understanding the movement data: first, the actual moving object movement can be played, dynamically showing how the moving object performed its movement in a particular region. Second, the line colors are displayed in saturation grades of red, reflecting the value of the point feature selected on the right side of the screen; a low value is colored with a light intensity of red, and higher values are colored with a more intense red. There is an automatic interaction between the two panels: the user can select a segment and/or point features in the right panel and the relative parts in the map on the left are highlighted. Conversely, the annotator can select a trajectory point in the map, and the corresponding segment and point feature are highlighted in the right panel. On the bottom of the map, the red color legend is presented to the annotator user to have an immediate perception of what is happening between the points sequence. Inside the map and in the top left, VISTA provides some typical Geographical Information System (GIS) visualization options, such as zoom-in and zoom-out, display or hide POIs and ROIs, and change the colors of the annotation classes (e.g., fishing or not-fishing).

In more detail, the right panel provides the following options and statistics: (i) On the top, it displays a summary computed from the trajectory data with its total number of points, total distance travelled in meters and the average sampling rate between the trajectory points; (ii) at the bottom, the user may choose to visualize the data as a line chart that shows the values of the point features following the temporal order or a scatter plot where the user can try to find correlations between two point features.

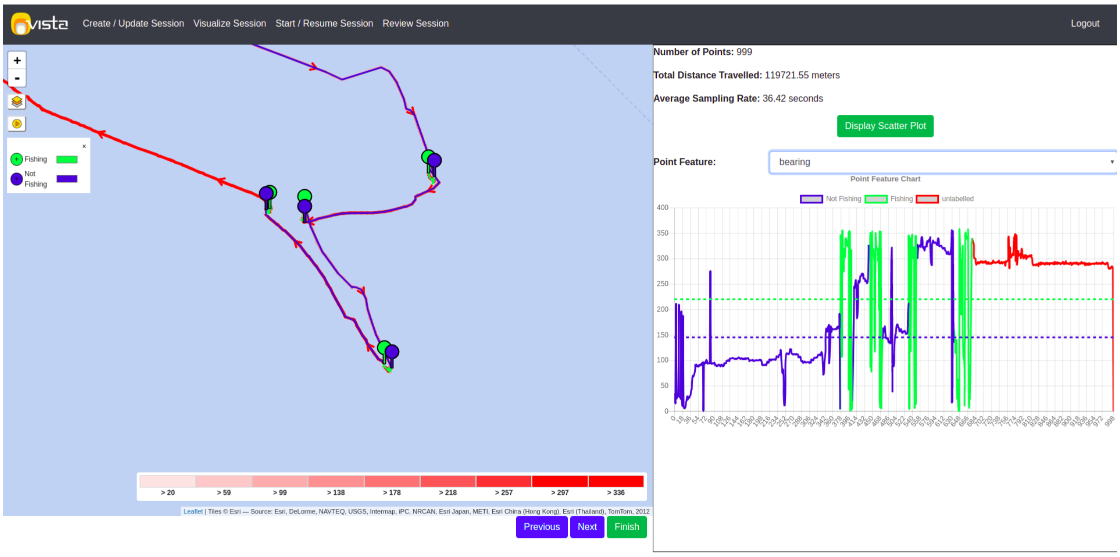
When a trajectory is shown on the screen, the annotator user is requested to provide the partitioning positions to split the trajectory into the segments representing uniform behavior to be assigned to the class labels. This is the most challenging functionality to develop since the correct segmentation is fundamental for a good quality annotation process. However, identifying the switch points is particularly difficult since many different aspects have to be considered at the same time. It is, therefore, challenging to support the user in this "multi-dimensional view" where the most crucial aspects have to be considered jointly. For this reason, we have created a drag and drop tool on the map where the user can add a new partitioning point to the screen, assign to a class label and pin exactly the switch point where to split the trajectory. By adding a new partitioning position, all the statistics regarding the classes of the trajectory have to be automatically recomputed since new labeled segments are provided. This is captured by the two panels described above. First, on the map panel, the colors of the trajectory segments change according to the class provided. Second, the colors of both the scatter plots and the line chart change to reflect the new information provided by the user. We also provide statistical measures regarding the trajectory segments and their classes. Trajectories are sent to user in a sequential way, one per interaction, which the user's objective is to segment it using the drag and drop pins provided in the left side of the panel. When a trajectory is completely annotated, the user can press the Next button on the bottom of the screen to receive a new trajectory to be annotated.

3.3 Summarizing annotations from users

When all the users conclude the annotation process, a summarizing screen (Figure 3) is created with the objective of exploring how the different users tagged the data. In VISTA, the users can confront their tagging with other annotators by exploring how they annotated their dataset and how the results of their tagging session are similar or not to the other users. The tagging session results can be compared for both point and segment features. Figure 3 shows the main screen with two panels: (1) on the left, the user is able to analyze statistics (e.g. minimum, maximum, average, standard deviation, and percentiles) of all point features available on the platform; (2) on the right, the user may want to analyze statistics regarding the segment features. For both charts, the average behavior per user and class are plotted with the objective of understanding if the users most likely agree or disagrees regarding some feature.

4 CONCLUSIONS AND FUTURE WORKS

We have proposed VISTA, an interactive tool based on visual analytics principles, supporting the users in semantically annotate trajectory data. A distinctive feature of VISTA is the support for the identification of trajectory segments and the assignment to the relative semantic label. We intend to expand this



Number of Points: 999

Total Distance Travelled: 119721.55 meters

Average Sampling Rate: 36.42 seconds

Point Feature: bearing

platform into two directions. First, we want to create a module that automatically suggests how to segment the trajectory by learning from the previous interactions with the platform. Second, we intend to improve the results comparing how the labels have been assigned by the different users, highlighting when users agree or disagrees in identifying a specific behavior of a moving object. The tool is available for testing at the URL https://bigdata.cs.dal.ca/resources.

ABSTRACT

Points of Interest (POIs) are indispensable to many modern applications, services, and products. From navigation applications, to social networks, tourism, or logistics, we use POIs to search, communicate, decide, and plan our actions. In this demonstration, we showcase SLIPO, a system prototype that addresses the limitations, gaps and challenges in integrating, enriching, and sharing POI data. Leveraging the Linked Data paradigm to effectively extract the most out of open, crowdsourced or proprietary real-world data sources, SLIPO tackles their inherent spatial, temporal, or thematic ambiguities in POI data. Hiding all Linked Data complexities in the background, SLIPO orchestrates state-of-the-art software customized for POI data integration, enabling stakeholders to increase the value of their data and relieving them from labor-intensive, manual, error-prone, and costly updates.

1 INTRODUCTION

Points of Interest (POIs) refer to physical locations of some particular interest or utility, such as restaurants, shops, hotels, sport venues, etc. They are useful in our everyday lives (e.g., navigation, social networks, tourism) as well as in various commercial domains (such as logistics, advertising, or geomarketing). A POI is minimally characterized by its *name*, a *category*, and a *location*; however, POI profiles may often be quite complex, containing composite, multi-faceted and multi-modal information. This complexity may concern extra *thematic attributes* (address, contact details, opening hours, etc.) or their *relationship* to other entities (e.g., a shop within a mall).

Integrating POI data from multiple sources to create quality-assured, enriched, updated datasets is challenging. The advent of *open* data, *crowdsourcing*, and *social media* has provided new data sources of even greater volume, heterogeneity, diversity, veracity, and timeliness. Any consistent approach towards *POI data integration* also needs to rely on robust, flexible and semantically-rich modelling of POI profiles and handling of POI identifiers, especially when dealing with cross-sector, cross-border, and cross-lingual content. The greater the *size*, *timeliness*, *richness*, and *accuracy* of POI data, the better the end product's *value*.

Motivated by the highly fragmented landscape on POI data integration, curation and update of missing, out-of-date, or inaccurate information, we propose a pragmatic, yet highly effective approach. In the context of the SLIPO project[1], while maintaining interoperability with de facto POI standards, we opt to apply de jure *Linked Data* standards (RDF[2], OWL[3], GeoSPARQL[4]) for the inner workings of data integration, also offering capabilities to harness open POI data sources (e.g., OpenStreetMap). Linked Data technologies are ideal for handling the inherent geospatial, thematic, and semantic ambiguities of POIs. To this goal, we have built an open-source prototype system with a complete suite of software tools and services to orchestrate iterative POI *integration workflows* over multiple POI datasets, across all stages of the POI data lifecycle (transformation, linking, fusion, enrichment). Stakeholders should not adapt their current processes to collect, update, or roll-out POIs across services and products, since SLIPO hides all Linked Data complexities, and allows them to focus on their task: increase the value of their data.

The paper is structured as follows. In Section 2 we discuss the challenges in POI data integration. Section 3 overviews the data integration lifecycle as applied in SLIPO. Section 4 outlines the current status of our prototype. Finally, Section 5 showcases how a typical POI integration scenario can be handled in SLIPO.

2 ISSUES IN POI DATA INTEGRATION

POI data are by nature *semantically diverse* and *spatiotemporally evolving*, representing different entities depending on their geographical, temporal, and thematic context. Due to their use in various domains and contexts, POI-related information is typically found in diverse, heterogeneous sources. Assembling such pieces of information together is seriously hindered by the lack of common POI identifiers and data sharing formats. In addition, stakeholders also have to cope with volatile data in a POI profile, e.g., its facilities, opening hours, prices, events, etc.

Since integrating POI data with current approaches remains labor-intensive and does not scale, most stakeholders restrict their focus on domain-specific or small-sized datasets. But at a larger scale, all this complex process raises several cases of *ambiguity* that may severely hinder data integration of POIs. Addresses, coordinates, and place names are equally used throughout applications as pseudo-identifiers; but practice shows that they fail to effectively disambiguate POIs. Next, we outline these challenging issues in POI data integration.

i) Geospatial ambiguity:

- *Same POI, differing coordinates.* Locations of the same POI among different datasets almost never match exactly due to varying data collection procedures (e.g., field work, map digitization, GPS readings, crowdsourced markers).
- *Same POI, different shapes.* Although POIs are usually abstracted as point locations, they usually have a *shape* with a spatial extent (e.g., a building). But such detailed geometries are only an approximation, and their accuracy may vary significantly.
- *Different POIs, same location.* Multiple POIs may be co-located within a larger structure (e.g., multi-storey building) or a facility (e.g., shops in a mall). If abstracted as *points*, those distinct entities end up superimposed at the same location.
- *POI within another POI.* If POIs are represented by detailed *shapes* (e.g., polygons), they may exhibit topological (e.g., containment) relations. Sometimes, it is not clear whether a certain shape is a separate entity or merely a *part of* the larger one.

[4] https://www.opengeospatial.org/standards/geosparql

Series ISSN: 2367-2005 10.5441/002/edbt.2019.59

ii) Temporal ambiguity:

– *Same POI, new location.* Location of a POI may change over time, e.g., a shop has moved to another (nearby?) place.
– *Defunct POI.* A POI may still be displayed on a map, a city guide, a navigation device, etc., but in the meantime may have stopped its operation or completely ceased to exist.
– *Same POI, change of type.* Often, the type of a POI or the operations, services and facilities it offers may change over time, e.g., a café turning to a restaurant or bar.

iii) Semantic ambiguity:

◇ *Same POI, different names.* POIs involving buildings, localities, etc. are often referred to by multiple names, in different contexts or time periods (e.g., "Acropolis/Parthenon", "Saint Petersburg/ Petrograd/ Leningrad"). The most typical case concerns *multi-lingual names* across datasets, possibly in different alphabets (e.g., "Acropolis" transcribed in Arabic, Cyrillic, or Chinese). Other textual characteristics can raise more concerns, especially *addresses* (e.g., renamed or renumbered streets).
◇ *Different POIs, same name.* It is relatively easy to disambiguate multiple locations or POIs with the same name when the spatial context is quite different (e.g., hotels with the same name in different cities). Instead, it can be quite challenging to infer what is the actual entity in the same spatial context (e.g., "Hyde Park" may refer to the park, to a nearby café, or to a hotel).
◇ *Same POI, different types.* Besides names, there is much heterogeneity in the use of *classification schemes*, category names and tags to semantically annotate and classify POIs. Each source typically employs its own vocabulary of categories and a hierarchy to classify POIs. Sometimes, user-defined *tags* may be assigned to POIs to describe them either instead of or in addition to predefined classification schemes.

All this makes it especially challenging and cumbersome to integrate and harmonize POI data from different sources. In SLIPO, our approach places particular emphasis to resolving ambiguity, as well as in coping with differing POI models, non-common identifiers, complex geometries, diverse attribute schemata, etc., by employing Linked Data technologies as explained next.

3 THE POI DATA INTEGRATION LIFECYCLE

In this Section, we provide an overview of the POI data integration *lifecycle*, as implemented in SLIPO. The underlying idea of our proposed system is to address the POI data integration challenges in the Linked Data domain, which is ideally suited to handle the inherent geospatial, thematic, and semantic ambiguities of POIs. Hence, POI data assets must first be transformed into RDF, so that POI profiles can be interlinked, fused, and enriched in successive steps. This is achieved through a virtuous cycle implementing iterative workflows (Figure 1) that progressively increase the size and/or the quality of the original POI data.. Next, we outline the processes and software tools involved in each step.

Transformation. In order to be handled in the Linked Data domain, POI assets from heterogeneous data sources must be transformed into RDF triples conforming to a common *OWL ontology*[5] for POI profiles. To provide a scalable and efficient transformation facility (shown as a thick red arrow in Figure 1), we extended our open-source software TripleGeo[6] to enable transformation of POI datasets from a variety of de facto geospatial formats into RDF triples with minimal overhead. Although TripleGeo is a general-purpose, spatially-aware ETL tool [3], we have included specific support for transforming POI data. This was possible through adaptable, configurable, and reusable mappings from existing attribute schemata into our POI ontology, and also supporting classification hierarchies in assigning categories to POIs. As TripleGeo inherently handles all geometry types and established coordinate reference systems, it can cope with the heterogeneity of POI formats and representations. Once data integration is complete, SLIPO introduces *reverse transformation* of the resulting integrated RDF data back to conventional POI formats (at the bottom in Figure 1), so that they can be exploited by existing products, systems, and services.

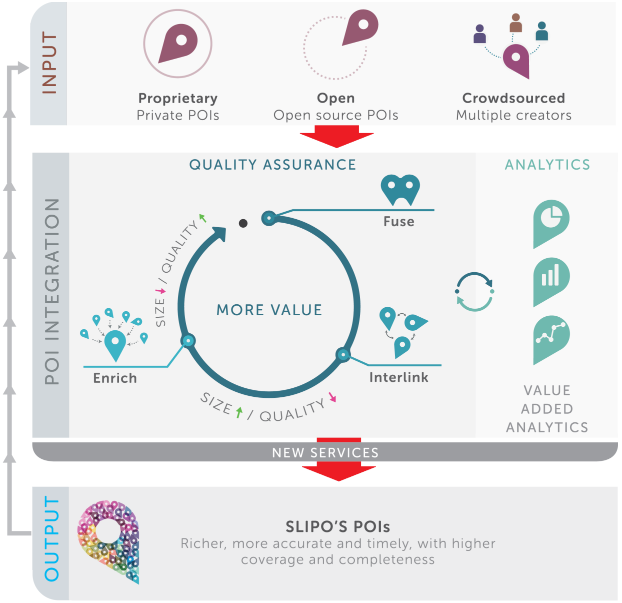

Figure 1: The POI data integration lifecycle.

All transformed RDF data are fed to a step-wise workflow abstracting a *virtuous circle*. This iterative cycle first increases the *size* (i.e., coverage, completeness, and richness) of POI data, and then refines them to increase *quality* of POIs by fusing intermediate results. For example, an expert user can repeatedly introduce additional data sources, apply different rules, etc. This iterative workflow involves the following stages:

Interlinking. This step is applied across the transformed RDF datasets coming from different sources in order to discover pairwise relations among real-world POI entities. We make use of Limes [5], a state-of-the-art interlinking software[7] that exploits the semantic structure of RDF data, textual similarities, proximity of geospatial representations, etc. In SLIPO, this actually concerns POI *deduplication*, as we wish to identify same real-world POIs based on user-specified metrics and thresholds. The output is `owl:sameAs` links between matching POI entities, which tackle the lack of common identifiers between POI entities across data sources, thus enabling their management at later stages of the integration process.

[5] Available at https://github.com/SLIPO-EU/poi-data-model
[6] Software available at https://github.com/SLIPO-EU/TripleGeo
[7] https://github.com/dice-group/LIMES

Enrichment. To produce enriched metadata and contextualize POI profiles based on information retrieved from external, third-party RDF data sources, we make use of Deer [4]. This software[8] identifies external (structured or unstructured) information related to POIs and creates extra properties. For instance, a POI profile can be enriched with opening hours, price ranges, event timelines, etc., available in SPARQL endpoints such as DBpedia[9]. It also discovers semantic interrelations between POI entities and other resources (e.g. areas, events, time), such as `partOf` relations (e.g., a shop is part of a shopping mall) or `occursAt` relations (e.g., events taking place at a certain venue).

Fusion. This stage consolidates linked POIs and their properties. From two linked POI entities it produces a unified representation, which is more complete, concise and accurate than the individual initial entities. In supporting scalable and quality-assured fusion of large POI datasets, we employ our fusion framework Fagi [1]. In SLIPO, we adapted and extended Fagi[10] with POI-specific similarity functions, learning mechanisms, and fusion actions. Such rules guide how POI properties will be fused (e.g., choose one, merge both) according to specific criteria (e.g. more complex, more timely) specified by stakeholders.

Value-Added Analytics. Having these integrated and enriched POI datasets it is then possible to provide added value services that involve *clustering* and *association discovery* among POIs. In SLIPO, we make use of Sansa [2], a software suite[11] that offers several large-scale aggregation strategies and predictive analytics, precious in geomarketing, tourism, logistics, etc.

As already mentioned, throughout this lifecycle we want to ensure that each phase produces correct and accurate results, taking into account dataset-specific and use-case-specific quality indicators and rules, including manual validation and authoring. Several indicators for such *quality assurance* can be used, most of them already adopted by industrial vendors that manage and exploit POIs: size, timeliness, coverage, accuracy, etc.

Last, but not least, we have implemented a service that allows users to track the integration and *evolution* of POI information across time and between different versions. This includes mechanisms for recording *provenance* by tracking the full history of changes per POI up to the current values of its various attributes. A graphical interface assists in visualizing and navigating through all available information, enabling users to intuitively explore where and how a POI actually changed across the various stages in the workflow.

4 THE SLIPO PROTOTYPE SYSTEM

We have been implementing a comprehensive, open-source software prototype that integrates tools for transforming, linking, fusing, enriching, and analyzing linked POI data aiming to support stakeholders in all stages of the POI data value chain. The SLIPO system[12] consists of the following main modules:

- *SLIPO Toolkit*: This is the collection of individual software components (Section 3) for transformation (TripleGeo), interlinking (Limes), fusion (Fagi), enrichment (Deer) and analytics (Sansa). Any tool can either be installed locally or invoked as part of the SLIPO workbench and APIs functionality.
- *SLIPO Workbench*: This web application allows users to orchestrate the Toolkit components and thus implement POI data integration workflows (like the one depicted in Figure 2) in a coherent, user-friendly, and flexible manner. It provides advanced capabilities for (a) uploading, searching and managing POI datasets in several formats, (b) designing, persisting and managing data integration workflows for POI datasets based on the features provided by the SLIPO Toolkit, (c) scheduling and monitoring the execution of data integration workflows, and (d) visualizing the results of such executions.
- *SLIPO APIs*: This is a collection of RESTful HTTP programming interfaces for invoking SLIPO Toolkit component functionality and integrating it into third-party systems. APIs only support the invocation of simple atomic functions (e.g., POI transformation). For composite operations, the Workbench web application must be used. Both SLIPO Workbench and APIs are exposed through the same web application server.

The SLIPO system is deployed within several virtual machines on top of the Synnefo cloud stack[13]. In the back-end, our prototype implements a workflow engine that executes data integration workflows and a scheduler for initializing workflow executions. The workflow engine and the SLIPO Toolkit components are deployed over a cloud infrastructure. Workbench and APIs exchange messages with the scheduler to execute workflows. A task is executed either in-process locally on the scheduler host, or remotely using Docker containers. Each component is deployed as a Docker Image and is responsible for providing a scalable instantiation for the requested operation (e.g., TripleGeo for transformation). A Toolkit component capable of partitioning its input and merging its output can also scale to multiple Docker containers. The scheduler only controls the total amount of resources allocated to a container, enforcing CPU/memory quotas derived from component-specific requirements and input size.

Thanks to its modular, service-oriented architecture, SLIPO offers stakeholders the option to directly use the provided functionalities following a Software-as-a-Service paradigm. Alternatively, they are able to select specific tools to customize, extend and incorporate in their own POI data management workflows using APIs according to their specific needs and requirements.

5 DEMONSTRATION

In this demonstration, we will showcase a data integration workflow using the SLIPO Workbench. This workflow accepts input POI datasets in a given geographical area (e.g., an island, a city, or a country). Data sources generally differ in schema, content, and quality; some concern *crowdsourced* information extracted from an open database (like OpenStreetMap[14] or GeoNames[15]), but others may be *proprietary* supplied by a commercial vendor.

Using the SLIPO Workbench, we will demonstrate how a user can define data integration workflows that deliver a single dataset in just a few minutes. Orchestrating the various tools into an executable workflow (like the one in Figure 2) can be carried out very quickly thanks to readily available profiles we have prepared for several common POI datasets. Such a workflow can be easily setup using drag and drop actions without the need to write any code, by only a basic parametrization per step (Section 3). This particular workflow first involves transformation of the input datasets. After discovering links between them, it fuses their

POI data integration in Corfu

A user friendly name

Description

POI data integration in Corfu based on datasets obtained from OSM & a Commercial data vendor

A short description of the data integration process

Figure 2: Designing a POI data integration workflow in the SLIPO Workbench application.

properties according to user-specified rules and finally enriches the integrated result with external sources (e.g., DBpedia).

After executing such a workflow, the unified output dataset will be enhanced with information from all input datasets:

- The output dataset will contain *more POIs*. Starting with a base dataset (one of the input datasets), POIs missing from it will be complemented with information from the rest.
- Geometry representations can get a *more detailed shape*, e.g., polygons obtained from OpenStreetMap can replace (or complement) the original point (lat/lon) locations of certain POIs.
- *Extra thematic attributes* will be derived in the integrated dataset, by bringing together information (e.g., fax numbers, opening hours, links to photos, multi-lingual names) across the original data sources.
- Attribute values per POI will be *more accurate* and complete, e.g., missing telephone numbers can be filled or updated after checking against all available input.

We have prepared a short video[16] that demonstrates such a scenario on Corfu Island with a commercial POI dataset (*GET*)[17] enriched from OpenStreetMap (*OSM*). The map in Figure 3 shows how integration results (POIs depicted in blue circles or blue polygons) supersede by far and enhance the original information of the base dataset (*GET*) shown with red stars. Also, thematic properties per POI are substantially enriched with more attributes, while missing values in the base dataset are properly updated. Improvement in quality can be tracked graphically per individual POI by inspecting how it evolved along the integration progress, but also through statistics (attribute gain, confidence, etc.) estimated over the final dataset.

Overall, we believe that this demo will offer more insight not only about the challenges, but also regarding the benefits of POI data integration using SLIPO. As we continue our efforts to enhance and further develop our software, we expect rapid uptake of our innovations by stakeholders in a production setting without affecting any operations and processes already in place.

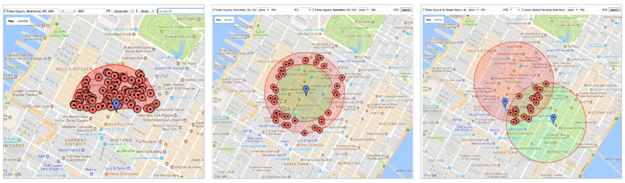
ABSTRACT

We propose a novel query language that can express complex spatial queries in a concise and intuitive way for map search. The proposed language can express conditions on the range, direction, and time distance within their spatial search queries. In this language, we introduce several spatial operators, such as “space character” operator which is used to represent the geographical distance between matching objects in a concise and intuitive way as well as arithmetic and directional operators which enables the combination and manipulation of spatial areas. We also show how a map search system supporting this query language can be implemented, and describe several applications created using this system to highlight how the query language can be put into practice. These applications include a web interface which allows developers to embed a function of spatial search by our query language into their systems. In addition, we developed a mobile Android application that allows nonprofessional users to easily search for nearby venues and routes by using the proposed query language. Finally, we outline the results of a study carried out to evaluate the potential usefulness of our proposed search system.

1 INTRODUCTION

In map search systems, keyword-based queries are widely adopted due to their ease of use. Such queries are however inadequate when more complex requests are needed. For example, consider the case where a software tool would need to be developed to help identify appropriate locations for real estate development. Such a software needs to deal with search requests which contain multiple constraints and spatial conditions. For instance, those interested in constructing a family-friendly apartment building would search for vacant locations that have many schools and playgrounds within traveling distance, but are far enough away from inappropriate locations or noisy public spaces.

In map search systems with simple keyword-based queries, such a search task requires multiple query transactions by user operations. For example, to find a good apartment for a family, the transactions need to (1) search for apartments by using a keyword query, (2) also identify schools on the map, (3) limit the query result to those within 4km from the found schools, and (4) also exclude those which are within 200m from some inappropriate locations. The same is true for various complex requests such as “Finding all the restaurants located between two famous tourist landmarks” (when developing an application for tourism) or “Finding all the shops located next to parks in a city” (for location-based recommender systems). As shown in these examples, it is difficult to process complex search requests using simple keyword-based queries. Systems only supporting such keyword-based queries require multiple steps including non-textual interactions to process them.



(a) ^ operation (b) - operation (c) * operation

Figure 1: Examples of map search using spatial operators.

On the other hand, there have been much research on spatial logic or algebra. In a spatial database of PostGIS[1], the spatial search task with location queries can be run in SQL, and they can represent complex spatial conditions in queries, but they require users to learn and understand the progrmming-language-like syntax, and as a result, they are too complicated for general users in many applications. They are, therefore, impractical for the use in such systems.

The goal of this research is to design a simple spatial query language which can represent such complex queries within a single query statement with a concise, and more intuitive syntax so that users can easily specify complex queries. Our language uses 10 spatial operators to represent conditions on directions, ranges, angles, and time distance, which allow users to incorporate spatial conditions and manipulation of spatial areas within their keyword-based-like queries. Fig. 1 shows examples of map search carried out by queries including spatial operators in our language, such as ([^] [−] [*]). For example, Fig. 1 (c) shows the result of a query (“my house”␣0.5km␣“pizza parlor”) * (“friends house”␣0.5km␣“pizza parlor”).

2 RELATED WORK

As explained in Section 1, there have been much research on spatial databases based on region algebra or region logic. However, most current commercial location-based services such as Google Maps or Bing Maps are designed mainly to help general users to execute two types of simple tasks: (1) find certain places and locations within a specified geographical area and (2) find the best route (e.g., shortest distance, most economical) between two given locations. Recent academic research in this domain also mainly focus on similar problems, such as locating comfortable, aesthetically pleasing or safe routes [2] and personalizing the search results by identifying locations which better match the latent interests of users [5].

Because most of the current commercial systems are focusing on general users executing these types of tasks, they use simple keyword-based queries instead of complicated query languages. For example, if users need to search for restaurants in London, they would simply input a query such as "Restaurants in London". For users who need more complex and precise search requests, however, such search systems are inadequate. Although various API systems[2] [3] have been created to provide access to the more advanced features of the location search systems, they are often limited to single-process tasks (finding locations within a specific distance, geo-coding a specific location name, etc.). Therefore, in this paper, we propose a novel query language to enhance the existing API systems, which allows users to express conditions on distance, space and time distance towards objects matching the query keywords through the use of spatial operators.

While the use of operators in keyword-based queries for map search is not common, the use of operators in keyword-based queries can be found in other domains. In document search, proximity operators have been proposed as a way to limit search results to those that contain the keywords in a specific order or within a specific distance [3]. Also in video database domain, Pradhan et al. [4] proposed operators which allow users to represent constraints on pairs of matching objects to be joined. In graph database domain, Cypher[4] is a declarative query language that allows users to state what actions they want performed upon their graph data without requiring them to describe (or program) exactly how to do it.

3 THE SPATIAL QUERY LANGUAGE

A description of our proposed spatial query language is described in this section. Overall, there are two main rules which are used to define the syntax for a spatial search unit in our query language.

Rule 1: The syntax of the most primitive unit of spatial queries is defined as follows: "A␣spatial length␣α" A and α are keywords, with A denoting the location of the origin for the spatial search for the object with the property α. It is permissible to either denote the spatial length by using a unit distance (i.e., 200m, 3 minutes) or by using continuous spaces. When continuous space is used, the spatial length would represent the N nearest locations with the property α, where N is represented by the number of continuous spaces.

(Example) : A␣800m␣α denotes a query statement to identify the α objects which exists inside the region 800m from the origin point A.

(Example) : A␣␣␣α denotes a query statement to identify the nearest 3 α objects from the origin point A.

Rule 2: The keywords (e.g., A and α) used in the primitive unit of the spatial query would be encapsulated within a double quotation mark (e.g., "Tokyo tower" or "Grand Central Terminal, New York" for A or "pizza shop" or for α).

In addition, various spatial, directional and distance operators can be used to impose conditions when conducting a spatial search.

Rule 3: Each primitive spatial search Unit can be combined with other units through the use of spatial, directional and distance operators in a mathematical equation format.

(Example) : (A␣800m␣α) + (B ␣300m␣α)

3.1 Spatial Operators

The standard set operators can also be used as spatial operations for the query unit defined previously. These include the union [+], difference [-], and intersection [*]. Users can use such operations to manipulate the spatial region they wish to search into. Examples of queries including these operators are as follows:

Union calculation (Ex.1) : (A␣3km␣α)+(B␣3km␣α) denotes the union of the spatial region *within* 3km from point A AND the spatial region *within* 3km from point B (see Fig. 2 (a)).

Difference calculation (Ex.2) :(A␣3km␣α)-(B␣3km␣α) denotes the spatial region *within* 3km from point A which is NOT *within* 3km from point B (see Fig. 2 (b)).

Intersection calculation (Ex.3) :(A␣3km␣α)*(B␣3km␣α) denotes the spatial region that is *within* 3km from point A which is ALSO *within* 3km from point B (see Fig. 2 (c)).

All set operators (+, -, *) can be used to search for objects with the properties identified in the query unit. For example, the aforementioned (A␣3km␣α)*(B␣3km␣α) query would search for objects with the property α which is located within the spatial region that is the result of the intersection between 3km from points A and B.

3.2 Directional and Distance Operators

Table 1 shows the 7 spatial operators which can be used to further denote distance and direction within our spatial query. Examples of four expressions which use these operators are described below:

Distance operation (Ex.4) : A␣3km␣α

[2] https://www.microsoft.com/en-us/maps/choose-your-bing-maps-api
[3] https://cloud.google.com/maps-platform/
[4] https://neo4j.com/cypher-graph-query-language/

retrieves the objects α which are *within* 3km from point A (Fig. 2(d)).

Within operation (Ex.5) : A␣*3km␣α

retrieves the objects α that are 3km *away from* point A (Fig. 2 (e)).

Direction operation (Ex.6) : A␣^3km␣α

retrieves the objects α which are to *the north* of, and within 3km from, point A (see Fig. 2 (f)).

Angle operation (Ex.7) : A␣3km@90␣α

retrieves the objects α which exist *within* 3km in the 90 *degree* counterclockwise direction from point A (see Fig. 2 (g)).

3.3 Range, Size, and Time Operators

Our proposed spatial query language also includes a variety of range operators which allows users to more accurately specify the desired search range within their query (see Table 1). For example:

Range operation (Ex.8) : A␣[1km-3km]␣α

retrieves the objects α in the region from 1km to 3km from point A (see Fig. 2 (h)).

In addition, size [$] and time operators [#] can be used to formulate search queries. The size operator $ extracts the size of the corresponding property of object α and uses it as a unit of measure (i.e., 1 city block = 0.5km). The same is true for time operations depend on the context (i.e., using A␣#3min to find venues which are 3 minutes walking distance from point A, when a user selects a "walking" direction).

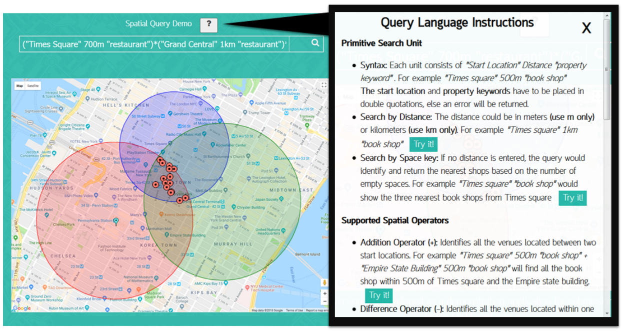
4 SPATIAL SEARCH SYSTEM

In this section, we explain the structure of our search system. The system consists of three main components: (1) an Input/Output component that processes user requests and outputs them to the appropriate format; (2) an interpreter component that parses and processes queries and (3) the data processing program component to link the search system to appropriate data sources.

Users of our system would send an HTTP request to the server with details of the spatial query as parameters. The query specified by the client is then passed to the interpreter and the data processing components. These components would parse the query, process the request and send the results back to the Web In/Output Processing component which would transmit the results back to the client as an HTTP response in a data format such as JSON or XML.

The role of the interpreter component is to process the spatial operators sent as the request. This component consists of a query parser, a spatial data converter, and a spatial data calculator. For the parser, the role is to analyze the user query and determine the appropriate operations and procedures to process it. For example, the following query: (A␣^3km␣α) + (B␣^3km␣α) would be processed by the parser into the following steps: Var1= A␣^3km␣α (step 1), Var2= B␣^3km␣α (step 2), and Result=Var1+Var2 (step 3).

These steps would then be processed by the interpreter. Each spatial variable is sent to the data converter to convert the elements (such as A␣^3km or B␣^3km) in the query to spatial regions which represents the correct distribution of those elements. The conversion program would access information provided by the data processing component to calculate the appropriate regions. For example, when processing the element "A␣^3km␣shops", the data processing component would calculate the geographical location of point A as well as the geographical locations of shops within a 3km radius. After the data has been converted, the spatial operators are then processed. For example, if the request query contains the intersection operator [*], it would calculate the region which is the overlap between the converted A␣3km and B␣3km regions. After all the calculations have been completed, the result is sent back to the client in the appropriate data type (JSON or XML etc.) as specified by the data processing component.



Spatial Query Demo ?

("Times Square" 700m "restaurant")*("Grand Central" 1km "restaurant")*

Query Language Instructions X

Primitive Search Unit

- **Syntax:** Each unit consists of *"Start Location" Distance "property keyword"*. For example *"Times square" 500m "book shop"* **The start location** and **property keywords** have to be placed in double quotations, else an error will be returned.
- **Search by Distance:** The distance could be in meters **(use m only)** or kilometers **(use km only)**. For example *"Times square" 1km "book shop"* Try it!
- **Search by Space key:** If no distance is entered, the query would identify and return the nearest shops based on the number of empty spaces. For example *"Times square" "book shop"* would show the three nearest book shops from Times square Try it!

Supported Spatial Operators

- **Addition Operator (+):** Identifies all the venues located between two start locations. For example *"Times square" 500m "book shop" + "Empire State Building" 500m "book shop"* will find all the book shop within 500m of Times square and the Empire state building. Try it!
- **Difference Operator (-):** Identifies all the venues located within one

Figure 3: Spatial query language demo application [5].

A prototype of the search system engine was implemented as a RESTFUL web service using nodeJS. The current system supports spatial map search, with the input being the requested as a spatial query (an HTTPS GET request) and the output is an array of locations which match the spatial query (returned using the JSON data format) together with details such as the name of the place and the address. The equation expression within the spatial query was parsed using the Shunting-yard algorithm. Google Maps API was used in the data processing proportion to identify the various locations specified in the primitive spatial query unit (i.e., "times square") and their geographical positions. The system could also later be easily adapted to utilize other data sources such as Open Street Map data or a customized SQL database as well.

5 DEMONSTRATION APPLICATIONS

To highlight how the system could be useful in practice, a number of web applications were created which utilized our proposed spatial search query language and would be shown during the demonstration. The first application was a web interface for our search system engine which users could use to test the query language or search for locations using spatial equations[3]. Users would be able to use the spatial, range and directional operations described in Section 3 as well as mathematical expressions such as brackets to compose their search queries. After clicking the search button, the system would send the user's query to the search system server and would then render the search results received from the server onto the map. For example, Fig. 3 shows the results of the query: (("Times Square"␣700m␣"restaurant")*("Grand Central"␣1km␣"restaurant"))*("Pennsylvania station"␣1km␣"restaurant"), which aims to identify all restaurants located within 700m of Times Square and 1km from Grand Central and Pennsylvania station. One potential use-case for such a query is for example to identify potential meeting places for three users based on their starting locations (For example, when one user works near Times Square and the other near Grand Central and the final near Pennsylvania station and the system

[5] http://yklab.kyoto-su.ac.jp/~sakata/spatialQueryDemo

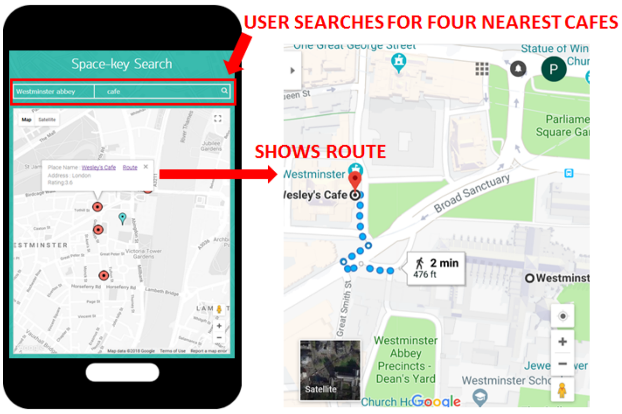


Figure 4: Space-key search application for novice users.

would need to find a restaurant that is equally near to all three of their workplaces for them to meet for lunch). The web interface system also provides an instruction page where the various operators in our query language are explained and a number of examples shown (see Fig. 3). Users could click on the "try it" button to examine the search results of the examples and could also freely modify the example equations.

Furthermore, another application which utilized our proposed query language (only using the "space-key" for a more simple and intuitive search) would also be shown during the demonstration. This application was conceptualized by looking at how non-professional common users generally used location-based mapping services. Although route navigation was a commonly used feature, users also generally used location-based services to quickly identify different types of nearby venues and then find out how they could travel to such locations. Therefore, we developed an android application ("space-key search" application) which utilized the primitive unit of our spatial query language to allow users to search for nearby venues (users are able to search for nearby locations using only the space-key). For example, the user would enter the query "Current Location␣␣␣␣␣Restaurants", to find the four nearest restaurants to them on auto adjust map zooming (see Fig. 3). Clicking on the markers would show details of the venue (the address, review scores etc.) as well as a link with the details of the route to the store. The application itself could be downloaded from Google play store[6]. A mobile web version of this application [7] was also developed for evaluation and demonstration purposes (Fig. 4 shows screen-shots of the applications). A demonstration video of the applications discussed in the paper which would be presented at the conference could be viewed from the following link [8].

6 USER STUDY

A user evaluation study was also carried out to evaluate the potential usefulness of our proposed query language. The main aim was to determine whether such an equation based query language would be feasible for developers to learn and use. 15 students from a university-level computer science course were recruited and asked to carry out a series of location search tasks. Each participant was asked to use both our proposed query language through the web interface system which was developed (spatial language condition) as well as through the Google Maps system (Google map system) to complete 5 search assignments. Each search assignment consisted of a task to search for places (e.g., pizza parlors) near a specific location (e.g., The White House). For example, one task consisted of trying to find the number of pizza parlors located within 500m of Times Square. In another task, participants were asked to find the number of pizza parlors located within 700m of Times Square which is also located 1000m from Empire State Building. Written instructions and examples were provided to help participants complete the tasks and introduce the various spatial operators. An objective measurement of performance was obtained by measuring the time users spent on each task. To measure subjective user experience, the System Usability Scale (SUS) was used [1], which involved the rating of perceived effectiveness, efficiency, and satisfaction.

Overall, participants rated a higher SUS score for the spatial language condition (Mean=70.17, SD=13.09) than the Google map condition (Mean=24.46, SD=10.61) (t(13)=7.24, p<0.001)). In addition, participants were able to complete the tasks using less time (seconds) in the spatial language condition (Mean=82.27, SD=28.18) then the Googlemaps condition(Mean=180.86,SD=49.25) (t(13)=-8.219, p<0.001). Therefore, it seems that at least for search tasks which involve the combination and manipulation of spatial regions, the proposed map search system could indeed be useful.

7 CONCLUSION

In this paper, we proposed a novel query language for spatial search which can be used to express complex queries in a text equation format. We implemented a prototype of our proposed system and developed two applications (a web based application and a mobile application) to showcase how the query language could be put into practice. In addition, we conducted a user study, The results of which highlights the potential usefulness of our query language.

In the future, we look to expand our query language to other search domains such as text and video search. Although we have shown how our language could be used in map search, our proposed query language could easily be applied to spatial search within documents and videos as well. For example, a query searching for text within a document that contains the word "B" and is within 5 sentences from the word "A" is expressed by "A␣5sentences␣B".

FaiRank: An Interactive System to Explore Fairness of Ranking in Online Job Marketplaces

Ahmad Ghizzawi[1], Julien Marinescu[2], Shady Elbassuoni[1], Sihem Amer-Yahia[2], Gilles Bisson[2]
[1]The American University of Beirut (Lebanon), [2]Univ. Grenoble Alpes, CNRS, LIG (France)
[1]{ahg05,se58}@aub.edu.lb, [2]firstname.lastname@univ-grenoble-alpes.fr

ABSTRACT

We demonstrate FaiRank, an interactive system to explore fairness of ranking in online job marketplaces. FaiRank takes as input a set of individuals and their attributes, some of which are *protected*, and a scoring function, through which those individuals are ranked for jobs. It finds a partitioning of individuals on their protected attributes over which fairness of the scoring function is quantified. FaiRank has several appealing features: (1) It can be used by different users: *the auditor* whose role is to monitor the fairness of ranking in a job marketplace, *the job owner* seeking to examine the influence of a scoring function and its variants on the ranking of candidates for a job, and *the end-user* who wants to assess the fairness of jobs on different marketplaces; (2) It is able to quantify fairness under different data and process transparency settings: when some attributes are anonymized and when only the ranking (and not the scoring function) is available; (3) It is interactive and lets its users explore different scoring functions and examine how fairness evolves; (4) It is generic and provides the ability to quantify different notions of fairness. Our demonstration will provide attendees with several scenarios for fairness of ranking in job marketplaces to experiment with and acquire an understanding of this important research question and its impact in practice.

1 INTRODUCTION

Freelancing marketplaces have become an online destination to find a temporary job. The ranking of individuals on platforms such as Qapa and MisterTemp' in France, and TaskRabbit and Fiverr in the USA, naturally poses the question of fairness. Fairness in ranking has recently received great attention from the data mining, information retrieval and machine learning communities (See for instance [1, 4, 6, 9, 10]). The most common definition of fairness in decision making was introduced in [2, 11] as *demographic parity*, and formalized in [3] as *group unfairness*. This definition captures the unequal treatment of a person based on *belonging to a certain group of people* defined using protected attributes such as gender and ethnicity. For instance, in the French Criminal Law (Article 225-1), 23 such attributes are listed as discriminatory.[1] The exact formulation of fairness varies and the purpose of FaiRank is to explore different formulations and unveil their impact on individuals.

User Roles. FaiRank appeals to different users. *The auditor*, whose role is to monitor the fairness of ranking in a marketplace, can use FaiRank to examine different jobs on that marketplace and quantify their fairness. *The job owner*, who wants to study the behavior of a scoring function and its variants, can use FaiRank to understand their impact on the ranking of individuals, and choose fairest one. Finally, *the end-user*, who is being ranked, can use FaiRank to assess the fairness of jobs on different marketplaces and make an informed decision.

Positioning. Most previous work on group-level fairness have either assumed that groups are pre-defined [9] or that they are defined using a single protected attribute (e.g., males vs females or whites vs blacks) [5]. FaiRank extends prior work to examine groups of people defined by *any combination of protected attributes* (the so-called *subgroup fairness* [6]). The scoring function yields one histogram per group as a score distribution. We use the Earth Mover's Distance (EMD) [8], a measure commonly used to compare histograms, to quantify the difference between score distributions across groups. The intuition is that if score distributions between groups differ significantly, the scoring function treats individuals in those groups unequally. This allows exploring different fairness formulations in FaiRank as any aggregation function over pairwise distances of score distributions in groups (highest average, lowest variance, etc.).

Since we do not want to focus only on pre-defined groups to quantify fairness, we must exhaust all possible ways of partitioning individuals into groups based on their protected attributes. This would capture cases where a scoring function treats males and females equally but is unfair to older African Americans compared to younger White Americans for instance. To examine all groups under different fairness definitions, we formulate an optimization problem as finding a partitioning of the ranking space, i.e., individuals and their scores, that exhibits some aggregation over pairwise partitions (e.g., the highest average EMD between partitions, the lowest average, the highest variance, etc.). Exhaustively enumerating all groups is exponential in the number of values of protected attributes. Therefore, to enable interactive response time, FaiRank relies on an efficient heuristic algorithm. At each step, the algorithm greedily splits individuals using the *most unfair* attribute according to the fairness definition. This local condition is akin to the one made in decision trees using gain functions [7]. The algorithm stops when there are no further attributes left to split on or when the current partitioning of individuals exhibits more unfairness than it would if its partitions were split further.

Data and Function Transparencies. In practice, data about individuals, i.e., their attributes, or the scoring function itself, may not be available. We integrate FaiRank with the k-anonymization ARX tool[2] and explore fairness for anonymized datasets. When the function is not available, FaiRank builds histograms using ranks of individuals rather than actual function scores.

Demonstration. Our demonstration combines the features of FaiRank to help attendees explore fairness of ranking in online job marketplaces and its impact in practice. It also sheds light

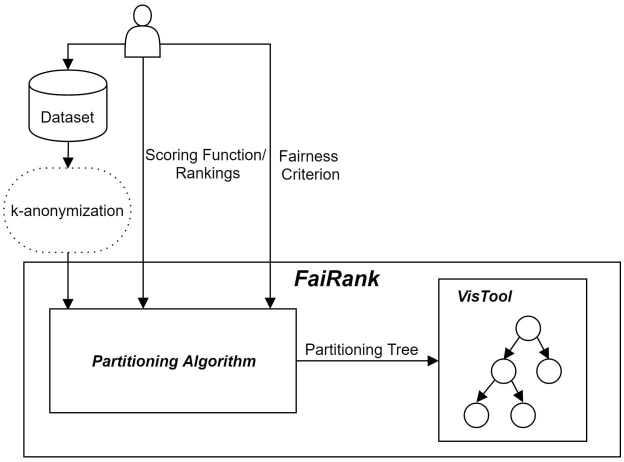

Figure 1: System architecture of FaiRank

on the interplay between data and function transparencies and the ability to quantify fairness. Additionally, FaiRank enables the exploration of different scoring functions, which can help choose the fairest for a given job. Finally, FaiRank can be used with standalone datasets and scoring functions, and since it can operate under various transparency settings, it can be used as a service to quantify fairness in existing blackbox job marketplaces.

2 SYSTEM OVERVIEW

Figure 1 depicts the system architecture of FaiRank. The user can select or upload a dataset which consists of a set of individuals and their attributes. The attributes can be protected such as gender, age, location, ethnicity, etc. or reflective of the performance or skills of the individuals such as reputation, knowledge in plumbing, writing skills, and mathematical abilities. Some of these attributes can also be anonymized. The user of the system can define or select a scoring function to rank individuals. The scoring function can be defined on a subset of the attributes of the individuals, for example a linear combination of an individual's reputation and plumbing skills, or of English writing skills and expertise in computer science. In addition, the user can filter the individuals based on protected attributes. This can be helpful in scenarios where the user is only interested in ranking a subset of individuals that satisfy certain criteria, say only individuals who speak Arabic or who are located in New York city. Instead of a scoring function, the user can also provide some ranking for the individuals (i.e., in the case that the scoring function is not transparent).

FaiRank solves an optimization problem that finds a partitioning of individuals over their protected attributes for which unfairness is subjected to an aggregation function (maximized, minimized, etc). The partitioning is displayed in a panel for the user. The user can interact with the returned partitions, view statistics such as the number of individuals in each partition, as well as a histogram of the scores of the individuals in each partition. The user can also choose to modify the scoring function or the fairness formulation, and obtain several panels to explore how that impacts fairness quantification. In the next section, we explain how we partition workers and quantify fairness of a scoring function given a set of individuals.

3 QUANTIFYING FAIRNESS

3.1 Model

To quantify fairness, we model the problem as aggregating a distance between the score distributions of all possible partitions of individuals. Unlike previous work where partitions were defined or known a priori (e.g., [5]), in FaiRank we explore the space of all possible groups defined by a combination of values of the individuals' protected attributes. The goal becomes finding an unfair partitioning of individuals under the scoring function. This can be formulated in many ways. For instance, the worst-case formulation would correspond to finding the *highest* distance between partitions. We cast this goal as an optimization problem as follows.

Definition 1 (Most Unfair Partitioning Problem). *We are given a set of individuals W, where each individual is associated with a set of protected attributes $A = \{a_1, a_2, ..., a_n\}$ and observed attributes $B = \{b_1, b_2, \ldots, b_m\}$. The protected attributes are inherent properties of the individuals such as gender, age, ethnicity, origin, etc. The observed attributes represent the skills of individuals for jobs and could include, for instance, the reputation and writing skills of an individual. We are also given a scoring function $f : W \longrightarrow [0,1]$, which is defined using observed attributes as follows: $f(w) = \sum_{i=1}^{m} \alpha_i b_i$, where α_i is a user-defined weight for observed attribute b_i. A weight of zero indicates that the corresponding attribute is not relevant for the user in ranking the individuals. Our goal is to* fully *partition the individuals in W into k* disjoint *partitions $P = \{p_1, p_2, \ldots, p_k\}$ based on their protected attributes in A using the following optimization objective:*

$$\begin{aligned} &\underset{P}{argmax} && unfairness(P, f) \\ &subject\ to && \forall i, j\ p_i \bigcap p_j = \phi \\ & && \bigcup_{i=1}^{k} p_i = W \end{aligned}$$

Another formulation, *Least Unfair Partitioning Problem*, would be to find the partitioning that results in the smallest unfairness (i.e., *argmin* instead of *argmax* in the formulation above).

We now define how to compute the amount of unfairness of a function f for a partitioning P, or *unfairness*(P, f) in the above optimization problem.

Definition 2 (Average Pairwise Unfairness). *For a set of individuals W, a full-disjoint partitioning of the individuals $P = \{p_1, p_2, \ldots, p_k\}$ and a scoring function f, unfairness of f for the partitioning P is quantified as the average pairwise Earth Mover's Distance (EMD) between the distribution of scores in the different partitions of P, which is computed as follows:*

$$unfairness(P, f) = \underset{i,j}{avg} \quad EMD(h(p_i, f), h(p_j, f))$$

where $h(p_i, f)$ is a histogram of the scores of individuals in p_i.

Another possible formulation is to compute unfairness as the maximum pairwise EMD, which would correspond to finding the partitioning with the highest maximum EMD between any pair of partitions.

Example. Consider the example dataset shown in Table 1 consisting of 10 individuals on a crowdsourcing platform who are ranked for some job using a scoring function f. Figure 2 shows one possible partitioning of those 10 individuals, that results

Table 1: An example dataset consisting of 10 individuals and a scoring function using Language Test and Rating

Individual	Gender	Country	Year of Birth	Language	Ethnicity	Experience	Language Test	Rating	f(w)
w1	Female	India	2004	English	Indian	0	0.50	0.20	0.29

Algorithm 1 QUANTIFY(*current*: a partition, *siblings*: a set of partitions, f: a scoring function, A: a set of attributes)

```
if $A = \emptyset$ then
    Add $current$ to $output$
else
    $currentAvg = avg(EMD(current, siblings, f))$
    $a = mostUnfair(current, f, A)$
    $A = A - a$
    $children = split(current, a)$
    $childrenAvg = avg(EMD(children, siblings, f))$
    if $currentAvg \geq childrenAvg$ then
        Add $current$ to $output$
    else
        for each partition $p \in children$ do
            QUANTIFY($\{p\}, children - \{p\}, f, A$)
        end for
    end if
end if
```

from splitting them based on Gender first, and then splitting only the Male partition based on Language to get the following partitioning of individuals: *Male - English, Male - Indian, Male - Other,* and *Female*. We quantify the unfairness of partitioning P as the average EMD between the pairs of partitions in P. To identify the most unfair partitioning, one must exhaust all possible *full disjoint* partitionings of individuals based on their protected attributes To do that, we generate a histogram for each partition as indicated in Figure 2 based on the function scores by creating equal bins over the range of f and counting the number of individuals whose function scores fall in each bin. The most unfair partitioning is then the one with maximum average pairwise EMD between its partitions' histograms.

3.2 Algorithm

Our optimization problem for finding the most unfair partitioning is hard since there are many possible partitionings P (exponential in the number of protected attribute values). For this reason, we propose an efficient heuristic algorithm to identify a partitioning of individuals with respect to our optimization objective within reasonable time. Our algorithm (pseudocode given as Algorithm 1) is *recursive*. We describe it with one unfairness formulation (the worst-case one provided in Equation 1 and with one aggregation function, namely average). Our algorithm decides whether or not to split a given partition by comparing the average EMD of that partition with its siblings to that of its children with its siblings. The intuition behind this is that it assesses what would happen to unfairness as measured by the average EMD if the partition was replaced by its children. It only splits a partition if its average pairwise EMD with its siblings is less than the average pairwise EMD of its potential children with the partition's siblings (that is in the case of the worst-case formulation of unfairness - other formulations require to change this test only). To invoke the algorithm for the first time, we first split the given set of individuals using the most unfair attribute and then the algorithm is called once for each resulting partition. After all recursive calls of the algorithm terminate, the output is returned as the final partitioning of the individuals.

4 DEMONSTRATION SCENARIOS

FaiRank caters to different user roles. A screenshot of the interface is shown in Figure 3. **A video of the demonstration is available at https://youtu.be/MckMJColcDk.** We propose to demonstrate it with 3 scenarios, one per role. During the demonstration, we will rely on two types of datasets, simulated datasets mimicking crowdsourcing platforms and real-data crawled from online freelancing marketplaces. In each case, we will explore various scoring functions representing different jobs as well as variants for the same job. We will also allow the exploration of transparency settings and their effect on fairness quantification, by making use of the ARX tool to k-anonymize the datasets[3] and by considering cases where the scoring function is available and cases where it is not.

Dataset: simulated-50 | **Scoring Function:** transparent-f7 | **Fairness Criterion:** avg

Figure 3: A snapshot of FaiRank's interface. The Configuration box on the left allows users to choose which dataset and which scoring functions they want to explore. It allows them to also choose a fairness criterion. The partitioning trees are displayed on the right in multiple panels, which allows the user to compare multiple scoring functions/datasets. General information about a partitioning tree can be found in the General box on the left, and the user can view statistics about a particular partition in the Node box by clicking on that partition in the tree.

AUDITOR Scenario. This scenario provides auditors with the ability to monitor a marketplace that offers multiple jobs, each with its own scoring function. It provides a big picture to auditors and lets them identify which jobs are most unfair to which individuals based on their rankings and under different notions of fairness. For instance, an auditor may be looking to draft a "fairness" report on a freelancing marketplace such as Qapa or TaskRabbit. The auditor would want to quantify the fairness for each job offered on the platform, and identify demographics groups that are least/most favored on the platform by each job. Additionally, the auditor might consider cases where the marketplace does not provide full transparency, either in terms of attributes of its users or in terms of the scoring functions used to rank those users, and we show the effect of this on quantifying fairness compared to the case when both attributes and the scoring function are available.

JOB OWNER Scenario. This scenario emphasizes the ability to define different scoring functions, and examine their impact on individuals. This exploration will help owners understand the behavior of their scoring functions and will guide them to choose the best function for their job, i.e., the one that satisfies some desired fairness. For instance, for an online job that requires people to write code, the owner can select those for whom the scoring function induces the least unfairness.

END-USER Scenario. This scenario offers end-users the ability to immerse themselves and simulate different cases in which they are to be ranked. For instance, an end-user wishing to find a job online, can examine how unfair some job is with respect to different groups of people. Given a group to which the end-user belongs (e.g., Young professionals in Grenoble) and a job of interest (e.g., installing wood panels), the end-user can see how well the marketplace is treating that group and make an informed decision of whether to target that job or not.

ABSTRACT

There is a new generation of databases specifically addressing *Big Data Variety*: *Multi-model* databases store and process structurally heterogeneous data, managing several data models in one integrated backend. Yet one of the many challenges these systems face is evolution management. In our demonstration, we present our prototype implementation of a tool called *MM-evolver*. *MM-evolver* carries out user-triggered schema modification operations over a multi-model database, and propagates them across all models. As a novelty, *MM-evolver* supports both inter- and intra-model schema modification operators. To the best of our knowledge, ours is the first tool addressing evolution management in the world of multi-model databases.

Figure 1: A multi-model data scenario [6]

1 INTRODUCTION

In recent years, the Big Data movement has broken down the borders of many technologies and approaches that have so far been acknowledged as mature and robust. One of the most challenging issues is the "*Variety*" of Big Data. Data may be present in various types and formats – structured, semi-structured, and unstructured – and produced by different sources, and hence natively have various models.

The challenge of handling variety has inspired a new generation of dedicated *multi-model databases* (MMDs), capable of storing and processing structurally different data, by supporting several data models in a single DBMS having a unified query language and API. The MMD way of solving the polyglot persistence problem offers advantages in data modeling, allowing to represent data in its most native model. This can be considered as opposite to the "*One Size Does Not Fit All*" argument [10]. However, it can be also understood as a way of re-architecting traditional database models to address new requirements [4]. Nothing shows the picture better than the Gartner Magic quadrant for operational database management systems [3], which (correctly) assumed that, by 2017, the majority of leading DBMSs will offer multiple data models in a single DBMS platform.

To illustrate the challenge of multi-model data management, consider the simple example depicted in Figure 1. There we have data with four distinct data models. Customer data is stored in a relational table – their ID, name, and credit limit. Graph data bear information about mutual relationships between the customers, i.e., who knows whom. In JSON documents, each order has an ID and a sequence of ordered items, each of which includes product number, name, and price. The fourth type of data, key/value pairs, bears a relationship between customers (or rather, their IDs) and orders (or rather, their IDs).

One of the many challenges [6] these systems are facing is evolution management. As user requirements change, the data structures evolve, and, consequently, also the respective storage strategy, queries etc. This problem is challenging even in the world of single-model databases. In simpler applications, we can rely on a skilled DB administrator, but in more complex situations it is a difficult and error-prone task. In addition, we can observe contradictory approaches to this problem in different types of DBMSs. In the world of traditional relational or XML databases, the evolution of data structures requires immediate changes in the schema. With NoSQL systems, we can (to some extent) exploit the schemalessness and ability to store data with similar, but not necessarily the same structure. Considering the existence of a schema, another complication is existence of schema-full, schema-less and even schema-mixed MMDs. Consequently, the problem of evolution management in MMDs is much more complex.

Consider again Figure 1. We may want to add a new property to one of the models (e.g., an address to JSON documents representing orders), which does not affect the other models. But, later we may decide to move this property to another model (e.g., to represent addresses in the relational model instead). Hence, we need to change data in both models. In addition, there might already exist a reference to the modified property, which then needs to be updated accordingly.

To address the indicated problems, we extend our previous research results [7, 8] for single-model systems (XML or relational) or systems with closely related models (namely aggregate-oriented NoSQL). In this demonstration, we present a tool called *MM-evolver*, which carries out user-required changes over a multi-model schema and propagates them across all sub-models. To the best of our knowledge, this is the first solution addressing the problem of evolution management in the world of multi-model databases. We see it as the first step towards a unification of evolution management across multiple models.

In the remainder of this paper, we introduce the ideas implemented in *MM-evolver* and outline our demonstration.

2 MULTI-MODEL EVOLUTION MANAGEMENT

There are two main approaches to supporting different models:

- **Complex engine** (e.g., CouchBase [2]) – The DBMS transforms all supported data types to a single core model. Its engine has to pre-process and map all operations to the core model.
- **Layer-based architecture** (e.g., Oracle Database 12c [1]) – The DBMS supports different models via different layers on top of an engine. Data are stored in the relevant model. Each data model has its own component which communicates with the engine.

We focus on the layer-based architecture, which is used in a significant portion of existing MMDs, because there is no need to introduce a generic approach for specific complex engines, since they often internally map all supported models onto a single model. Figure 2 shows two main layers of the layer-based approach inspired by the principles of the Model Driven Architecture: *model-specific* and *model-independent*[1]. For the sake of simplicity we assume that the data in the individual models have a schema. However, such a schema does not have to be explicitly defined. It can be a kind of an agreed structure, as often used in practice. The engines in the model-specific layer can thus differ also with regards to this aspect.

The MMD engine is located in the model-independent layer. It is a facade for functions of the database, such as queries, and distributes queries and commands to the respective individual models. Also, it collects data from them and creates the final result for the user.

2.1 Database Schema Evolution Language

Our aim is a general solution for schema evolution in MMDs and the following models as the most common representatives: (1) relational, (2) column, (3) graph, (4) key/value, and (5) document (i.e., JSON or XML). By the generic term *kind*, we refer to an abstract label that describes or groups related records. In the relational model, this corresponds to a table. Some MMD vendors use the terms *class* (as in OrientDB[2]) or *collection* (as in ArangoDB[3]).

First, we settle on a common set of operations which can be supported by all models. For this purpose, we extend the work from [9], where the *NoSQL Schema Evolution Language* (NoSQLSEL) covers most of the representatives, namely the aggregate-oriented NoSQL databases, i.e., document, column and key/value models. It involves three basic operations that affect all entities of a given kind to (1) *add* (introducing a new property with a specified default value), (2) *delete* (removing a property), and (3) *rename* (changing the name of a property). It further involves operations to (4) *move* (removing a property from one kind of entity and adding it to another one), and (5) *copy* (copying a property from one kind of entity to another one).

In order to avoid complex extensions of NoSQLSEL towards the missing models, we use a strategy common to most of the existing MMDs [5], i.e., a kind of a unification of the models. For example, we can treat the graph model like ArangoDB, where special edge collections bear information about edges in a graph whose nodes correspond to documents. Similarly, we can assume that entities are represented as rows in a specific table and their properties are columns of the table, where each entity has a unique identification *id*. We call this extension covering the model-specific layer the *Database Schema Evolution Language*.[4]

2.2 Multi-Model Schema Evolution Language

Having a common interface supported by all models in the model-specific layer, we can introduce the *Multi-Model Schema Evolution Language* (MMSEL) which is executed in the model-independent layer. The multi-model engine has to distinguish which models are affected by a given operation and propagate the operations to them. We can divide the operations into two separate groups:

- *Intra-model* operations (i.e., *add*) affect just one model.
- *Inter-model* operations (i.e., *copy*, *move*, *delete* and *rename*) can affect multiple models[5]. The first two can also trigger data transfer between a *source* and a *target* model; the last three can trigger changes in other models, due to references that need to be updated accordingly.

Figure 3 shows the EBNF grammar for the MMSEL syntax and Figure 6 shows an example statement. Intra-model operations, as well as inter-model operations operating within a single model are propagated by the multi-model engine to the specific target model(s) which is/are already able to ensure correct data processing.[6] When entities should be transferred between models (i.e., copied or moved), the multi-model engine gets all entities of the given kind from the source model and inserts them into the target model. In case of operation *move*, it has to delete them from the source model. It is also able to track all cross-model references. When the engine detects a change in a referenced entity, it propagates these changes to the referencing entity.

2.3 Implementation of MMSEL

The core logic of the MMSEL happens in the model independent layer. Internally, MMSEL schema modification operations are translated into a lower-level language, which we introduce next. To distinguish between the models, we introduce the *data model set* $DMS = \{column, document, key/value, graph, relational\}$ and a *model key* δ: $\delta \in DMS$. To create an abstract model of the MMD, we follow the notation from [9] which uses the term *application state* for the current state of the application space. It is a non-persistent application memory. *Database state* is the current state of the database and it represents all stored data.

We need to call specific schema evolution functions in specific models. Consequently, we introduce a modified set of functions called Multi-Model Database Programming Language (MMDPL) which extends the NoSQL Database Programming Language [9] with DMS operations (see Figure 4). The main difference is in operations for getting entities from the database and to save them in the database. Function *empty* does not modify the application space or the database. Despite the original plan of having a common set of operations, we decided to use it for the key/value model, where there is no support for operation *move* since in this model, entities do not have several properties, just a single, opaque value. Otherwise it could be implemented as *rename*. The remaining operations are extended with the DMS, but their logic remains. Rule 7 extends function $put(\delta, \kappa)$ by parameter δ to distinguish where the entity with the key κ is stored. For that purpose we introduce function $model(\kappa)$ which returns a

[1] We borrow from the idea only two layers (levels) and call them slightly different to express our specific context.

[2] https://orientdb.com/

[3] https://www.arangodb.com/

[4] We refer interested readers to the extended version [11] for technical details.

[5] But they can be restricted to intra-model only, like they are in existing MMDs.

[6] We assume re-use of existing single-model change propagation approaches and therefore focus on the novel problem of multi-model change propagation.

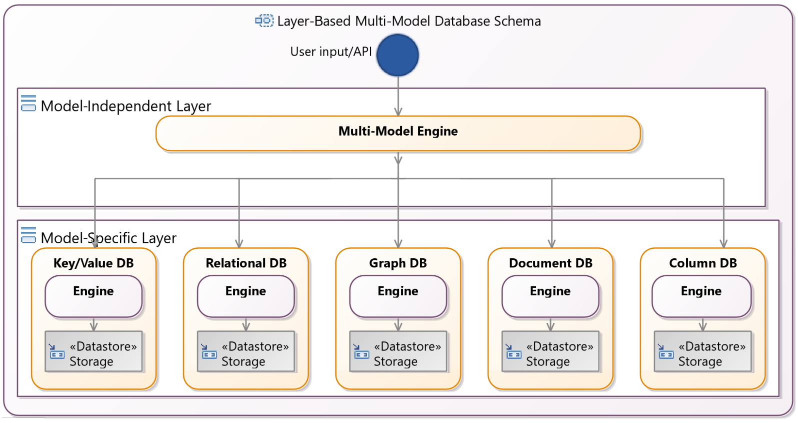

Figure 2: Architecture of a layer-based MMD

kind     ::= mname "." kname;
mname    ::= identifier;
kname    ::= identifier;
pname    ::= identifier;
```

Figure 3: EBNF syntax of MMSEL

model where the entity occurs. We use this approach to detect the affected model in all modified functions. In Rule 8 we extend function $delete(\delta, \kappa)$ by key of the model δ which contains the entity with key κ. Rules 9, 10, and 11 add parameter δ to function get. All modified functions get load entity/entities from the specified model by key δ to the application space. Rule 12 is also extended by the model key δ to load the property from the specified model.

2.4 Reference Evolution in MMDs

We next discuss how referential integrity is maintained as schema modification operations are carried out.[7] In the first version of our solution, we consider the reference simply as a pointer from a property of a referencing entity to a property of a referenced entity. We describe the source or target of a reference by a triple *(model, entity, property)*. A reference is then represented as a pair $(source, target)$ and we assume that at least one model is able to store the pairs in a *reference space*.

Next we can divide operations into two groups: *Safe* operations (i.e., *add* and *copy*) do not trigger any reference updates, whereas *unsafe* operations (i.e., *delete*, *rename*, and *move*) can.

To avoid complex extensions and instead stay within the MMDPL framework, we internally represent a reference as a special type of entity. It has three properties: (1) the referenced property of the entity, (2) the key of the property in the MMD, and (3) an array of triples describing entities referencing it. Each triple in the array consists of three properties: a model, a kind, and a property.

During our analysis of reference migration, we discovered that WHERE conditions make the solution much more difficult. It is caused by the nature of MMDs which allow a user to move a subset of the properties. This behavior can split, delete or move completely an existing reference based on the affected set of the values. We introduce a solution for operations without WHERE conditions and keep it as an open challenge.

Another point to discuss is the behavior when a referenced property is removed. We have two options what can happen with the referencing property: (1) set to a default value, (2) delete the property. We decided to use the second approach, because it is a clear solution for the used models. (The first approach has to define what should be the behavior when a MMD contains an entity without a referencing property, as well as default values for all models. Also, the default value can be considered as a value of the property in an application so it can be confusing.)

The next step defines operations for creating and managing references in the MMDPL. We need to create a reference, store it, remove it and find it. Let *reference store model* (RSM) be a store which is able to persist the reference entities. We use the RSM to extend the MMDPL and define functions which help us to implement reference management in the MMSEL. Figure 5 shows the extension of the MMDPL which provides functions for the mentioned operations. We introduced a special type of entities for the references which is stored in the RSM, but we work with the type in the same way as with other database entities.

3 DEMONSTRATION OUTLINE

For the purpose of experimental evaluation of the above described ideas, we have implemented a first prototype called *MM-evolver*. The application is based on the .NET framework and is written in C#. To be able to experiment in the future with various models, not just those provided by a particular MMD, we created an *abstract* layer-based model, where each particular model can be represented by a separate DBMS. To test also this feature, in the first version we use MongoDB[8] and MariaDB[9] representing the document model and the relational model.

In our demo of *MM-evolver*, we build two use cases – one around real-world data, which is based on the Internet Movie Database (IMDb)[10], and the other on the multi-model benchmark UniBench[11]. As shown in Figure 6 for the first case, the data is stored both in the document model (such as `movies.Contributor` to the left), as well as in the relational model (`name_basics` to the right). To the top, we show an inter-model schema modification operation that we are about to execute. We further highlight the affected data (relational in red, document in blue). In interaction with our audience, we will gradually evolve the database state, simulating realistic demands. We intend to make the benefits of the declarative language evident, so that attendees get a clear picture how they would use it in practice. For each supported operation (both intra-model and inter-model), we demo:

(1) the state of the database before and after the change,

[7] Note that the earlier language NoSQLSEL does not consider references, because most NoSQL databases do not support them. Maintaining referential integrity is therefore another new contribution of *MM-evolver*.

ABSTRACT

As the scientific interest in the Internet of Things (IoT) continues to grow, emulating IoT infrastructure involving a large number of heterogeneous sensors plays a crucial role. Existing research on emulating sensors is often tailored to specific hardware and/or software, which makes it difficult to reproduce and extend. In this paper we show how to emulate different kinds of sensors in a unified way that makes the downstream application agnostic as to whether the sensor data is acquired from real sensors or is read from memory using emulated sensors. We propose the Resense framework that allows for replaying sensor data using emulated sensors and provides an easy-to-use software for setting up and executing IoT experiments involving a large number of heterogeneous sensors. We demonstrate various aspects of Resense in the context of a sports analytics application using real-world sensor data and a set of Raspberry Pis.

1 INTRODUCTION

The growth of the Internet of Things (IoT) has led to many disruptive technologies and applications such as smart homes, autonomous vehicle fleets, health and well being, personal and home security, and natural disaster management. In such applications, the IoT data (i.e., sensor data generated by devices connected to the Internet) may get very large and may involve billions of sensors [6]. Therefore, efficient means to automatically collect, store, and analyze massive amounts of IoT data plays an important role in our modern information-based society.

IoT research connects two communities: The database community deals with sensor data acquisition [3, 12, 14] and distributed query processing [8, 15]. The infrastructure and networking community deals with network connections, application and resource management across sensor nodes, and cloud computing [4, 9, 10].

For database researchers, it is important to develop and test data management solutions on IoT testbeds which include large numbers of sensor nodes and provide real networking and data processing conditions. However, it is hard to conduct repeatable experiments on such testbeds for two main reasons: *(i)* One needs to fine tune and test different versions of algorithms (A/B or split testing), but sensors data varies over time which leads unequal test conditions. *(ii)* Applications need to be tested on rare events which leads to extremely long test durations. For example, consider a sports analytics application that predicts injuries in real time. Player injuries are rare and highly important, but one cannot repeat them in the real world. Being able to replay sensor data (e.g., data recorded from sensors on players' body) on real test beds solves the issues stated above and enables database researchers to run repeatable experiments.

In this paper we present Resense, a framework which transparently emulates sensors and provides an efficient way to replay and record sensor data. Resense emulates sensors at the operating system level such that it is transparent for applications whether they acquire values from real sensors or from memory using emulated sensors. One can install Resense on testbeds without changing any application and gains the flexibility to switch between live sensor data and replayed sensor data easily.

Resense further provides mechanisms to orchestrate IoT experiments involving a large number of heterogeneous sensors. Our framework allows users to easily configure many different physical and/or emulated sensors as well as the data to be replayed. We provide an intuitive user interface for loading experiment configurations, for deploying experiment data to a large number of sensor nodes, and for starting/stopping experiments on all (or some) sensor nodes. The automatic deployment of the required data, the centralized configuration of sensor nodes, and the centralized control and monitoring of experiments reduce the administrative overhead when running IoT experiments and developing IoT applications.

Our demonstration highlights how easy it can be to setup and run experiments on a real testbed. We show various aspects of Resense using a set of Raspberry Pis as sensor nodes and some physical sensors. In particular, we demonstrate the record and replay functionality where attendees can attach physical sensors to a Raspberry Pi and use the graphical user interface to inspect the (physical) sensor readings, record them, and replay the recorded data. We also demonstrate setting up and executing a full scale IoT experiment based on real-world data from the DEBS 2013 Grand Challenge dataset [13]. The data consists of about 15 000 position events per second which were recorded at a football match in which sensors were embedded on the shoes of the players as well as the ball. Attendees will be able to use the Resense UI to deploy, control, and monitor the experiment and configure the sensor nodes.

In summary, this paper makes the following contributions:

(1) We show how to transparently emulate sensors in order to record and replay sensor data.
(2) We provide an easy to use software for setting up and executing IoT experiments involving large numbers of heterogeneous sensors.
(3) We demonstrate our software by recording and replaying real world sensor data in the context of sports analytics on a set of Raspberry Pis.

Resense is available as open source project[1] and runs on any GNU/Linux system independent of the underlying hardware (e.g., x86-based servers and ARM single-board computers).

The rest of the paper is organized as follows: in Section 2, we give an overview of our approach for transparently emulating sensors and orchestrating IoT experiments. Section 3 gives a

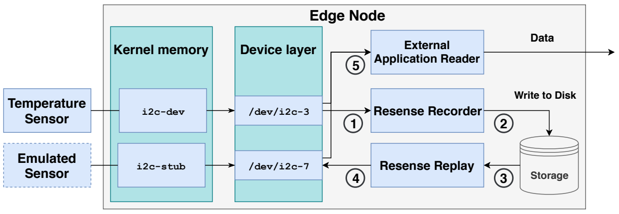

Figure 1: Recording and replaying data with Resense.

description of our demonstration. We discuss related work in Section 4 and conclusion in Section 5.

2 EMULATING SENSORS

Implementing the emulation of sensors while being capable of replaying scientific datasets is hard since the number of sensors that can be involved in a single experiment can vary. On top of this, the heterogeneity of the sensors makes it hard to include every possible sensor architecture in a single emulator. In this section we discuss the decisions behind the architecture of Resense and show how we overcome these obstacles.

2.1 Emulation Abstraction & Replaying Data

The first major contribution of this paper is to emulate a sensor transparently. Transparent emulation allows applications that request data from sensors to treat the emulated sensor as if it was a physical one. The applications cannot distinguish between physical and emulated sensors and expect the same behavior from them. The GNU/Linux kernel provides modules with a stable API and implementations suited for such a task. For example, it provides kernel drivers for commonly used sensor protocols like I2C, SPI, and UART among others. These kernel modules are fully featured drivers that emulate physical devices. We employ their capabilities in Resense in order to provide emulated sensors that are indistinguishable from physical sensors from the point of view of an application.

In more detail, the kernel modules allow the addition and removal of emulated sensors using file descriptors at the device layer of the host operating system. These file descriptors have a consistent naming scheme and are allocated in memory by the kernel module in order to be subsequently perceived as physical components by other parts of the system. Since different file descriptors provide the same API to external applications, it allows Resense to emulate different sensor types regardless of their underlying protocol (and communication bus) for which the host operating system includes its respective kernel module.

Figure 1 shows an end-to-end example from the perspective of a single edge node. A physical temperature sensor is attached to the edge node through an I2C bus. In addition, there is an emulated sensor provided by Resense. The `i2c-dev` kernel module[2] makes all I2C sensors accessible from userspace using character device files. Each device gets assigned a number, starting from 0. The device files follow the pattern of `/dev/i2c-{0,1,2,...}`. In our example, `i2c-dev` has allocated `/dev/i2c-3` for the temperature sensor. The `i2c-stub` kernel module[3], which is also depicted in Figure 1, is responsible for creating character device files for *emulated* devices. The emulated device files follow the same pattern as the ones created from `i2c-dev` and are indistinguishable from the point of view of a userspace application. In our example, the emulated sensor is allocated to `/dev/i2c-7`.

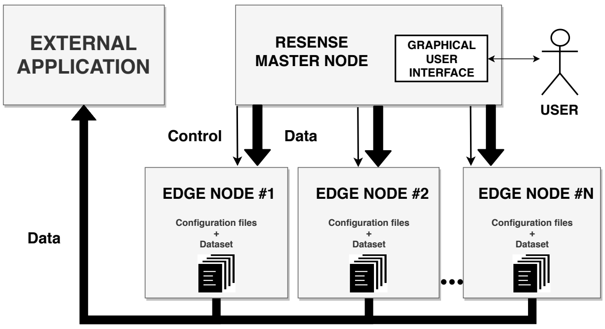

Figure 2: Resense architecture.

Three applications operate on top of physical and emulated sensors in our example: *(i)* The Resense Recorder, *(ii)* Resense Replay, and *(iii)* a reader of an external application. The applications act as follows: The `Resense Recorder` reads sensor values ① and stores them for later use ②. This allows for capturing events in order to replay them later on. The `Resense Replay` module can read the sensor values stored by the recorder ③ and replay them through the emulated sensor ④. We consider this process a *replay* of an experiment. The external application reader can access all sensors (the physical temperature sensor and the emulated sensor) in the same way ⑤.

The `Resense Recorder` and the `Resense Replay` module act as a bridge between the physical sensors of an edge node and the emulated sensors. Any application which consumes sensor data can consume values from both, physical and emulated sensors, since both types of sensors are exposed through device files. Our current approach replays data at the same rate at which they were captured. In future, we plan to support more fine grained control over the rate of recording and replaying. Moreover, our future work also includes time synchronization mechanisms across edge nodes in order to provide reliable and accurate replaying of sensor data. As a remark, the maximum number of physical and emulated sensors per edge node is limited by the host operating system as well as the node's hardware.

2.2 Experiment Orchestration

In order to administrate a huge number of edge nodes and sensors, Resense employs a Master/Slave approach. A visualization of the interaction between master and slave nodes can be seen in Figure 2. Users can control Resense through the graphical user interface of the master node. From there, users can deploy sensor data to sensor nodes, replay and record data, and monitor the progress of experiments. For external applications it is transparent whether they read data which originates from physical or emulated sensors.

Resense stores experiment setups pertaining to applications in configuration files in order to reload and rerun experiments as needed. An experiment consists of sensor data, edge nodes, emulated sensors, and physical sensors. Listing 1 shows an example configuration file. We first define the name of the experiment in Line 1. Starting from Line 2, we provide the list of edge nodes associated with the experiment. Each edge node has a unique id (Line 4), an IP address or domain name (Line 5), and the user name and password for remote access (Lines 6 and 7). Each edge node may host many sensors listed starting from Line 8. Each sensor has a unique id, an output type, and a sensor address. The sensor id refers to a sensor contained in the data file associated with the experiment. In our example, we connect two sensors from the DEBS 2013 grand challenge.

```

Listing 1: An excerpt of sample configuration file.

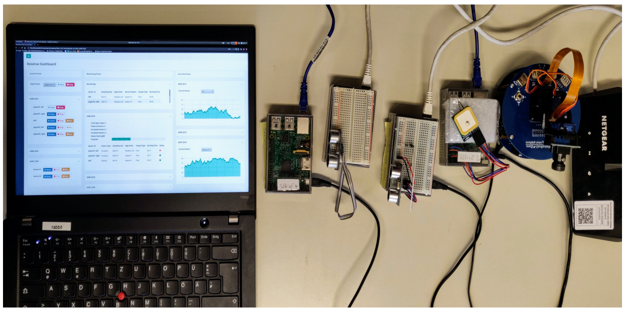

Figure 3: Resense demonstration setup.

In order to run an experiment with Resense, users first create a configuration file through the graphical user interface or load an existing experiment configuration. Resense automatically splits datasets associated with the experiment such that each result file contains the data of one individual sensor declared in the configuration file. The master node deploys the sensor data and the node configuration to each edge node as needed. Each edge node now creates the file descriptors for the emulated sensors according to the configuration provided by the master node. Once the deployment and setup are complete, the user can start the experiment from the dashboard. Edge nodes will then replay sensor data as described in Section 2.1 and shown in Figure 1. Users can also pause, resume, stop, and restart experiments through the dashboard. During execution, Resense monitors the progress of the experiment and displays the status of sensors and edge nodes as well as the currently replayed data.

3 DEMONSTRATION

We demonstrate Resense on a Raspberry Pi testbed as shown in Figure 3. In our setup, the laptop machine acts as the master node, five Raspberry Pis as edge nodes, and some of the edge nodes are equipped to read data from physical sensors (a GPS, an accelerometer, and couple of ultrasonic sensors).

In our demonstration, attendees can record sensor data, replay the recorded data, and set up experiments with data from real-world data sets. Thereby, users can combine physical and emulated sensors installed onto our demonstration platform. Through the Resense dashboard, users can monitor edge nodes and sensors. We further provide an example application which is independent of Resense, reads data from emulated and physical sensors, and streams the live-data to a visualization dashboard.

3.1 Real-World Testdata

As an example, we use the datasets of the DEBS 2013 Grand Challenge [13], which was recorded at a football match and contains the speed, acceleration, and position of the players, the referees, and the balls used during the match. We chose this dataset because it provides sensor values recorded at a high data rate. The tracking frequency is 200Hz for players and of 2000Hz for the ball. Players are tracked with two sensors located on their shoes. Goal keepers are equipped with two additional sensors located at their hands. Overall the dataset provides values from 37 sensors with a total data rate of 15000 position events per second.

3.2 Demonstration Platform

The Raspberry Pi single board computer is our platform of choice for this demo. Its cost effectiveness, its plethora of available connection protocols as well as the fact that it is popular for sensor-based research were the most important factors that lead to our decision. We use Raspberry Pi 3 Model B for our demonstration and the latest version of the operating system that is available, specifically version `2018-10-09` as of January 21, 2019.

For our demo, we choose to focus on the I2C protocol and the `i2c-stub` kernel module to emulate sensors from file descriptors. The protocol supports serial, 8-bit oriented, synchronous, bidirectional data transfer. Synchronization of devices on the bus uses a Master/Slave architecture. Moreover, I2C supports multi-master configurations with collision detection. We chose I2C over the other protocols that are available on a Raspberry Pi board because of the simplicity of the protocol and the maturity of the code of the kernel modules associated with it.

It is worthy of note that Resense is not tied to this demonstration platform. Resense runs on any GNU/Linux based operating system and is agnostic to the hardware architecture. This allows for running experiments with Resense on a large variety of hardware architectures and helps to emulate sensors that lack driver support for multiple architectures.

3.3 Demonstration Scenario

Figure 4 shows a screen shot of Resense's UI. The dashboard has three panels: a control panel on the left, a monitoring panel on the center and a live-view panel on the right.

The control panel allows either for selecting an existing experiment or creating a new one to be run. For each running experiment, the panel shows the list of sensors involved and the available controls. The controls depend on whether the sensor is physical or emulated. Readings from physical sensors can be stopped, resumed, or can be recorded (for replaying later). For emulated sensors, their readings can either be stopped or resumed. By default, all sensors are activated upon starting an experiment. The monitoring panel displays statuses of current recordings and experiments that are running. In particular, the box for recordings shows details about sensors and data that is being recorded. The box for each experiment shows progress, number and type of sensors, number of edge notes, and details about the sensors and the data being read. Finally, the live-view panel shows time series data for sensor readings for currently running experiments and allows to select specific sensor(s) from which data should be rendered.

During the demonstration, the attendees will run an experiment by selecting an existing configuration file (e.g., based on the DEBS 2013 dataset) or by creating a new one. Attendees can interactively control individual sensors and view readings in the live-view panel. Attendees will also be able to create an experiment involving available sensors, record sensor data, and replay recorded data.

4 RELATED WORK

In the existing literature, Chernysov et al. [1] give an overview on the topic of emulating and simulating IoT infrastructure. According to their work, IoT simulators are categorized into three different sets: *(i)* perceptual emulation, emulates all of the layers of an IoT infrastructure, *(ii)* network emulation, focuses on network properties and *(iii)* application level emulators, emulate workloads only on the application layer. To the best of our knowledge, our work cannot be constrained to only these three types because our implementation is capable of ingesting sensor data at the kernel level of the host operating system. Thus, it is fully transparent to external software that can itself be already in one of these aforementioned categories.

In contrast to the work on IoT simulators [4, 5], our implementation differentiates between the edge nodes and the sensors and focuses on emulating the sensors and reading from sensors. This allows for more granularity while replaying sensor data and can give a more detailed view of the experiment. While other solutions [7] require a fixed full-stack emulation, our work provides a mixed approach since it is able to integrate emulated as well as physical sensors. This makes it easier for testing new physical sensor architectures with existing ones.

Emulating sensors for conducting experiments have also been studied using FPGAs [2, 11]. Usually, FPGAs are first designed using a hardware description language (like VHDL/Verilog) and later implemented into the actual hardware. Our solution reduces the time and the cost involved in prototyping an experiment as it does not depend on any specialized hardware.

5 CONCLUSIONS

In this paper we showed how to emulate sensors to replay recorded sensor data independent of the underlying hardware or software. We presented the Resense framework that allows transparent record and replay of sensor data and provides an easy to use software for setting up and executing IoT experiments. We demonstrated various features of Resense using real world sensor data, a set of Raspberry Pis, and some physical sensors.

ABSTRACT

Named Entity Recognition (NER) is a challenging problem in Natural Language Processing (NLP). Deep Learning techniques have been extensively applied in NER tasks because they require little feature engineering and are free from language-specific resources, learning important features from word or character embeddings trained on large amounts of data. However, these techniques are data-hungry and require a massive amount of training data. This work proposes Human NERD (stands for Human Named Entity Recognition with Deep learning) which addresses this problem by including humans in the loop. Human NERD is an interactive framework to assist the user in NER classification tasks from creating a massive dataset to building/maintaining a deep learning NER model. Human NERD framework allows the rapid verification of automatic named entity recognition and the correction of errors. It takes into account user corrections, and the deep learning model learns and builds upon these actions. The interface allows for rapid correction using drag and drop user actions. We present various demonstration scenarios using a real world data set.

1 INTRODUCTION

Named Entity Recognition (NER) is a challenging problem in Natural Language Processing (NLP). It corresponds to the ability to identify the named entities in documents, and label them with one of entity type labels such as person, location or organization. Given the sentence "Trump lives in Washington DC", traditional NER taggers would identify the mentions 'Trump' and 'Washington DC' to person and location labels, respectively. NER is an important task for different applications such as topic detection, speech recognition, to name a few.

However, there is a long tail of entity labels for different domains. It is relatively simple to come up with entity classes that do not fit the traditional four-class paradigm (PER, LOC, ORG, MISC), such as, in Police report documents, *weapon type* is none of the above. For these cases, labeled data may be impossible to find. Even, orthographic features and language-specific knowledge resources as gazetteers are widely used in NER, such approaches are costly to develop, especially for new languages and new domains, making NER a challenge to adapt to these scenarios[10].

Deep Learning models have been extensively used in NER tasks [3, 5, 9] because they require little feature engineering and they may learn important features from word or character embeddings trained on large amounts of data. These techniques from Deep Learning are data-hungry and require a massive amount of training data. While the models are getting deeper and the computational power is increasing, the size of the datasets for training and evaluating are not growing as much [14].

In this work, we address this problem by including humans in the loop. Several methods have been proposed to improve the efficiency of human annotations, for instance in computer vision applications [11, 14] and NER tasks via active learning [2, 7, 8, 12, 13]. Those methods are promising for NER but still leave much room for improvements by assuming the annotation cost for a document measured regarding its length, the number of entities or the number of user annotation actions, for instance. While these are important factors in determining the annotation and misclassification cost, none of them provide the ability to create and incrementally maintain deep learning models based on iterative annotation. Indeed, all of them expect NER tasks to have very few labels. Prodigy [1] is a promising annotation tool that works on entity recognition, intent detection, and image classification. It can help to train and evaluate models faster. However, we could not explore Prodigy, since it is not free. In this work, our goal is to provide an interactive framework called Human NERD (stands for Human Named Entity Recognition with Deep learning) to assist the user in NER classification tasks from creating a massive dataset to building/maintaining a deep learning NER model. Human NERD provides an interactive user interface that allows both the rapid verification of automatic named entity recognition (from a pre-trained deep learning NER model) and the correction of errors. In cases where there are multiple errors, Human NERD takes into account user corrections, and the deep learning model learns and builds upon these actions. The interface allows for rapid correction using drag and drop user actions. We need to point out that our framework consider two types of user: reviewer and data scientist. The reviewer is a domain

Series ISSN: 2367-2005

10.5441/002/edbt.2019.64

expert that can correct possible classification errors and enrich the labels while data scientist focuses on tuning the models. In the next Sections, we provide more details and a screencast is available at YouTube[1].

To the best of the authors' knowledge, this work is the first that simplifies the task of annotating datasets, minimizing supervision, and improving the deep learning NER model, which in turn will make the overall system more efficient. To achieve this end, we first propose the framework in Section 2. Then, we present the demonstration scenarios in Section 3. Section 4 draws the final conclusions.

2 HUMAN NERD

For a large document collection, Human NERD keeps the user engaged in the process of building a large named entity dataset. The input to the framework is a set of documents to annotate and a set of NER labels. The output is a set of annotated documents, a deep learning model for entity recognition and the evaluation metrics values that can estimate the *operational cost* during the annotation time and the *gain* regarding model accuracy.

We incorporate deep learning NER models as the Entity Recognizer models from Spacy [2] framework into Human NERD to reduce the cost of human time dedicated to the annotation process. Indeed, these models have led to a reduction in the number of hand-tuned features required for achieving state-of-the-art performance [6]. Human NERD can also incorporate models such as [3, 5].

Human NERD suggests a potential entity annotation in every interaction loop, and the user as a reviewer can accept or reject individual entities. He/she can also tag a new excerpt from the document text with an entity that was not suggested by the NER model. The feedback is then used to refine the model for the next iteration and enrich the dataset. Our framework simplifies the task of building large-scale datasets, minimizing supervision, and improving the deep learning NER model, which in turn will make the overall system more efficient.

The general workflow of Human NERD follows five main steps (overview in Figure 1): (1) collecting a large set of unlabeled documents; (2) the current NER model recognizes and annotates entities in the document according to labels drawn from a given set of entity classes L (i.e., person, location, among others); (3) user as a reviewer can accept or reject individual entities; he/she can also manually label the document according to L; (4) generating a deep learning NER model for each iteration; (5) estimating the *gain* over the iterations and the *loss*, for improving the model accuracy and the operational cost during annotation time, respectively.

First step. Starting from a large pool of unlabeled documents $T = \{t_1, ..., t_m\}$ collected from different and heterogeneous resources (as Twitter, Wikipedia, Police reports, among others), where t_i is a variable-length sequence of input symbols $t_i = \{w_1, ..., w_n\}$. A sequence of consecutive w_i with the same label λ_j are treated as one mention of such label. Input symbols are word tokens w_i drawn from a given vocabulary V. Let $L = \{\lambda_j : j = 1...q\}$ denotes the finite set of labels in a learning task. We aim at annotating t_i with a sequence of output symbols $Y = \{y_1, ..., y_p\}$. Output symbols are labels λ_j drawn from a given set of entity classes L.

Figure 1: Overview of Human NERD. Given a set of documents for annotating as input, the system alternates between NER model classification and requesting user feedback through human tasks. The outcomes are the documents annotated to improve the NER model.

Second step. Human NERD acquires entity classes (i.e., person, location, among others) for T from a deep learning NER model as [3, 5] or using Spacy's models (i.e., Entity Recognizer model - which is trained using multilinear perceptron and convolutional network). The deep learning model is initially trained with $D = \{(x_i, Y_i) : i = 1...m\}$, a set of labeled training examples x_i, where $Y_i \subseteq L$ the set of labels of the i-th example. At this step, the pre-trained model classifies the entity mentions on $T = \{t_1, ..., t_m\}$ using the labels described on L and outputs $O = (t_i, Y_i) : i = 1...m$, where $t_i \in T$ and $Y_i \subseteq L$ the set of labels of the i-th document.

Third step. Human NERD presents to the user an interactive web-based annotation interface used for adding entity annotations or editing automatic pre-annotations in O. As the entities are labeled in O, users (as reviewers) then accept or reject these to indicate which ones are true. Each document $t_i \in O$ is presented to one user. Thus no two users labeled the same document at the same instant of time. This step outputs O with its user corrections. Human NERD logs both the time elapsed during the labeling process, and the number of labeling *actions* taken for each document t_i, i.e., it keeps track of actions like labeling an entity or removing a label incorrectly assigned to an entity.

Fourth step. Based on the user corrections, the NER model can learn and improve from O. In the interactive interface, the user as a data scientist can demand Human NERD to incrementally update the pre-trained deep NER model or build a new one from O. At this step, the system logs the *accuracy* and *loss* over the iterations of the model construction. These data are useful in the next step.

Fifth step. By putting humans in the loop, Human NERD has a *gain*, since the users help to improve the NER model by validating a new massive training set over time. With such data, we expect to increase the NER model accuracy and decrease its

[1] https://youtu.be/KGJeWKO_3Xw
[2] https://spacy.io/

error in short-term. On the other hand, the *drawback* is the human effort by adding entity annotations or editing pre-annotations (third step). To estimate the framework *loss*, we measure the user efforts for annotating the document regarding its length, number of characters, number of entities or number of user annotation actions (editing or adding new entities). As much the deep NER model learns, Human NERD framework becomes more efficient and minimizes the user supervision.

To measure the agreement between the deep NER model (second step outputs) and the user (third step outputs), Human NERD computes the kappa coefficient (k). Cohen's kappa [4] measures the agreement between two raters who each classifies N items into L mutually exclusive categories.

$$k = \frac{p_0 - p_e}{1 - p_e} \tag{1}$$

such that

$$p_0 = \sum_{i=1}^{|L|} \frac{n_{ii}}{n}; p_e = \frac{1}{n^2} \sum_{i=1}^{|L|} n_{i.} \times n_{.i}; \tag{2}$$

where n_{ii}, $n_{.i}$ and $n_{i.}$ are the number of entities: labelled by the NER model and the user in category i, labelled by the NER model in category i, labelled by the user in category i, respectively. Let n be the total number of entities in T. The closer k is to one, the greater the indication that there is an agreement between the model and the user (as a reviewer). On the other hand, if k is closer to zero, the greater the chance of the agreement be purely random. We expect to increase the NER model accuracy over time and to improve the kappa coefficient to a value as close to one as possible.

3 DEMONSTRATION DETAILS AND SCENARIOS

We cover various scenarios that demonstrate the usefulness of Human NERD. An interactive interface is the access point for the user to: (i) upload several unlabeled documents; (ii) validate each individual entity annotation from the output generated by a pre-computed model executed over those documents; The user can also manually label new entities; (iii) re-build the deep NER model to learn from the annotated documents after the user feedback; and (iv) estimate the *gain* and *loss* regarding the improved NER model and the human efforts.

Human NERD considers two types of user: reviewer and data scientist. The former can perform only the task (ii) described above. The later can perform (i), (iii) and (iv). Moreover, the data scientist can remove or add new labels and texts into L and T, respectively.

To examine the quality of our framework, we use a real dataset with unlabelled texts from Police reports. The dataset contains real-world stories in Portuguese language regarding homicides from Fortaleza city (Brazil). We started by using a pre-computed NER model called Wikiner from Spacy framework which includes only four labels: PER, LOC, ORG, and MISC. We removed MISC and added more than 20 label classes like firearm, melee weapon, wrongful death, among others. After that, the Wikiner model classified the reports according to the labels, and the expert reviewers by means of a web interface added and edited entity annotations. From those reviews, Human NERD created a new deep learning NER model for police domain. This data example confirms that Human NERD can be applied in different contexts and languages.

Figure 2: User (as a reviewer) validates the documents annotated by the pre-trained NER model.

It is worth to mention that Human NERD improved Wikiner model with the human help, including its extension for covering new labels and a new data domain. The demonstrated scenarios are as follows.

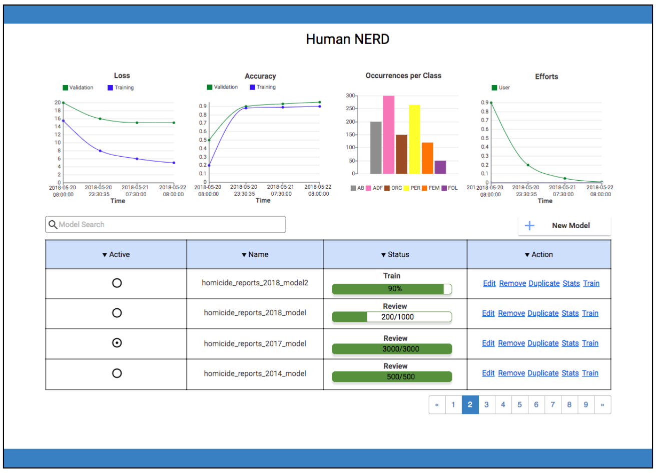
A. Reviewer in the Loop

Human NERD puts the pre-trained model and the human in the loop, so they can actively participate in the process of improving the NER model, using what both know. The model learns as the user goes, based on the labels the user assigns to text excerpts. As shown in Figure 2, the reviewer as a user interacts with the framework through a click-and-drag interface. The framework initially presents a set of documents annotated by the pre-trained model according to a set of label classes L. Each label receives a different color for better visualization.

The reviewer validates one document per time. If he/she agrees with the annotations of the current document (shown in Figure 2), he/she saves the document. Human NERD appends each validated document in a historical dataset, which will be used to improve the deep learning NER model. The reviewer can reject individual entities, in this case, he/she can click on the "x" button. If the reviewer identifies an entity not annotated by the model, he/she can manually label it. In this case, first, he/she should click on the class label (on top of the Figure 2), then the class will appear in evidence. After that, the reviewer selects the sequence of words in the document to annotate. Most annotation tools avoid making any suggestions to the user, to prevent biasing the annotations. Human NERD takes the opposite approach: demands the user to annotate but as little as possible considering that the NER model is continuously improving over time.

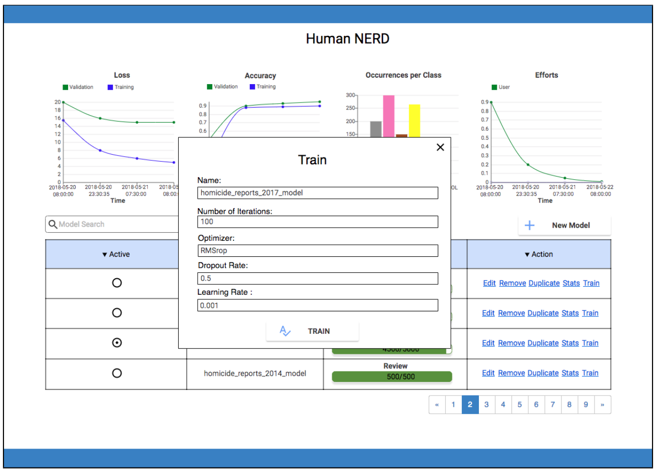
B. Data scientist in the Loop

Human NERD offers a full view of the imported or already trained NER models to the data scientist (Figure 3). A model is active if the framework is currently using it to annotate the documents during the user review (the previous scenario). The framework reports the status of review and train processing. The former corresponds to how many documents the reviewer already validated, and the later to how many epochs already finished during the model training. The data scientist can request the framework to train, duplicate, remove, edit the settings and visualize the statistics of NER models which were imported or trained by the framework.



▾ Active	▾ Name	▾ Status	▾ Action
○	homicide_reports_2018_model2	Train 90%	Edit Remove Duplicate Stats Train
○	homicide_reports_2018_model	Review 200/1000	Edit Remove Duplicate Stats Train
⊙	homicide_reports_2017_model	Review 3000/3000	Edit Remove Duplicate Stats Train
○	homicide_reports_2014_model	Review 500/500	Edit Remove Duplicate Stats Train

Figure 3: Data scientist visualization.



Train

Name: homicide_reports_2017_model

Number of Iterations: 100

Optimizer: RMSrop

Dropout Rate: 0.5

Learning Rate : 0.001

TRAIN

Figure 4: Human NERD enables the data scientist to train a model.

Figure 4 shows the interface presented to the data scientist which enables him/her to train a new model or update a previous one based on the texts validated by the reviewer. Human NERD requires for this functionality the inputs: number of iterations (epochs), optimizer, dropout rate, and learning rate. When the data scientist asks to edit the model settings, he/she can remove or add new label classes.

When the data scientist requests the visualization of statistics, Human NERD framework reports the *gain*, since we expect that the NER model improves over time, and the *user efforts* for annotating documents. Figure 5 summarizes those statistics collected over time when Human NERD trains a model or during documents annotation/validation performed by the reviewer.

4 CONCLUSION

In this demonstration, we proposed a framework called Human NERD to improve named entity recognition models by using a human in the loop. Human NERD relies on deep neural architectures for NER tasks that are free from language-specific resources (e.g., gazetteers, word clusters id, part-of-speech tags) or hand-crafted features (e.g., word spelling and capitalization patterns). We validate Human NERD framework with a real data set from Police reports in the Portuguese language, and we built upon Wikiner from Spacy a new deep learning NER model for this domain. A future work would be to improve the deep learning NER models by using ensemble techniques. Another direction is to provide a collaborative framework to allow multiple concurrent active models and reviewers.

ABSTRACT

This paper demonstrates CURARE, an environment for curating and assisting data scientists to explore *raw* data collections. CURARE implements a data curation model used to store structural and quantitative metadata semi-automatically extracted. It provides associated functions for exploring these metadata. The demonstration proposed in this paper is devoted to evaluate and compare the effort invested by a data scientist when exploring data collections with and without CURARE assistance.

1 INTRODUCTION

The emergence of new platforms that produce data at different rates, is adding to the increase in the amount of data collections available online. Open data initiatives frequently release data collections as sets of records with more or less information about their structure and content. For example, different governmental, academic and private initiatives release open data collections like Grand Lyon in France[1], Wikipedia [2], Stack Overflow [3] and those accessible through Google Dataset Search [4]. Releases often specify minimum "structural" metadata as the size of the release, the access and exploitation license, the date, and eventually the records structure (e.g., names and types of columns). This brings an unprecedented volume and diversity of data to be explored.

Data scientists invest a big percentage of their effort processing data collections to understand records structure and content and to generate descriptions. Useful descriptions should specify the values' types, their distribution, the percentage of null, absent or default values, and dependencies across attributes. Having this knowledge is crucial to decide whether it is possible to run analytics tasks on data collections directly or whether they should be pre-processed (e.g., cleansed). Therefore, several questions should be considered by a data scientist. For example, whether one or more data collections can be used for target analytics tasks; whether they are complementary or not, or whether they can be easily integrated into one data set to be analyzed; whether certain attributes have been cleaned, computed (e.g., normalized) or estimated. Keeping track of cleansing changes is important because such operations can bias certain statistics analysis and results.

Therefore, the data scientist must go through the records and the values exploring data collections content like the records structure, values distribution, presence of outliers, etc. This is a time consuming process that should be done for every data collection. The process and operations performed by the data scientist are often not described and preserved, neither considered as metadata. Thus, the data scientist effort cannot be capitalized for other cases and by other data scientists.

Curation tasks include extracting explicit, quantitative and semantic metadata, organizing and classifying metadata and providing tools for facilitating their exploration and maintenance (adding and adjusting metadata and computing metadata for new releases) [3, 4, 6]. The problem addressed by curation initiatives is to address the exploration of data collections by increasing their usefulness and reducing the burden of exploring records manually or by implementing ad-hoc processes. Curation environments should aid the user in understanding the data collections' content and provide guidance to explore them [1, 2, 5, 8].

Our work focuses on (semi)-automatic metadata extraction and data collections exploration which are key activities of the curation process. Therefore, we propose a data collections' curation and exploration environment named CURARE.

CURARE provides tools in an integrated environment for extracting metadata using descriptive statistics measures and data mining methods. Metadata are stored by CURARE according to its data model proposed for representing curation metadata (see Figure 1). The data model organizes metadata into four main concepts:

- Data Collection: models structural metadata concerning several releases like the number of releases it groups, their aggregated size, the provider, etc.
- Release: models structural metadata about the records of a release (file) including for example the columns' name in the case of tabular data, the size of the release, the date of production, access license, etc.

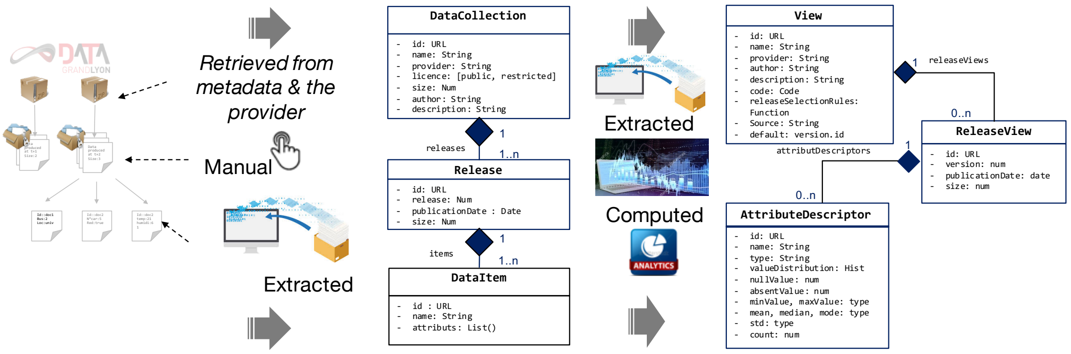

Figure 1: CURARE Model

- Release view: models quantitative metadata of the release records of a data collection. For example, the number of columns and the number of records in a release. A release view can store, for every column in all the records of a release, its associated descriptive statistics measures (mean, median, standard deviation, distribution, outlier values).
- View: models quantitative aggregated metadata about the releases of a data collection.

CURARE also provides functions for exploring metadata and assist data analysts determining which are the collections that can be used for achieving an analytics objective (comparing several collections, projecting and filtering their content). Rather than performing series of self-contained queries (like keyword search or relational ones when possible), a scientist can stepwise explore into data collections (i.e., computing statistical descriptions, discovering patterns, cleaning values) and stop when the content reaches a satisfaction point.

The demonstration proposed in this paper is devoted to evaluate and compare the effort put by a data scientist when exploring data collections with and without CURARE assistance. Through a treasure seeking metaphor we ask users to find cues within non curated Stack Overflow releases. Then, we compare the effort for finding cues by exploring metadata extracted by CURARE. The tasks are intended to show the added value of using metadata to explore data collections for determining whether they can be used for answering target questions.

The remainder of the paper is organized as follows. Section 2 describes the general architecture of CURARE and the extraction of structural and quantitative metadata. Section 3 describes the demonstration scenario for CURARE and the tasks used for measuring user experience during the demo. Section 4 concludes the paper and discusses lessons learned from the demonstration.

2 CURARE

The curation tasks implemented by CURARE are coordinated through a general iterative workflow consisting in three steps: (i) data collections' harvesting (manually or automatically) and preservation; (ii) structural and statistical meta-data extraction; (iii) exploration. The workflow is iterative because data collections can be updated with new releases and therefore releases are harvested recurrently. Similarly, as a result of curated data collections exploration, new metadata can be defined and the processing step can be repeated to include new metadata and store them.

Figure 2: CURARE data curation workflow

2.1 General architecture

Figure 3 shows the architecture of CURARE consisting of services that can be deployed on the cloud. The current version of CURARE are Azure services running on top of a data science virtual machine. The services of CURARE are organized into three layers that correspond to the phases of the curation workflow. They are accessible through their Application Programming Interfaces (API's). Services can be accessed vertically as a whole environment or horizontally from every layer.

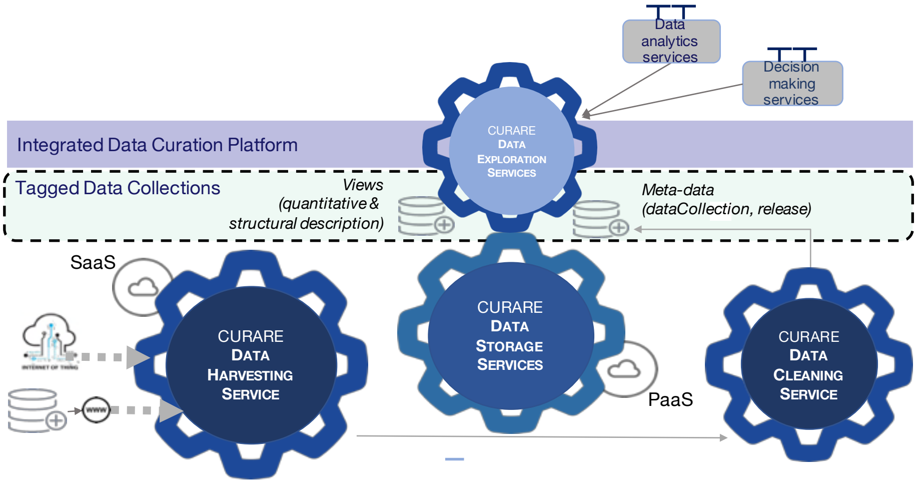
- The first layer is devoted to harvesting data collections and extracting structural metadata like the size, the provenance, time and location time-stamps.
- The second layer addresses distributed storage and access of curated data and metadata.
- The third layer provides tools for extracting quantitative metadata by processing raw collections.

The structural and quantitative metadata of CURARE are organized into four types of persistent data structures implementing CURARE data model (i.e., *data collection, release, view and release view*). According to the CURARE approach, a data collection consists of several sets of data released at a given moment. For example, Stack Overflow is a data collection consisting of packages of records (i.e., releases) produced periodically. A Stack Overflow release provides a kind of snapshot of the whole interactions happening in this social network. It is made available at some point in time. A release view, and a view, are data structures that provide an aggregated and quantitative perspectives of resp. a data collection and its several associated releases.

These data structures are then explored using ad-hoc operators within semi-declarative expressions or programs instead of directly exploring raw data collections. For example, is a release included in another? To which extent a release has new records with respect to others? Which is the percentage of missing values of the releases of a data collection?

2.2 Extracting structural metadata

The *data collection model* shown in the left hand side of Figure 1 provides concepts for representing data collections as sets of releases of raw data. Each release consists of a set of items (e.g.



Data analytics services
Decision making services
Integrated Data Curation Platform
CURARE DATA EXPLORATION SERVICES
Tagged Data Collections
Views (quantitative & structural description)
Meta-data (dataCollection, release)
SaaS
CURARE DATA HARVESTING SERVICE
CURARE DATA STORAGE SERVICES
PaaS
CURARE DATA CLEANING SERVICE

Figure 3: General functional architecture of CURARE

records). The data collections model is used by the data harvesting and cleansing services for organizing structural and context metadata related to collections (provider, objective, URL, item structure).

The demonstrated version of CURARE provides a data collection upload facility for CSV files, which is an explicit data harvesting process. During this process, the structure, the size and release date of the file are extracted automatically. Then, other metadata for example the URI of the provider and the type of license can be provided by the data scientist by filling a formulary.

As said before, metadata are stored by CURARE. Thus, in the exploration phase a data scientist can search for releases of a given size, with a "open source" licence, or produced by a specific provider, expressing queries or executing explicit exported methods.

2.3 Extracting quantitative metadata

The *view model* of CURARE shown in the right hand side of Figure 1 provides concepts for representing quantitative and analytic aspects of the releases of a data collection. For instance, statistics of the content including the distribution of the values of each attribute across the items of a release, missing values, null values.

Depending on the attribute type (only atomic types are considered for statistics) the strategies for computing measures can change. CURARE first defines for every attribute in a tabular file, for example, its type and it approximately discovers possible null, absent and default values. Then, it computes description statistics measures (mean, mode, median, standard deviation, distribution) of the values of every attribute of the structure of the data collection in tabular format. It interacts with the data scientist to decide what to do with those attributes with a domain containing "dirty" values. Should these values be excluded from the computation? Or how can they be adjusted if they should be considered? If values are modified, should CURARE create a new release? Should it be preserved completely tagging the modified values as modified and indicating the applied formula or procedure. This is specified by the data scientist and managed by CURARE. For computing statistics of string values, CURARE processes the strings and creates frequency matrices and inverted indexes for the terms.

CURARE processes collections with many attributes and records that can be somehow costly depending on the tasks the data is used for, and the data volume. Thus, CURARE uses a Spark environment for computing statistics measures that sits on the data science virtual machine [5]. This strategy can be related to existing approaches like the one proposed in [7].

3 DEMONSTRATION OVERVIEW

The demonstration of CURARE uses a Jupyter notebook prepared for performing the tasks intended to test the use of metadata (i.e., entities of the CURARE data model) for exploring data collections. We use the Azure Notebooks environment [6] to run the demonstration. The back-end of the demonstrated version uses the Python data science libraries, nltk [7] for dealing with the processing of string typed attributes. We use ATLAS [8], the clustered public service of MongoDB for storing metadata associated to raw data collections.

The demonstration provides 3 releases of Stack Overflow [9] made available between the 1st. and 4th. January 2018 each consisting in five files "badges", "comments", "posts", "users" and "votes". These files range between ca. 300 KB to 20 MB.

CURARE extracts structural metadata and stores them as Data Collection documents according to its data model. It extracts quantitative metadata and stores them as Views documents. For the demonstration purposes we use a notebook that shows the process and the results. The releases used in the demonstration are processed and the results are stored in Atlas. The result weights 126,5 MB in Mongo and the data collection of structural metadata 9,5 KB.

Demonstration scenario. The demonstration of CURARE shows in which situations it can be useful to have an integrated curation and exploration environment. This can be evaluated through a set of tasks proposed by the demonstration scenario with a game called *The cure challenge*. The objective is to compare the effort when performing tasks to explore Stack Overflow releases manually and with CURARE.

Figure 4: Assessment dashboard results of the demonstration scenario

When the game is activated it gives access to raw data collections and to CURARE metadata. The game consists of two curation matches where a data scientist has to perform the following tasks.

(1) Data collections exploration tasks:
   - Discover the release of the Stack Overflow data collection with the best quality. That is, the one with less missing, null and default values in the posts.
   - Compare the releases size in terms of number of records.
   - Compare releases in terms of values distribution for a given attribute.
   - Compare releases with respect to the topic by comparing terms of a given attribute.

(2) Discover the attribute(s) of the Stack Overflow posts that can be used to compute the popularity of the answers and the reputation of the author (stared answers and authors).

(3) Discover the attribute(s) that can be used to identify the most trendy topics addressed in the release. Will missing, null, default values bias the observation of the trends?

(4) Choose the attributes that can be used as sharding keys to fragment the release using a hash based and an interval based strategy.

In the first match the tasks are done by exploring directly the raw data collections. The second using CURARE's exploration facilities. For both matches a dashboard shown in Figure 4 automatically measures the degree of effort given by comparing with the accuracy/precision and correctness of the answers against time used for providing an answer. These measures are completed with an explicit score for every task given by the data scientist (one star low effort, three stars high effort).

Measuring data exploration effort. The experiment is assessed by comparing the evaluation results of the tasks performed in the two matches. We evaluate:

- Whether the metadata in views provide representative information of the raw content of a release (Q_1 and Q_2)
- How easy it is to see data collection quality in terms of consistency of the structure, the degree of missing, null and absent values of the attributes (Q_2)
- Usefulness of views for exploring the data collections to determine which kind of analytics questions they can answer. (Q_3, Q_4)

4 CONCLUSION AND RESULTS

We demonstrate CURARE that implements a data curation approach integrating metadata describing the structure, content and statistics of raw data collections. Thereby raw data collections can be comfortably explored and understood for designing data centric experiments through exploration operations. The demonstration shows the usefulness of CURARE by measuring the effort of a data scientist for performing exploration tasks in predefined Stack Overflow releases, used as demonstration examples.

5 ACKNOWLEDGEMENT

This work was partially funded by the Rhône-Alpes region through the project AMBED of the ARC 7 program[10] and the LDE Centre for BOLD Cities [11]. The implementation of CURARE was partially funded by the CONACYT "beca mixta" fellowship program of the Mexican government awarded to Irving Hernández Gallegos.

ABSTRACT

We present SparkER, an ER tool that can scale practitioners' favorite ER algorithms. SparkER has been devised to take full advantage of parallel and distributed computation as well (running on top of Apache Spark). The first SparkER version was focused on the *blocking* step and implements both *schema-agnostic* and *Blast meta-blocking* approaches (i.e. the state-of-the-art ones); a GUI for SparkER, to let non-expert users to use it in an unsupervised mode, was developed. The new version of SparkER to be shown in this demo, extends significantly the tool. *Entity matching* and *Entity Clustering* modules have been added. Moreover, in addition to the completely unsupervised mode of the first version, a supervised mode has been added. The user can be assisted in supervising the entire process and in injecting his knowledge in order to achieve the best result. During the demonstration, attendees will be shown how SparkER can significantly help in devising and debugging ER algorithms.

1 INTRODUCTION

Entity Resolution (ER) is the task of identifying different representations (*profiles*) that pertain to the same real-world entity. ER is a fundamental and expensive task for Data Integration [2]. The naïve solution of ER (i.e. comparing all profiles to each others) is impracticable when the data volume increases (e.g. Big Data), thus *blocking* techniques are employed to cluster similar records and to limit the number of comparisons only among the profiles contained in the same block.

In a real-world scenario, to identify a blocking strategy (i.e. the *blocking key*) yielding high recall and precision is a hard task [4]. In particular, in the Big Data context, *schema-aware* techniques have two main issues: (i) schema alignment, hardly achievable with a high heterogeneity of the data; (ii) labeled data to train classification algorithms, or human intervention to select which attributes to combine. To overcome these problems, the *schema-agnostic* approach was introduced [10]: each profile is treated as a *bag of words* and schema-information is ignored. For instance, *Schema-Agnostic Token Blocking* considers as blocking key each token that appear in profiles, regardless of the attribute in which it appears (Figure 1(b)). However, *schema-agnostic* methods produce a very low precision.

So, to mitigate this problem, they are typically coupled with *meta-blocking* [6, 10, 13]. The goal of *meta-blocking* is to restructure a blocking collection by removing least promising comparisons. This is achieved in the following way: profiles and comparisons are represented as nodes and edges of a graph, respectively; each node is connected to another one if the profiles co-occurs in at least one block. Then, the edges are weighted on the basis of the co-occurence of its adjacent profiles and for each profile a threshold is computed. Finally, the graph is pruned removing the edges which have a weight lower than the threshold. A toy example is shown in Figure 1(c): each edge is weighted counting the co-occurring blocks of its adjacent profiles, and is retained if its weight is above the average. The dashed lines are the removed comparisons.

Figure 1: Schema-agnostic (meta-)blocking process.

In [13] we proposed *Blast*, which introduces the notion of *loose schema information* extracted from the data and composed of: (i) *attribute partitioning* and (ii) *attribute partition entropy* (Figure 2(a)). The idea beyond *attribute partitioning* is that more values two attributes share, more are similar, thus similar attributes are put together in the same partition. Then, the *meta-blocking* takes into account the generated attributes' partitions: the blocking key is composed by tokens concatenated to partition IDs; in this way, the token "Simonini" (Figure 2(b)) is split into two tokens, disambiguating "Simonini" as author ("Simonini_1"), and

Series ISSN: 2367-2005

10.5441/002/edbt.2019.66

"Simonini" as cited author; note that "Simonini_1" do not generate any block, since it appears only in p_2.

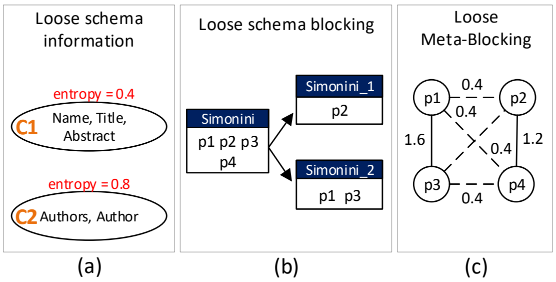

Figure 2: Meta-blocking with loose schema information.

Attribute partition entropy computes the entropy of each cluster and gives more importance to the profiles that co-occurs in blocks generated from clusters with high entropy. The idea is that finding equalities inside a cluster with a high variability of the values (i.e. high entropy) has more value that finding them in a cluster with low variability (i.e. low entropy). The *attribute partition entropy* is used in order to improve the edges weights: each edge of the *meta-blocking* graph is re-weighted according to the entropy associated to the block that generates it (i.e. the entropy of the partition from which the blocking key belongs), as shown in Figure 2(c). This affects the meta-blocking by helping to remove more superfluous comparisons than the ones removed by schema-agnostic blocking (the two retained red edges of Figure 1(c) are now removed).

At the end of the pruning step, the *meta-blocking* produces the *candidate pairs*, i.e. pairs of profiles related to the same entity. Then, these pairs have to be resolved, i.e. it is necessary to decide if a pair is a true match or not, this task is called *entity matching*. Several techniques can be applied to perform this task, e.g. resolution functions, classifiers, crowdsourcing, etc. Finally, , the retained matching pairs are clustered (*entity clustering*) in order to group together all the profiles associated to the same entity.

Several tools were proposed to cover the full Entity Resolution stack [9, 11]. In particular, JedAI [11] is more devoted to work with semi-structured data, a *schema-agnostic* approach, and the *entity matching* phase uses only unsupervised techniques (i.e. no labeled data are required). In contrast, Magellan [9] is meant to work with structured data and a supervised approach, so the user has to align the schema, to provide matches examples to perform *entity matching*, and supervise each step. Moreover, JedAI covers the *entity clustering* step, while Magellan not.

Nevertheless, none of these tools exploits the benefits of distributed computing. Works on the *meta-blocking* parallelization have been proposed [5], but they are implemented using *Hadoop MapReduce*, that is not the best paradigm to exploit modern cluster architectures [3, 12]. SparkER[1] is an Entity Resolution tool for Apache Spark[2] designed to cover the full Entity Resolution stack in a big data context.

Our approach. The first SparkER version [14] was focused on the *blocking* step and implements using *Apache Spark* both *schema-agnostic* [10] and *Blast* [13] *meta-blocking* approaches (i.e. the state-of-the-art ones). The description of the algorithms that we devised for Apache Spark (and any MapReduce-like system) can be found in our technical report [15]. Also, we developed a GUI for SparkER to let non-expert users to use it in an unsupervised mode.

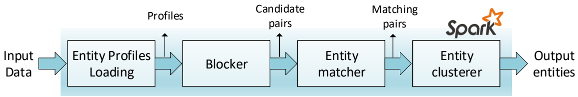

Figure 3: SparkER architecture.

The new version of SparkER that will be shown in this demo, extends significantly the tool. *Entity matching* and *entity clustering* modules have been added. Moreover, in addition to the completely unsupervised mode of the first version, a supervised mode has been added. The user can be assisted in supervising the entire process and in injecting his knowledge in order to achieve the best result.

In the following Section 2, we present the main modules that compose SparkER and in Section 3 the process debugging. Finally, in Section 4 we present the demonstration for the EDBT attendees.

2 SPARKER

SparkER is a distributed entity resolution tool, composed by different modules designed to be parallelizable on Apache Spark. Figure 3 shows the architecture of our system. There are 3 main modules: (1) **blocker**: takes the input profiles and performs the blocking phase, providing as output the candidate pairs; (2) **entity matcher** takes the candidate pairs generated by the blocker and label them as match or no match; (3) **entity clusterer** takes the matched pairs and groups them into clusters that represents the same entity. Each of these modules can be seen as black box: each one is independent from the other.

2.1 Blocker

Figure 4 shows the blocker' sub-modules implementing the *Loose-Schema Meta-Blocking* method described in the introduction.

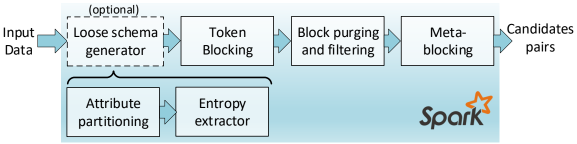

Figure 4: Blocker module

Loose Schema Generator-Attribute Partitioning: attributes are partitioned in cluster using a *Locality-sensitive Hashing* (LSH) based algorithm. Initially, LSH is applied to the attributes values, in order to group them according to their similarity. These groups are overlapping, i.e. each attribute can compare in multiple clusters. Then, for each attribute only the most similar one is kept, obtaining pairs of similar attributes. Finally, the transitive closure is applied to such attributes pairs and then attributes are partitioned into nonoverlapping clusters (Figure 2(a)). All the attributes that do not appear in any cluster are put in a *blob* partition.

[1] https://github.com/Gaglia88/sparker
[2] http://spark.apache.org

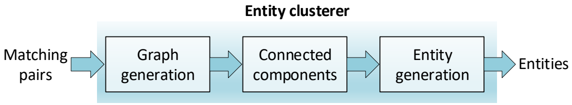

Figure 5: Entity clusterer.

Loose Schema Generator-Entropy Extractor: computes the Shannon entropy for each cluster.

Block Purging and Filtering : the block collection is processed to remove/shrink its largest blocks [10]. *Block Purging* discards all the blocks that contain more than half of the profiles in the collection, corresponding to highly frequent blocking keys (e.g. stop-words). *Block Filtering* removes each profile from the largest 20% blocks in which it appears, increasing the precision without affects the recall.

Meta-Blocking: Finally, the *meta-blocking* method [10, 13] introduced in the introduction is applied. The parallel *meta-blocking*, implemented on Apache Spark, is inspired by the broadcast join: it partitions the nodes of the blocking graph and sends in broadcast (i.e, to each partition) all the information needed to materialize the neighborhood of each node one at a time. Once the neighborhood of a node is materialized, the pruning function is applied.

The output of the `blocker` module are profile pairs connected by an edge, which represent candidate pairs that will be processed by the *entity matcher* module.

2.2 Entity Matcher and Clusterer

Regarding Entity Matching, any existing tool can be used. In the demo we will show the one implemented in Magellan [9]. The `Entity Matcher` produces *matching pairs* of similar profiles with their similarity score (*similarity graph*). The user can select from a wide range of similarity (or distance) scores, e.g.: Jaccard similarity, Edit Distance, CSA [1].

The `Entity Clusterer` receives as input the similarity graph, in which the profiles are the nodes and the matching pairs represent the edges, and partition its nodes into *equivalence clusters* such that every cluster contains all profiles that correspond to the same entity. Several entity clustering algorithms have been proposed in literature [8]; at the moment, we use the *connected component* algorithm[3], based on the the assumption of *transitivity*, i.e., if p_1 matches with p_2, p_2 matches with p_3, then p_1 matches with p_3. At the end of this step, the system produces clusters of profiles: the profiles in the same cluster refer to the same real-world entity.

3 PROCESS DEBUGGING

The tool can work in a completely unsupervised mode, i.e. the user can use a default configuration and performs the process on its data without taking care of the parameters tuning. Otherwise, the user can supervise the entire process, in order to determine which are the best parameters for its data, producing a custom configuration. Given the iterative nature of this process (e.g. the user try a configuration, if it is not satisfied changes it, and repeat the step again), it is not feasible to process the entire input data, as the user should waste too much time. Thus, it is necessary to sample the input data, reducing the size. The main problem is to take a sample that represents the original data, and also contains matching and non matching profiles. This problem was already addressed in [9], where the authors proposed to pick up some random K profiles P^K, then for each profile $p_i \in P^K$ pick up $k/2$ profiles that could be a match (i.e. shares a high number of token with p_i) and $k/2$ profiles randomly. K and k are two parameters that can be set by the user based on the time that she wants to spend (e.g. selecting more records requires a higher computation time).

Each step can be assessed using precision and recall, if a ground-truth is available; otherwise the system selects a sample of the generated profile pairs (e.g. pairs after blocking, matching pairs after matching, etc.) and shows them to the user who, on the basis of his experience evaluates whether the system is working well or not.

In the `blocker` each operation (blocking, purging, filtering, and meta-blocking) can be fine tuned in order to obtain better performances, e.g. the purging/filtering are controlled through parameters that can change the aggressiveness of filters, or the *meta-blocking* can use different types of pruning strategies, etc. Moreover, if the *Loose Schema Blocking* is used, it is possible to see how the attributes are clustered together, and how to change the clustering parameters in order to obtain better clusters.

In the entity matching phase, it is possible to try different similarity techniques (e.g. Jaccard, cosine, etc.) with different thresholds.

At present no tuning activity is possible in the *clustering* step since the connected component algorithm used does not have any parameters. At the end of the process, the system allows to explore the generated entities and to store the obtained configuration. Then, the optimized configuration can be applied to the whole data in a batch mode, in order to obtain the final result.

4 DEMONSTRATION OVERVIEW

During the demonstration, participants will explore the features of our system on the `Abt-Buy` dataset[4]. It contains 2,000 products extracted from *Abt.com* and *Buy.com* catalogs, denoted respectively in red and blue. The dataset comes with a ground-truth that allows to analyze the performances of each `SparkER` step. Also, different datasets can be used[5] during the demonstration.

In this demo we focus on showing the attribute partitioning unsupervised/supervised step, the use of Attribute Partition Entropy was illustrated in our previous paper [7] and the meta-blocking step including entropy.

The tool displays the attributes partitions, recall/precision, the number of blocks (blocking keys) generated, the number of candidate pairs in the blocks, and the number of false positives (i.e. the pairs that are in the ground-truth but are lost during the blocking process) obtained after blocking. Through the interface it is possible to modify the clustering threshold and other parameters (*Advanced settings*) which influence the algorithm in a more marginal way.

We start setting the threshold to the maximum value (1) e.g a schema-agnostic token blocking is applied and all the attributes fall in the same *blob* cluster (Figure 6(a)). Then the user decreases the threshold (0.3) and looks at what happens (Figure 6(b)). Two clusters are created, representing, respectively the name with the

[3] This approach is implemented by using the GraphX library of Spark (https://spark.apache.org/graphx/) that natively implement the *connected component* approach.

Figure 6: Process debugging. The figure shows how it is possible to debug the blocking phase.

description, and the prices of the products. However, we see how precision slightly increases but the number of candidate pairs has been reduced.

Now, the user try to modify the clusters, as apparently separating the attributes that refer to the name from those which refer to the description of products (Figure 6(c)) seems a good idea. He looks at the result and sees that unfortunately the number of false positive increases.

By the *Debug* button it is possible to understand where the false positives come from (Figure 6(d)). The tool shows the list of false positive pairs (i.e. pairs that are in the ground-truth but are not present after the blocking). By clicking on a pair, its profiles and shared *blocking key* are shown and the user can understand why this pair was lost. In the example we can see that the lost pairs match on blocking keys referring to the name and description attributes. So, partitioning descriptions and names was a wrong choice and the automatic solution proposed by the tool was better (Figure 6(b)). Moreover, it suggests that the choice of partitioning the attributes on the bases of their names (i.e. exploting schema information) can be wrong.

Finally, Figure 6(e) shows the debugging of the meta-blocking phase, with the Entropy's values obtained by the Entropy Extractor module. We can see a large decrease in the number of candidate pairs w.r.t. 6(b) thus proving the effectiveness of our technique.

ABSTRACT

Time Series (TS) data are ubiquitous in enormous application fields, such as medicine, multimedia, and finance. In this paper, we present the demonstration with **SE4TeC**: A **S**calable **E**ngine for efficient and expressive **T**ime S**e**ries **C**lassification, which is applicable to certain fields in Big Data context, where the TS features and their extraction process should be interpretable. *SE4TeC* improves the state of the art solutions by proposing a scalable and highly efficient method to classify TS based on characteristic subsequences (i.e., shapelets). We explain the techniques we adopt, and show how to use *SE4TeC* for exploring the real-life datasets in medical diagnosis and in industrial troubleshooting.

1 INTRODUCTION

Tony is informed unhealthy heart status on the basis of his electrocardiogram (ECG) during a medical diagnosis. An experienced doctor can easily correlate the abnormal ECG with the diseases, then explain to Tony the symbolic abnormality in the ECG and the relevant treatment. Nowadays, Machine Learning technique can partly replace the role of an experienced doctor and do the diagnosis very accurately. In Tony's case, the electrical activity of the heart from physiological sensor is collected as Time Series (**TS**). From the perspective of the machine, the diagnosis can be considered as a Time Series classification (**TSC**) problem.

The classical approaches [1] on TSC problems are usually based on the statistical features extracted from time series, such as mean, standard deviation of subsequences, which are assumed to represent the global characteristics of time series. Intuitively, they get very superficial information with low noise tolerance. On the basis of solving these limitations, the **Shapelet** approach [12] has attracted great interest over the past years, owing to its high discriminative feature and good interpretability. However, extracting shapelets from data series has a large computation cost. Even for small sized datasets, the algorithm can take days. This is mainly due to the repeated similarity search between a sub-sequence (i.e., a candidate shapelet) and TS instances in the database. Some typical speed-up techniques (i.e., indexing [11], lower-bounding [6] and early abandoning [12]), introduce always extra parameters, which is difficult to operate without prior knowledge. Some low-dimensional representation methods have also been proposed, such as Piece-wise Aggregate Approximation (PAA) [4], which computes the mean of each subsequence of time series in a given length, and transforms the raw data in coarse-grained sub-components. Symbolic Aggregate approXimation (SAX) [5], transforms subsequences of raw time series into value-characterized symbols, which is eligible for a hierarchic indexing iSAX [2] to accelerate similarity search. Nevertheless, scalability remains the bottleneck.

Our work is biased towards raw time series processing which has a higher accuracy performance, but a relatively high time complexity [12]. Unlike some hardware-based implementations, such as using GPUs to accelerate the similarity calculation [3], we focus on the scalability of TSC based on shapelet extraction. Traditional TSC algorithms on raw TS data are not applicable for big data context, because of their low scalability. Here are our contributions in this paper:

(1) We propose a novel method to assess the importance of shapelets in batches
(2) We introduce a scalable engine to extract the shapelets
(3) Based on the scalable engine, we propose an optimization strategy to speed-up the shapelets extraction.

The rest of this paper is organized as follows. In Section 2, we review the background and state the research problems. We present our scalable engine for Time Series Classification in Section 3. Section 4 shows an empirical evaluation of our method, as well as a guidance for the demonstration. Finally, we give our conclusions and perspectives for future work in Section 5.

2 BACKGROUND

2.1 Definitions and Notations

We start with defining the notions used in the paper:

Definition 1: *A Time Series T* is a sequence of real-valued numbers T=$(t_1, t_2, ..., t_i, ..., t_n)$, where n is the length of T.

Definition 2: *A subsequence* $T_{i,m}$ of Time Series T is a continuous subset of values from T of length m starting from position i. $T_{i,m} = (t_i, t_{i+1}, ..., t_{i+m-1})$, where $i \in [0, n-m+1]$.

Definition 3: *Shapelet* $\hat{s}$ is a time series subsequence which is particularly representative of a class. As such, it shows a shape which can distinguish one class from the others.

Definition 4: *A Dataset D* is a collection of time series T_i, and its class label c_i. Formally, $D = <T_1, c_{j_1}>, <T_2, c_{j_2}>, ..., <T_N, c_{j_N}>$, where N is the number of instances in D. $C = c_1, c_2, ..., c_{|C|}$ is a collection of class labels, where $|C|$ denotes the number of labels.

Definition 5: *Z-Normalization Time Series* is a formal representation of Time Series, which is defined as $ZNormal(T) = \frac{T-\mu}{\sigma}$, where μ is the sample mean, σ is the standard deviation:

$$\mu = \frac{1}{m}\sum_{i=1}^{n} t_i, \quad \sigma^2 = \frac{1}{m}\sum_{i=1}^{n} t_i^2 - \mu \tag{1}$$

Z-Normalization allows us to focus on the structural feature of T, rather than its amplitude value. It addresses the problem of data stability. For instance, assume that the Euclidean Distance(ED) between two time series $T_{x,m}$, $T_{y,m}$ is expressed as follows:

$$ED_{x,y} = \sqrt{\sum_{i=1}^{m}(t_{x,i} - t_{y,i})^2} \tag{2}$$

10.5441/002/edbt.2019.67

Some little changes (e.g., the noise) will cause an evident bias for the result, Z-Normalization is a way of smoothing the bias value.

Definition 6: *Normalized Euclidean Distance(N-ED)*, is expressed by the formula $\sqrt{\frac{1}{m}\sum_{i=1}^{m}(t_{x,i} - t_{y,i})^2}$

Definition 7: *Distance Profile* DP_i is a vector which stores the Normalized Euclidean Distance between a given subsequence/query $T_{i,m}$ and every subsequences $T'_{j,m}$ of a target Time Series T'. Formally, $DP^m_{i,j} = dist(T_{i,m}, T'_{j,m}), \forall j \in [0, n' - m + 1]$

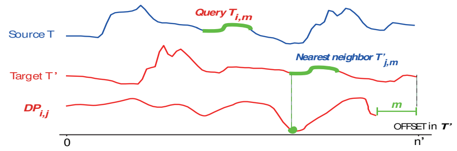

Figure 1: Distance Profile between Query $T_{i,m}$ and target time series T', where n' is the length of T'. Obviously, $DP_{i,j}$ can be considered as a meta TS annotating target T'

Definition 8: *MASS*, namely Mueen's ultra-fast Algorithm for Similarity Search, computes Distance Profile based on Fast Fourier Transform(FFT), which requires just $O(nlogn)$ time, other than $O(nm^2)$ time in classical *N-ED* similarity search.

Definition 9: *Matrix Profile MP* is a vector of distance between subsequence $T_{i,m}$ in source T and its nearest neighbor $T'_{j,m}$ in target T'. Formally, $MP^m_i = min(DP^m_i)$, where $i \in [0, n - m + 1]$.

Unlike the distance profile, the matrix profile is a meta TS annotating the source time series. The highest point on MP corresponds to the TS discord, the lowest points correspond to the position of a query which has a similar matching in target TS.

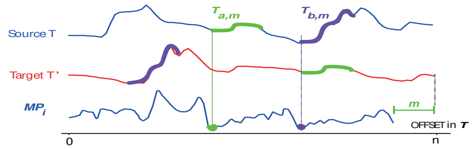

Figure 2: Matrix Profile between Source time series T and Target time series T', where n is the length of T. Intuitively, MP_i shares the same offset as source T

2.2 Evaluation of Candidate Shapelets

The quality of a candidate shapelet $\hat{s}$, can be assessed by its ability to separate the instances of different class in the dataset D. A prerequisite of the quality measure for $\hat{s}$, is that a set of distance $D_{\hat{s}}$ must be calculated, where $D_{\hat{s}} = D_{\hat{s},1}, D_{\hat{s},2}, ...D_{\hat{s},n}$, n is the number of T in dataset D.

Information Gain, an evaluation method based on Decision Tree, is widely adopted in previous works [12]. An iteration test of $D_{\hat{s}}$ is conducted to extract the split distance which brings the highest Information Gain. The distance instance will be applied as a property of candidate Shapelet, to check the inclusion between the candidate and time series. Another simple approach, is to use the F-Statistic [7], based on the difference of means in an Analysis of Variance A(NOVA). The main idea of this statistic method, is to assess the difference in distributions of $\hat{s}$ between the class distances.

2.3 Problem Statement

The high degree of coupling inside classical TSC algorithm [12] leads to the problem of not being able to parallelize. The speedup method such as Early Abandoning [12] is based on classical Euclidean Distance measure, which has a time complexity of $O(N^2n^4)$ with several orders of magnitude higher than *MASS* [8]: $O(N^2n^3logn)$. Another common trick played by previous work [12]: If we know $\hat{s}$ is a low-quality candidate, then any similar subsequence $\hat{s}'$ to $\hat{s}$ must also result in a low quality and therefore, a costly computation of the distance set $D_{\hat{s}'}$ (evaluation of $\hat{s}'$) can be skipped. However, a candidate shapelet is evaluated by its quality ranking among all candidates of the same length. Assume that the distributed nodes have generated from dataset a collection of candidates $\hat{s}_l$, an aggregation operation between nodes is required to extract the candidate with the best quality. Extra aggregations will be made along with the iteration of candidate length. Apparently, the acceleration from the classical pruning techniques can be easily offset by the communication cost caused by the aggregation.

3 SYSTEM OVERVIEW

The main idea of our system is that the calculation should be shared and executed independently, less communication between the nodes, more powerful the algorithm would be.

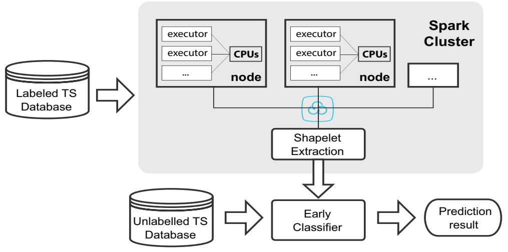

Figure 3: System overview

3.1 Main Structure

The conventional Time Series classification problems are tackled with nearest neighbor (kNN) algorithm [12] due to its easy-design feature. As shown in Figure 3, on the basis of kNN, an early classifier [10] adopted in the system allows to give the prediction result as earlier as possible without waiting for the entire sequence. The processing of labelled Time Series data requires to be flexibly arranged for nodes in the cluster, where the executors share the CPU/memory resource. To this end, a suitable algorithm is applied here allowing assignment of computing tasks which are relatively independent of each other.

3.2 SMAP: Shapelet Extraction on MAtrix Profile

Matrix Profile provides a meta-data which facilitates the representation of a complex correlation between two time series. As shown in *Algorithm 1*, *SMAP* takes the time series as the smallest processing unit between nodes, and utilizes the normalized quality to extract the most important parts in each processing unit and then merges them by an aggregation process. For this reason, the number of candidate shapelet could be greatly reduced. Moreover, a single aggregation is required to get the global shapelet result of different class. In *line 5*, dataset is broadcast to distributed nodes in order to reduce the communication cost caused by accessing the common data. Then, each cluster partition shares the computing tasks for a set of time series. The function *computeDiscrimP* aims at computing in batches the quality of candidate shapelets. The visualized process is shown in **Figure 4**.

The batch quality of instances in a TS is defined by *Discrimination Profile*, which refers to the concept *Representative Profile*:

$$RP(T_i^C, D) = avg(MP_{T_i^C, T_j}) \tag{3}$$

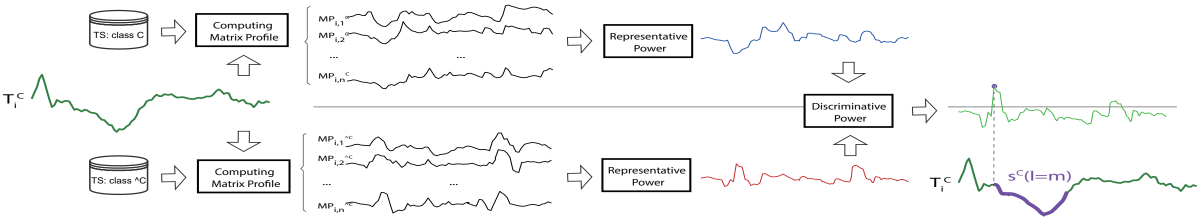

Figure 4: Discrimination Profile Extraction

Algorithm 1: SMAP(Shapelet on MAtrix Profile)

```
   Input: Dataset $D$, classSet $\hat{C}$, $k$
   Output: $\hat{S}$
1  $minLength \leftarrow 2$, $maxLength \leftarrow getMinLen(D)$
2  double[] $DiscmP \leftarrow []$, double[] $DistThresh \leftarrow []$, $\hat{S} \leftarrow \emptyset$
3  $D$.cache(); //cache all the dataset in the cluster, where each time series has an unique ID
4  MapPartition $(Set\ of < ID, T >: T_{set})$
5      for $< ID, T > \in T_{set}$ do
6          for $m \leftarrow minLength$ to $maxLength$ do
7              $DiscmP[m], DistThresh[m] \leftarrow computeDiscmP(T, D, m)$
8              $DiscmP[m] \leftarrow DiscmP[m] * \sqrt{1/l}$
9          $DiscmP \leftarrow pruning(DiscmP)$
10         emit(DiscmP, DistThresh)
11 MapAggregation $(class, (DiscmP, DistThresh))$
12     for $c \in \hat{C}$ do
13         $\hat{S}' \leftarrow getTopk(DiscmP[c], DistThresh[c], k)$
14         for $\hat{s} \in \hat{S}$ do
15             $\hat{s}.matchingIndices \leftarrow getMatchingIndices(\hat{s}, D)$
16         $\hat{S} \leftarrow \hat{S} \bigcup \hat{S}'$
17 return $\hat{S}$
```

where $T_j \in D^C$. Representative Profile targets thus on the minimal processing unit (i.e., time series) in SMAP, which shows a vector of Representative Power of each instance in the processing unit. To put it simply, the *Representative Power* of a subsequence in class C, is its normalized distance to the global instance cluster of class C. Intuitively, it represents the relevance between the subsequence (i.e., the candidate shapelet) and the class.

The fact that a subsequence is discriminative for its class towards others, can be expressed by the difference of Representative Power from class C to others *(OVA, one-vs-all). Discrimination Profile* is then defined as follows:

$$Discm_{Profile}(T_i^C, D) = -(RP(T_i^C, D^C) - RP(T_i^C, D^{!C})) \qquad (4)$$

A quality *Normalization* in *line 8* is made which allows to assess the Discrimination Power for shapelet of different length in an uniform way. Similar as the concept *Information Gain*, but Discrimination Profile is a technique more interpretable serving to assess the candidate shapelets. Moreover, in this manner, a split distance can be given directly, other than iterating every possible distance and deciding the best one with the highest Information Gain, in time $O(N^2n^2)$. A strategy to check if T contains a shapelet can be defined as the following:

$$sInT(T, \hat{s}^C) = \begin{cases} true, & if\ dist(T, \hat{s}^C) \le RP(\hat{s}^C, D^C) \\ false, & otherwise \end{cases} \qquad (5)$$

3.3 Optimization Strategy

The pruning function in *line* 9 is capable of eliminating the number of candidate shapelet, and then reducing the communication cost during the aggregation process. We can simply take the "TopK" strategy, which extracts the biggest K values of the *Discrimination Profile*. However, such a technique is far from lightening the computation during *MapPartition* process.

Since each processing unit should be independent from each other, a tenable technique for updating the profile of a long range query could be adopted. The *Lower Bounding distance* [6] is defined to estimate a minimal possible Z-Normalized Euclidean Distance between two subsequences $T_{i,l+k}$ and $T_{j,l+k}$, based on the distance already computed between $T_{i,l}$ and $T_{j,l}$. Compared to a linear time complexity of computing the exact distance, LB Distance Profile can be calculated in a constant time, which can accelerate greatly the computation of Matrix Profile in *Figure 4.* For example, from shapelet length $l = m$ to $m + 1$, the time complexity of computing the distance $d_{i,j}^{l+1}$ is $O(n\frac{m(m-1)}{2}m)$, where $j \in [0, n\frac{m(m-1)}{2}]$ which represents the number of subsequences in D, n is the number of instance in D, m is the length of the longest instance in D. Accordingly, LB distance takes $O(n\frac{m(m-1)}{2})$ which shows an apparent advantage when the query length is relatively long. Lower Bounding distance [6] is defined as:

$$LB(d_{i,j}^{l+k}) = \begin{cases} \sqrt{l}\frac{\sigma_{j,l}}{\sigma_{j,l+k}}, & if q_{i,j} \le 0 \\ \sqrt{l(1 - q_{i,j}^2)}\frac{\sigma_{j,l}}{\sigma_{j,l+k}}, & otherwise \end{cases} \qquad (6)$$

where $q_{i,j} = \frac{\sum_{p=1}^{l} \frac{(t_{j+p-1} t_{i+p-1})}{l} - \mu_{i,l}\mu_{j,l}}{\sigma_{i,l}\sigma_{j,l}}$

Empirically, the matching subsequence $T_{j,l}$ which is the nearest neighbor of $T_{i,l}$, can deduce a longer subsequence $T_{j,l+1}$, which is probably the nearest neighbor of $T_{i,l+1}$. Assume that the matching subsequence keeps in the same position in T_{target} when query $T_{i,l}$ length increases, then the time complexity for computing the minimal distance between $T_{i,l}$ and T_{target} is $O(l)$, other than $O(l(n - l + 1))$. As mentioned in **Definition 9**, $MP_i^m = min(DP_i^m)$, the main idea here is to utilize LB Distance to accelerate the computation of $min(DP_i^m)$, rather than computing the entire DP_i in a higher time complexity.

4 ABOUT THE DEMONSTRATION

This demonstration is intended to show a distributed approach to extract features from large-scale time series and to make the extraction process and extracted features very easy to understand and interpret, thanks to the visual power of shapelets. Through this demonstration, the attendees will have a general understanding of time series, as well as its application areas and the current challenges. With two real datasets, attendees will have the opportunity to experience and interact with *SE4TeC* from two aspects:

(1) *Practical operation for distributing computation tasks:* The attendees are invited to connect to our elastic cluster, and will further explore the distribution mechanism for feature extraction. For instance, the relationship between performance and adjustable parallelism, the progress monitoring of parallel tasks on each distributed node, etc.
(2) *Exploration of shapelet extraction process:* Based on a small-sized dataset, the attendees can interactively perform each intuitive step shown in *Figure 4,* and are invited to analyze the hidden meaning behind each intermediate features.

In the view of the attendees, the reliability of extracted shapelets can be proved by utilizing naked eyes or a smart classifier, on a test instance.

4.1 Demonstration Platform

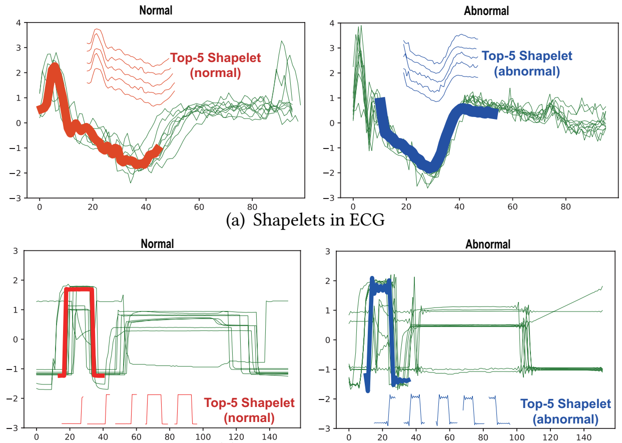
SE4TeC is implemented by Python3.6, powered by Apache Spark. The program is executed on AWS EMR cluster. We provide also an 1-click cluster based on Docker, to facilitate the attendees to replay the distributed test offline. The baseline of the evaluation is **USE** in [9], which utilizes the traditional method for shapelet extraction based on Information Gain. **1NN** classifier is applied for all accuracy tests, and **5** shapelets are extracted for each class.

4.2 Demonstration Scenario

Due to page limitations, here we show two examples, more details and videos can be found on the demonstration page[1].

4.2.1 ECG medical diagnosis. The dataset **ECG200**, from MIT-BIH Long-Term ECG Database (ltdb), is collected by two electrodes which record the brain activities in distinct body positions. Each heartbeat has an assigned label of normal or abnormal. All abnormal heartbeats are representative of a cardiac pathology known as supraventricular premature beat. ECG200 contains **100** labelled records with a fixed length of 96.

4.2.2 Wafer industrial troubleshooting. To put the evaluation into larger scale context, we choose the time series dataset **Wafer**, which contains **1000** training records with a fixed length of 152. The dataset, collected during the manufacture of semiconductor microelectronics, comprises a collection of sequences for the measurements recorded by one vacuum-chamber sensor during the etch process applied to one silicon wafer. The class of manufacture quality can be normal or abnormal.



(a) Shapelets in ECG

(b) Shapelets in Wafer

Figure 5: Interpretable Shapelet Feature Results

Reliability & Interpretability: Through the demonstration, the attendees are capable of extracting the shapelets in various manners, and comparing their difference. The shapelets extracted by SMAP are shown in *Figure 5*, which has a relatively higher prediction accuracy than USE: 84%|76% (ECG), 97%|92% (Wafer).

Scalability: The performance results are shown in *Figure 6*. $SMAP_{LB}$ shows a gain in performance: **24.5X** (ECG), **587.3X** (Wafer) faster. As the size of ECG (i.e., 100) is lower than the parallelism power when we expand the cluster to 10 nodes, therefore, according to the time $O(N^2 n^3 logn)$, the instance length n will be the decisive factor in execution time. We should know that the speed-up performance relies on the computing power of the cluster. We are more inclined to consider its parallel capability which can be assessed by the aggregation cost between distributed nodes. From 1 to 30 nodes on cluster mode, the aggregation cost for *Wafer* increases by **181%**, the total cost drops to **0.68%**. Obviously, considering the gain, the aggregation cost can be ignored when we expand the cluster to a larger scale.

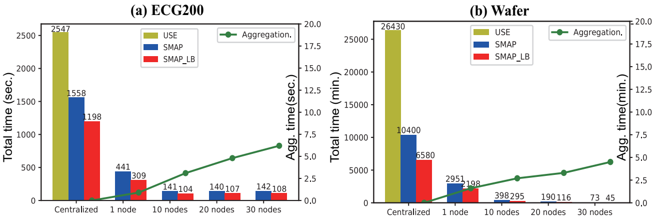


Figure 6: Scalability performance

5 CONCLUSION

In this paper, we have proposed a novel methodology, namely SMAP, for Time Series Classification. SMAP adopts the concept of Matrix Profile, and extracts the shapelet features in an interpretable and scalable manner. Within SMAP, the Discrimination Profile is defined to assess in batches the quality of candidate shapelets. On the basis of Lower Bounding, we have proposed an acceleration strategy that benefits from distributed environment. The satisfactory results proved the efficiency and competitiveness of our approach. Different optimizations are in our planning list. Specifically, we intend to expand SMAP for longer time series, while ensuring its high accuracy and scalability. This may lead us to combine SMAP with dimensionality reduction.

ABSTRACT

We demonstrate a methodology of masking system failures in a way that doesn't require programmer or operational intervention, and that strives to be imperceptible to the client. High Availability SQL (HASQL) masks system failures in a clustered database-system by *seamlessly* restoring a transaction's state against a different machine in the cluster. We have implemented HASQL in Comdb2, an open source RDBMS developed by Bloomberg L.P.

To demonstrate, we allow participants to kill (via a button) database instances one at a time, and all instances simultaneously, as we execute an ongoing transaction against a Comdb2 cluster. Upon achieving this, viewers will see the command-line session and transaction pause briefly as the Comdb2 client-API connects to a different cluster node and re-establishes the transaction's state, allowing it to resume processing at the exact point of the disconnect. We repeat this demonstration, showing that a transaction's state can be correctly re-established even though it is midway through consuming a result set.

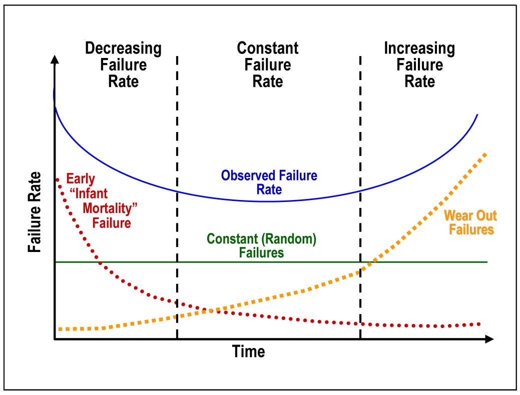

Figure 1: 'Bathtub curve' hazard function, adopted from [1], describes the failure rate of a single-component.

1 INTRODUCTION

Plummeting hardware prices have created increasing pressure on software developers to design redundant systems, as the chance for failure for any component of a system increases over time (see figure 1). For RDBMS systems, *High-Availability* solutions attempt to restore service quickly and minimize the effects of outages[2]; indeed, many commercial RDMBS systems[3, 5, 6] support automatic failover to provide uninterrupted service under the loss of part of a database cluster. In traditional failover strategies, a crashed server will return a `CONNECTION LOST` error to the client. Application writers address this by programming defensively, marrying database API calls to complex and often poorly tested retry logic[7]. Handling a `CONNECTION LOST` error in response to a `COMMIT` directive gives the programmer the additional burden of determining the fate of that transaction.

Our contribution is unique in that we show how to provide *seamless* continuation of in-flight transactions under an *optimistic concurrency control (OCC)* system: HASQL clients do not reissue SQL in the face of machine failure, and need not be aware that a machine failure has occurred, as every in-flight transaction will be automatically re-established and continued against another machine in the cluster, and any partially consumed result set will continue to be returned, as the system we describe guarantees that the client will never experience duplicate or missing data.

Oracle's *Application Continuity*[4] feature is a proprietary implementation which achieves the same goal. As we have implemented this as part of an open source system, we are able to describe our methodology explicitly, and we hope that by doing so, other systems can likewise provide this feature to their users. We note that any correct methodology will ensure that the replayed SQL modifies the same set of records that would have been modified on the original host, but that in an OCC system, write conflicts for replayed transactions are handled in the same manner as write conflicts for any two competing transactions: the winning transaction will be allowed to modify the rows in its write-set, while the losing transaction will return a verify error to the client. So even though HASQL provides the ability to perfectly replay a read-write transaction, as with every transaction in an OCC system, the replayed transaction will only be able to commit successfully if the rows in its write-set have not been modified.

In this paper, we describe HASQL as implemented in Comdb2, an open source RDBMS developed at Bloomberg L.P.[1], noting that a brief overview of HASQL was outlined in [8]. As this method relies on a limited number of architectural features, we describe it generally, trusting that it should be straightforward to implement HASQL in a similar system. Our motivation for this feature grew organically from Bloomberg's business need to have an *always available* database server and to provide an intuitive and reliable software infrastructure layer to its application developers. HASQL achieves this by shifting the responsibility for handling hardware failures from the client application to the database system.

2 SYSTEM OVERVIEW

We now describe the architecture and methodology for implementing HASQL. See [8] for a comprehensive review of Comdb2's architecture.

2.1 Architecture

A *database cluster* consists of N *database instances* running on N physically separate machines sharing no components and connected to each other by a network. Each instance contains a complete copy of the data, and is able to start and maintain arbitrary point-in-time snapshot transactions.

The cluster maintains a single *master* which may modify database state, and which synchronously replicates these modifications to every other instance in the cluster. We assume that transactions are immutable and are applied atomically on the master in a serial order defined by the global order of transaction `COMMIT`s.

For any two committed transactions, T1 and T2, if T1 is committed first, a point-in-time snapshot transaction started at T1's commit point will observe all the effects of T1's modifications, and none of the effects of T2's modifications, while new snapshot transactions will observe the effects of both T1 and T2. Modifications are applied to non-master instances (or *replicants*) atomically in the same serial order as they were applied on the master.

A *point-in-time token (or PIT-token)* identifies a specific point in the serial order of committed transactions. Given a PIT token, each instance is able to produce a snapshot view corresponding to that point in the serial order. The *transaction-id (tid)* is a unique identifier for a transaction; it is generated by the client API at the beginning of a transaction.

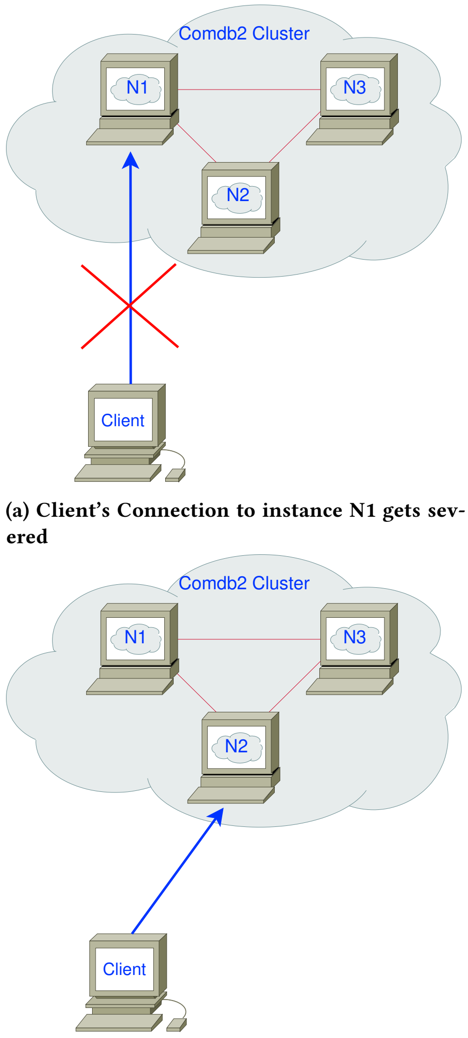
Writes performed against a replicant are not executed locally, but rather validated and executed on the master after the client issues a `COMMIT`. The client API is aware of the cluster's topology and maintains a single connection against an arbitrary replicant.

2.2 Methodology

At the beginning of a transaction, the client API generates a tid, establishes a connection against a replicant (if not already connected), and retrieves from that instance a PIT-token corresponding to the current state of that instance. As transactions are applied in the same order on replicants as they are on the master, the snapshot described by this PIT-token is guaranteed to be equivalent to the current or some former state of the data as it existed on the master, and may be used on any instance to recreate the same snapshot so long as that instance has applied transactions at least up to that point. During the course of the transaction, all write statements and the most recent read statement are cached by the client API. It's important to note that the results returned by the most recent read statement need not be retained: rather, the API retains only a count of the rows already retrieved from an in-flight `SELECT` statement.

Upon losing connection with the cluster, the client API reconnects to a different instance and begins a snapshot transaction at the time described by the original PIT-token, as doing so ensures that the client's view of the database on that instance will be identical to its view on the original. The client API then re-issues the transaction's write statements. If the connection was lost while the client was consuming results of a read statement, the client API re-issues the most recent read statement using the cached count to skip (or alternatively, ask the server to skip) records that have been previously returned to the user.

At commit time, the tid is used as a key to store the transaction's result in a replicated *global-transaction-table*. The pre-existence of a tid in the global-transaction-table indicates that the transaction has already executed, and that the current thread should roll back any work that it has done and return the original result to the client. The tid and the global-transaction-table ensure that a transaction will only be executed once should the client API replay a transaction after issuing a `COMMIT`.



(a) Client's Connection to instance N1 gets severed

(b) Client reconnects to instance N2

Figure 2: Connection to Cluster gets severed and Client subsequently reconnects to a different instance.

2.3 Illustrated Example

We describe a concrete example using the event diagram shown in Figure 3. Events in green represent SQL statements submitted by the user. Events in blue represent operations executed on behalf of the user by the client API code. Server responses are displayed in black.

As previously described, upon beginning a transaction, the API generates a unique tid, which is sent to the server along with the `BEGIN` statement. The server responds with the PIT-token. Each write statement of the transaction is cached locally as it is sent to the server. Figure 3 shows a failure occurring after reading the second record of a `SELECT` statement. The client API reconnects to Node 2, begins a transaction at the point-in-time described by the PIT-token, reissues the transaction's write statements, and the most recent incomplete `SELECT`. As the first two rows have been returned to the application, the client API skips them, returning the third result row to the caller. The client finally issues a COMMIT to complete the transaction.

2.4 Considerations

The HASQL scheme as described above works with SQL which behaves deterministically. It requires that each participating instance impose the same implicit order for results not sorted by an ORDER BY clause. We note also that the implicit ordering requirement does not exclude server-side parallelism, but concede that any ORDER BY clause, either explicit or implicit, may incur a performance penalty.

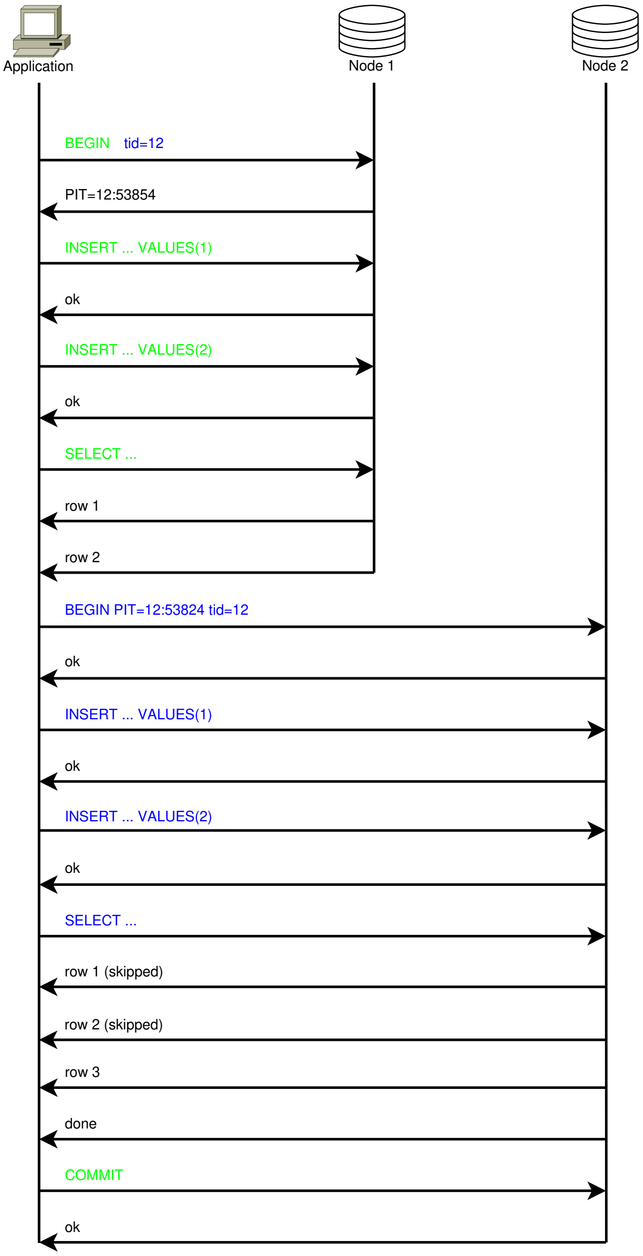


Figure 3: Example HASQL sequence: After connection to Node 1 is severed, Client Application reconnects to Database Cluster Node 2, and continues processing where it left off.

We now consider strategies for handling other non-deterministic SQL. Rather than attempting to address this exhaustively, we consider two situations which can employ a similar strategy; we offer this strategy as a blueprint for how non-determinism might be addressed.

```
BEGIN
DELETE FROM schedule WHERE updatetime <= NOW()
SELECT * FROM schedule
COMMIT
```

Listing 1: SQL using the NOW() function

If replayed, the NOW() function will execute at a different time on a second machine, and delete a different set of records. A replay which occurs during the SELECT could have already returned records which are deleted on the retry. The replay would subsequently skip over *non-deleted* records, as the client API's cached count pertains to the original result set. To address this, we propose that NOW() be frozen during the course of a snapshot transaction, always returning the wall clock time of the BEGIN issued on the original node. This time can be included as part of an extended PIT-token.

```
BEGIN
UPDATE contestants SET winner = 1 WHERE
    ticketnumber = (SELECT ticketnumber FROM
    contestants ORDER BY RANDOM() LIMIT 1)
SELECT * FROM contestants ORDER BY ticketnumber
COMMIT
```

Listing 2: SQL using the RANDOM() function

Because RANDOM() can return a different value on the replay machine, the re-issued UPDATE statement can update a different record. Should a replay event occur while retrieving results from the SELECT, the result set can show that two different contestants have winner set to 1. A system could work around this issue by making note of the RANDOM() number generator's current *seed* value at the beginning of a transaction. A replicant which seeds its RANDOM() number generator with this value should return the same sequence of random numbers as the original machine. As with NOW(), the seed value could be included as part of an extended PIT-token.

3 DEMO

We present a simple interactive demonstration which exhibits the HASQL scheme. We begin by starting a 3-node cluster and presenting a volunteer with three buttons, each programmed to stop and restart the database instance running on one of the cluster nodes. From a separate machine, we open a command-line session and begin a transaction against this cluster. Our volunteer will be instructed to press, at his or her discretion, the kill-and-restart-button corresponding to the machine that is currently executing the transaction. We present this as a simple game, allowing us to demonstrate the HASQL feature in a lighthearted and engaging way.

When the volunteer kills the correct instance, spectators will see the client-session pause briefly as the client API reconnects to a different cluster machine. We encourage our volunteer to kill and restart the active cluster node multiple times as we continue the transaction, being sure to demonstrate HASQL's ability to resume a transaction in the middle of retrieving a result set.

We then perform a second demonstration which is identical to the first, except that instead of killing a single cluster node, we ask

three volunteers to kill all three cluster nodes simultaneously. As the cluster restarts, spectators will see again that the transaction is resumed seamlessly.

We proceed to describe our implementation of HASQL, and repeat both demonstrations with additional trace enabled, which allows audience members to witness the sequence of events outlined in Figure 3. In contrast to seemlessly continuing a transaction, this demonstration seeks to exhibit HASQL's underlying mechanism.

We further explore HASQL's behavior by repeating both demonstrations, this time with an increased number of database instances, and with varying levels of background writes. Spectators will observe that HASQL's performance is unaffected by the increased cluster size, but that it is directly impacted by external writes to a table which an HASQL transaction reads. We use this as a starting point for a discussion of Comdb2's implementation of point-in-time snapshot isolation and other architectural features of Comdb2.

4 FUTURE WORK

A transaction which survives a machine crash naturally takes longer to complete. While this does not effect the correctness of a read-only query, the increased transaction time increases the likelihood that a write transaction, T1, will fail, as it allows greater opportunity for a competing transaction to write in the space of T1's write-sets. This is a small concession to make, as prior to HASQL, a machine crash would certainly cause T1 to fail, and there are a great number of non-intersecting write loads that would permit T1 to commit.

Future work includes finding ways to minimize the amount of time it takes to restore a partially completed transaction. We observe that the slowness is most pronounced when a machine crash occurs after a client has retrieved a substantial part of a large result set which must be skipped.

We could gain substantial improvement by maintaining simultaneous connections to multiple cluster machines, using the original PIT-token from the *primary* connection to establish one or more *secondary* connections. Each SQL statement would be issued to the primary and to the secondary handles in lock-step. In the normal case, the redundant sessions are essentially wasted computing power, but as hardware resources continue to become cheaper, this may eventually be a valid concession to make.

5 CONCLUSION

HASQL's contribution is one of resiliency: application developers need not know or care if the underlying system has experienced a critical error. We believe this is superior to other failover schemes, where a machine failure, in addition to failing all outstanding transactions, can stall clients for several minutes before a failover machine is available. An API return code which does not designate the success or failure of an operation places a disproportionate burden on the application programmer in answering a question which would be more appropriately addressed by the database system itself. Though we concede that this is unavoidable at times, HASQL addresses a significant subset of these errors. As hardware is guaranteed to fail, it is the responsibility of system designers to minimize the impact of failure. HASQL demonstrates an intelligent way to utilize increasingly less expensive hardware to create more robust service.

ABSTRACT

In this paper, we explain the demonstration of the DataEconomist, a framework for query-driven data minimization in relational DBMS conformable to law. Our approach automatically minimizes user access rights based on the analysis of SQL query logs and thereby enables a parsimonious data processing. A minimization of data collection is reached by automatic detection and manual deletion of data belonging to unneeded schema elements.

In contrast to existing approaches, the DataEconomist supports privacy officers by focusing on the queries instead of making them trawl through a vast amount of collected personal data and specify legal use cases for their processing. SQL queries easily show who has processed when which data for which purpose and make it easy for the privacy officers to decide about the queries' compliance with data privacy regulations. Our framework does not require any knowledge of SQL by providing a graphical tool for searching and filtering queries and visualizations of query result sets.

1 INTRODUCTION

The new EU General Data Protection Regulation (GDPR) has an impact on every organization around the world [16], but most of them are prepared inadequately and are not aware of upcoming legal requirements [4]. They face the challenge of adapting their handling of personal data to become compliant to the contemporary requirements of data privacy. Art 5(1) GDPR postulates data minimization, which is one of the six general data-protection principles of the GDPR [1]. It requires that all collection and processing of personal data is only for a specific purpose, and that the quantity of these data is kept down as much as possible, so they are stored only as long as it is required to reach the intended purpose [15]. There are approaches like privacy by design [17] that include privacy protection in the overall conception of technical systems, but the vast majority of current systems does not consider these approaches. In order to ensure conformance to the principle of data minimization it is not sufficient to analyze the collected data sets only. This does not provide a possibility to verify that the data processing is exclusively for a specific purpose. But the responsible privacy officers often lack technical knowledge, which is usually required for the evaluation of data processing.

Problem Statement. In order to enable privacy officers to ensure data privacy in established systems, novel approaches are required, which provide mechanisms that do not premise profound technical knowledge to determine who collects personal data from where and who processes when which data for which purpose. The mechanisms must provide user-friendly interfaces and a data-processing description close to natural language [7].

Contribution. We demonstrate an extensible framework for query-driven data minimization in existing IT landscapes. We analyze SQL query logs and enrich queries with meta-information about the query structure, their environment, their execution, and their context. In contrast to currently trending approaches, queries are our first-class citizens for analysis of conformance to data privacy, instead of trawling through data stores that harbor vast amounts of personal data. Our framework aims to complement such approaches and supports privacy officers in minimizing user access to personal data, minimizing the storage of personal data to what is really necessary, and preventing future collection of unnecessary data.

Our framework is minimally-intrusive because it has no impact on productive operations. It can serve as a foundation of a system that automatically identifies unneeded schema relations and attributes in target databases (DBs), based on the queries running on these systems. Queries can be classified manually as legal or illegal regarding data-privacy regulations. User access rights can automatically be customized, and unnecessary data can be automatically deleted from the target DBs. Furthermore, we list the queries and the related users that have inserted unneeded data into the target DBs.

This paper describes the client-server architecture of our framework (cf. sec. 2.1), illustrates the conceptual schema for the query characteristics, i. e. the queries and their meta-information (cf. sec. 2.2), and outlines the reference implementation of the DataEconomist (cf. sec. 2.3). In [12], we have already described a user story from a healthcare scenario to emphasize our approach's benefits for ensuring data privacy, especially data minimization.

2 SYSTEM OVERVIEW

The software system is implemented with a client-server architecture using Web technologies. An end user can have three different roles: administrator, DB user, and privacy officer. Each of them needs to interact with the system, so it has to be accessible from different personal machines. Splitting the application into a client and server part allows for that and additionally simplifies initial setup for end users.

2.1 Client-Server Architecture

Internally, the DataEconomist server uses a PostgreSQL DB to persist query characteristics. It also connects with target DBs when needed to retrieve meta schemas required to understand the queries and execute them when requested. It supports all major relational DBMS and the Java JDBC API as well as standard SQL and several of its dialects.

The multi-user Web client is platform independent and does not require any kind of installation for the end user. It communicates with the server over HTTP using a RESTful JSON API.

The backend is implemented in Java using Apache Calcite [6] and the Spring Framework[1]. Fig. 1 shows its architecture.

The *Query Manager* and the *Database Manager* take care of ensuring consistency between main-memory representations of Query and Database objects and their DB entries. We must store additional information about these objects to control the redundancy. For queries, this information includes syntactical correctness, the number of restrictions, compliance with user privileges, and other potentially interesting properties. For target DBs, we fetch and store the schema in Java objects on the server.

The *Query Controller* and the *Database Controller* perform actions requested by the API on the resp. objects. They can only cause updates on the internal DB by using a manager module.

The *Search Module* maps search requests from the visual search form onto the internal DB. On top of that, it makes use of the *Query Manager* to consider information only available on the server application.

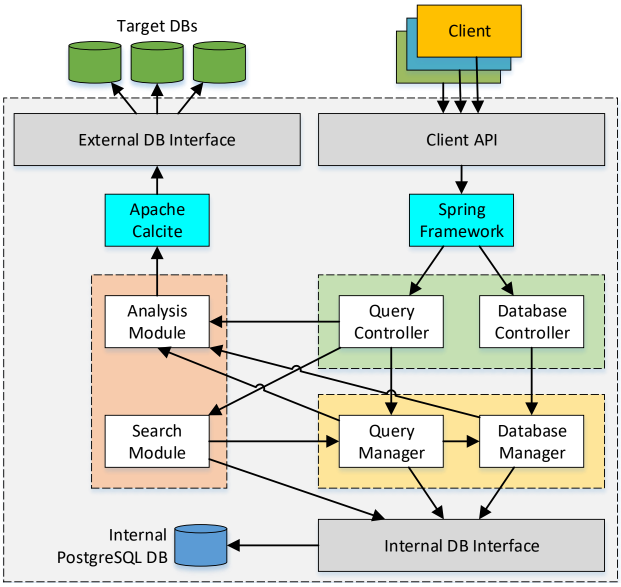

Figure 1: Architecture of the DataEconomist

2.2 Conceptual Schema

Fig. 2 shows an Entity-Relationship diagram containing the DataEconomist's conceptual schema to hold the queries and their meta-information. The Query entity is identified by the Text attribute, holding the query text. The complex, multi-valued attribute Relations stores the query's relations and attributes. It contains the two nested attributes RelName and Attributes. For each relation, we store its name in RelName and the names of all the relation's attributes in the multi-valued attribute Attributes.

The purpose of the Project entity is to group several target DBs in order to analyze their queries collectively. The Database entity holds connection information to target DBs.

A Query Execution reflects the run of a certain Query by a certain User on a certain Database at a certain Timestamp. The entity's further attributes are the RunTime in case of a successful query execution and the ErrorMessage if the query failed.

The Query Context points out a user's intention or the situation in which a Query Execution happens. Regarding this, privacy officers can specify the query's priority and its legitimacy concerning data privacy in this context. A query execution can only happen in one context, but a context may contain many query executions.

Fig. 2 highlights four groups of query characteristics in color. Some of them can be derived automatically; others must be entered manually. The Query Environment group is derived from the user and her initial connection to the target DB. The Query Execution group bundles when which query ran with what runtime successfully or not. Finally, the Query Context group cannot be derived automatically at all; it must be entered manually as it externalizes tacit user knowledge.

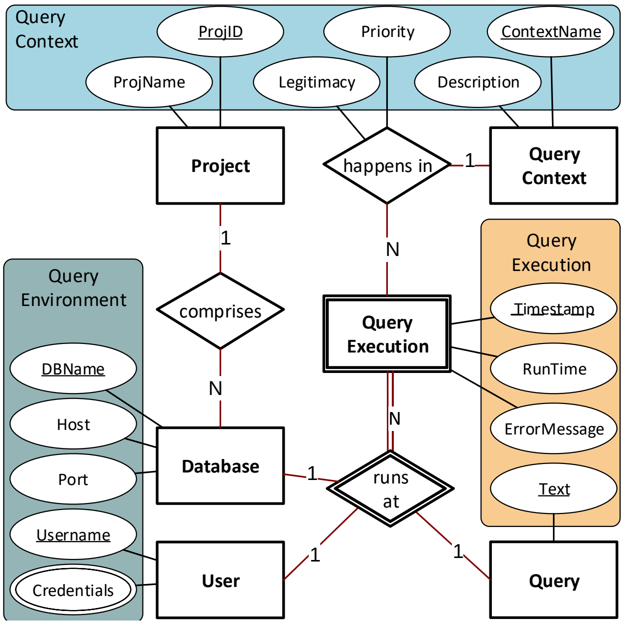

Figure 2: Conceptual schema of the DataEconomist

2.3 Reference Implementation

As first step, Apache Calcite performs basic syntax checking for each query. When checking which tables and columns are used by a query (a task that belongs to the core functionality of our DataEconomist), syntax alone is not sufficient. We additionally need the schema information. Asterisk selections are a trivial example to illustrate that. In order to detect used schema objects, Calcite's query planner transforms the query into a logical query plan. Calcite performs a query optimization and normalization. By applying the visitor pattern, the query-plan object is traversed and all used tables and columns are detected and collected for later review.

To provide the HTTP API, we use the model-view-controller module of the Spring framework. It maps HTTP requests onto the corresponding Java methods and serves as a bridge between Java objects and their JSON representation. The API mainly follows a CRUD approach, offering endpoints for entity creation, retrieval, update, and deletion.

[1] http://spring.io/projects/spring-framework

The frontend is implemented in Angular[2], a widely used Web framework written in TypeScript. It allows for the use of advanced GUI techniques such as reusable components and programming patterns such as reactive programming.

Fig. 3 shows the functionalities of the frontend interface. They are partitioned in three main views for projects, target DBs, and queries. The admin role can create projects and relate one or several target DBs. The admin needs to specify credentials for the target DBs so that the DataEconomist can connect to them and can fetch their schema information and import query logs. The admin role can also add and modify queries in our frontend, whereas the DB-user role can only choose a project and run the related queries.

Privacy officers can browse through all queries. We support them with a tool for extensive search-query formulation that can be utilized with purely visual means and does not require any knowledge of SQL. They can span a search-query tree by arbitrarily nesting search conditions concerning query structure or query characteristics. Any result set of queries can be manually filtered to be used in the next step for automatic detection of unneeded schema elements. Privacy officers can then check and adjust the DataEconomist's proposal of user-access-right minimization. The final configuration can be enforced to the target DBs with a single click.

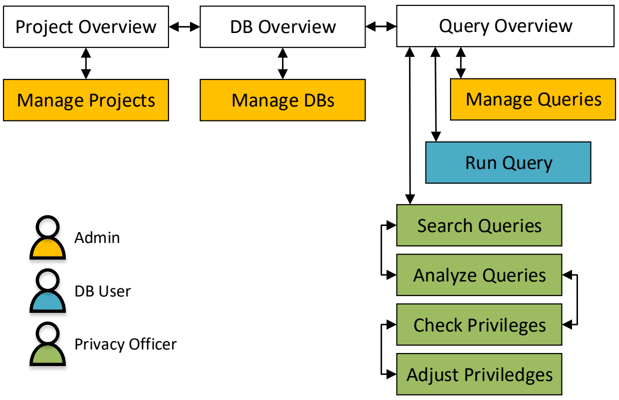

Figure 3: Frontend Use of the DataEconomist

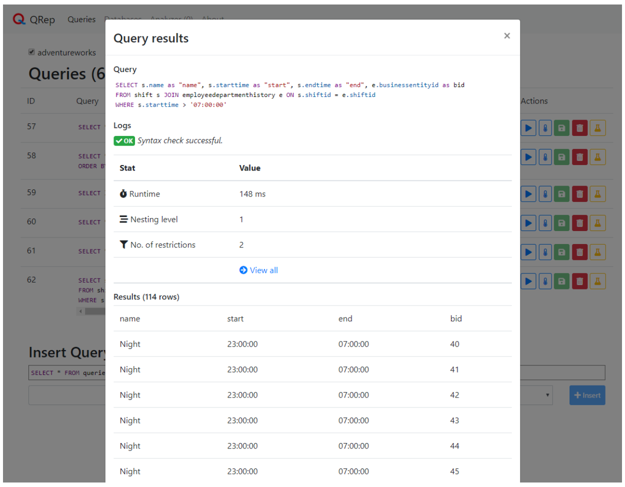
3 DEMONSTRATION WALKTHROUGH

For this demonstration, we will shortly present our approach's fundamental concepts to the conference attendees. Then they will be briefed to use our framework and learn about various aspects of the current version of our DataEconomist. Attendees may go through three different demonstration scenarios that build upon each other, but do not require the preceding steps for understanding. Most steps in the process include interaction with the attendees.

Setting up a project and analyzing queries. We have prepared a substantial SQL query log containing queries of different complexities from an enterprise scenario, stored in a MS-SQL DB. The attendees can choose the queries to be investigated. When a query is added to the DataEconomist, it will automatically start to find various properties of that query and to make them available for a potential search (see next scenario).

After the analyzing step is finished, attendees can see its results. The derived properties include the number of restrictions, the level of nesting, the number of different columns used by a query, and more.

Along with these properties, a sample of the query result is shown as well to help understand the query (see Fig. 4).



Query results

Query

```
SELECT s.name as "name", s.starttime as "start", s.endtime as "end", e.businessentityid as bid

Figure 4: Query stats and results dialog

Finding potentially illegal queries. For this scenario, we challenge the attendees to play the role of a privacy officer and to find queries violating data-privacy regulations. The attendees can use the visual-search interface and track down queries that retrieve for example data revealing racial or ethnic origin, political opinions, or religious or philosophical beliefs. To achieve a high level of flexibility, the visual-search queries can be nested and combined with Boolean operators (see fig. 5).

The attendees can directly consider accessible properties, such as the names of DB users, query-execution times, SQL strings, and all other query characteristics mentioned before.

We will examine two different cases that require different approaches. One requires the correct choice of properties to check. The other additionally requires a correct combination of properties. Both demonstrate the possibilities offered by the search-query formulation implemented in the DataEconomist.

Minimizing user privileges and deleting unnecessary data. When illegal queries have been found, we demonstrate how the DataEconomist displays which tables and columns are used by a query or a set thereof (see Fig. 6).

Attendees can then adapt the user privileges by unchecking tick boxes at all schema objects the user should no longer have access to. These user privileges will actually be enacted on the MS-SQL server through the interface. To show the effects, we will then try to execute an illegal query on the DB, which will fail, and inform the user about the illegal access attempt.

After that, attendees can use the DataEconomist to automatically determine unnecessary schema elements, i. e. data that have no user access to them. Again, by a single click, all these data will be deleted on the MS-SQL server.

4 STATE OF THE ART

Srivastava et al. provide a relational framework for managing queries [5]. We adopt their way of administrating queries together with their meta-information in a relational model. There are

several systems dedicated to query management, e. g. [2, 10]. However, these tools are aimed at experts and lack usability for privacy officers. During the query-log analysis of [3], we considered the query structure and detected similarities among queries. However, we did not yet provide a way to report user-specific meta-information about queries.

QueRIE [9] performs a query-log analysis to give personalized query recommendations. Manta and SQLDep[3] visualize schema lineage of SQL queries. None of these approaches considers query context and other meta-information. This is also the case for several graph-based approaches to representing SQL queries, e. g. [8, 11]. Tools like the Query Patroller [14] or the DataLawyer [13] provide a wide range of mechanisms for query analysis. However, they aim at SQL experts and the latter is even limited to a particular DBMS.

5 CONCLUSION AND FUTURE WORK

The DataEconomist supports several aspects of data minimization: Based on the query-driven approach, user access to unneeded schema elements can be automatically customized. Completely unneeded data can be automatically detected and deleted. These features minimize data processing. In first measurements, we determined the average latency for analyzing the structure (117ms) and detecting unneeded schema elements (19ms) of a single query. The structure analysis includes the generation of the query execution plan, the detection works with this execution plan. We intend to present more detailed measurement results in a follow-up publication.

Our framework also points at queries inserting unneeded data and at these queries' authors. That allows privacy officers to take specific measures in minimizing data collection.

Up to now, privacy officers have to manually classify illegal queries regarding data privacy, which can be an outrageous effort. Therefore, we work on a semi-automatic classification of illegal queries to minimize user interaction. We are also enhancing our framework by an intuitive visualization of all data processed by a query to fully support non-expert SQL users in classification. Furthermore, we aim to additionally consider unneeded tuples for a more fine-grained data minimization.

ABSTRACT

Grid-based clustering algorithms are well-known due to their efficiency in terms of the fast processing time. On the other hand, when dealing with arbitrary shaped data sets, density-based methods are most of the time the best options. Accordingly, a combination of grid and density-based methods, where the advantages of both approaches are achievable, sounds interesting. However, most of the algorithms in these categories require a set of parameters to be specified while usually it is not trivial to appropriately set them. Thus, we propose an **I**nformation-**T**heoretic **G**rid-based **C**lustering (ITGC) algorithm by regarding the clustering as a data compression problem. That is, we merge the neighbour grid cells (clusters) when it pays off in terms of the compression cost. Our extensive synthetic and real-world experiments show the advantages of ITGC compared to the well-known clustering algorithms.

1 INTRODUCTION

Among various clustering approaches some of them attract more attentions because of their advantages. Partition-based clustering algorithms are popular due to their simplicity and the relative efficiency [7], [2]. K-means [7] is a well-know and well-studied representative for this approach where initially the data is partitioned into k non-empty sets and iteratively the data points are assigned to their nearest cluster. Despite the mentioned advantages, the clustering algorithms in this group suffer from some drawbacks. For instance, the number of clusters k should be specified in the beginning and the results are not deterministic because of their sensitivity to the initialization. Moreover, they are not suitable to discover clusters with non-convex shapes. As a subset of this group, model-based clustering algorithms consider a specific distribution model to represent the data sets. Among them, Expectation-Maximization (EM) algorithm interpret the data as a mixture of Gaussian distributions [5]. On the other hand, density-based clustering algorithms [6], [3] are appropriately designed to deal with clusters having an arbitrary shape. Unlike the partition-based algorithms, the algorithms in this approach are able to deal with noisy data sets. However, in order to find dense regions we need to specify two parameters representing the radius and the density of a neighborhood. Additionally, density-based algorithms are not designed to efficiently deal with clusters with various densities. Spectral clustering [9] is another approach which has become popular due to its simple implementation and its performance in many graph-based clustering. It can be solved efficiently by any standard linear algebra software. However, this approach is expensive for the large data sets since the Computing eigenvectors is the bottleneck.

Another well-known approach is grid-based clustering where any data set is partitioned using a set of grid-cells and data points are assigned to the appropriate grid cell. Grid-based methods [1], [14], [11] quantize the object space into a finite number of cells (hyper-rectangles) and then perform the required operations on the quantized space. The main advantage of grid-based methods is their fast processing time which depends on the number of cells in the grid. In the other word, no distance computation is required and the clustering is performed on summaries and not on the individual objects. Thus, the complexity of grid-based algorithms is usually *O(number of populated grid cells)* and not *O(number of objects)*. Beyond their ability to deal with noisy data sets, grid-based clustering algorithms are able to identity clusters irrespective of their shapes. Unlike most of the clustering algorithm which require an initialization phase, the algorithms in this category are insensitive to the order of input records and therefore are deterministic.

Despite the valuable advantages of grid-based clustering algorithms, to the best of our knowledge, all of them are parametric algorithms where a user is required to specify the parameters. However, most of the time it is not trivial to appropriately set them. Thus, utilizing the principle of Minimum Description Length (MDL) we propose a non-parametric **I**nformation-**T**heoretic **G**rid-based **C**lustering algorithm where we regard the clustering task as a data compression problem so that the best clustering is linked to the strongest data compression. First, an adaptive grid is constructed corresponding to the statistical characteristics of any data set and non-empty cells are considered as single clusters. Then, we combine the concept of density and grid-based methods and employing our compression-based objective function we start merging clusters with their neighbour grid cells only if it pays off in terms of the compression cost.

In this paper we propose an information-theoretic clustering algorithm offering the following contributions:

- **Adaptive partitioning:** We utilize the statistical characteristics of any data set, e.g. local and global dispersion, in order to introduce an adaptive partitioning of the data.
- **Non-parametric clustering:** Employing the MDL-based objective function, we iteratively merge clusters when it pays off in terms of the compression cost automatically. Thus, no parameter needs to be specified.
- **Insensitivity to the shape of clusters:** ITGC employs the concept of density-based methods in order to select the next merging candidate. Thus, it is insensitive to the shape of clusters whether they are Gaussian, arbitrary or even having various density regions.
- **Scalability:** Analogous to other grid-based clustering algorithm, the complexity of ITGC depends on the number of cells not on the number of objects which leads to a scalable algorithm in terms of the number of objects.

2 INFORMATION-THEORETIC GRID-BASED CLUSTERING

In order to introduce a grid-based clustering algorithm we need to address two fundamental questions: (1) how to find a specific appropriate partitioning (grid) corresponding to any data set; (2) how to efficiently merge the cells to discover the hidden clusters. Thus, our proposed algorithm ITGC consists of two main building blocks: (1) finding a suitable grid corresponding to specific characteristics of any data set and (2) employing MDL principle to effectively and efficiently merge the cells without any parameter to be specified.

2.1 Partitioning the Data

Finding a suitable partitioning with respect to the data is a crucial task in a grid-based clustering algorithm. Inspired by [8], we utilize the characteristics of any data set to introduce the best fitting partition. That is, we are looking for a partition which leads to high internal homogeneity in the cells and high external heterogeneity of each cell with respect to its neighbors for every single cell. Thus, for any cell C_j consisting of n_j data points the statistical indicators are defined as:

$$\bar{X_j} = \frac{\sum_{i=1}^{n_j} X_{ij}}{n_j} \quad and \quad S_j = \sqrt{\frac{\sum_{i=1}^{n_j} (X_{ij} - \bar{X_j})^2}{n_j - 1}} \tag{1}$$

Where X_{ij} is the distance of the $i - th$ data point in C_j to the center of this cell. Thus, $\bar{X_j}$ is the average distance of data points to the center of C_j and S_j is the standard deviation of the cell. These are statistical indicators on the local level (each individual cell), similar indicators are calculated on the global level (the entire grid) as:

$$\mu = \frac{\sum_j \bar{X_j}}{N} \quad and \quad \sigma = \sqrt{\frac{\sum_j (\bar{X_j} - \mu)^2}{N - 1}} \tag{2}$$

Where μ is the average center - distance of all cells, N is the total number of cells and σ is the standard deviation of all cells. Based on these indicators, we define $CV_{Local}(j)$ and CV_{Global} as the coefficient of variation (CV) corresponding to any cell C_j and the global variation, respectively. That is,

$$CV_{Local(j)} = \frac{S_j}{\bar{X_j}} \quad and \quad CV_{Global} = \frac{\sigma}{\mu} \tag{3}$$

In another point of view, the above scores show how widespread the data points are indicating the relative dispersion at the local (cell) and global (grid) levels. Finally the partitioning cost is defined as:

$$gridCost = \frac{CV_{Global}}{avg \quad CV_{Local}(j)} \tag{4}$$

Considering the cost corresponding to any grid size $k \times k$, we iteratively increase k starting from 1 until it pays off. However, it is not trivial to justify a terminal for this process without observing its trend. Initially, the grid cost increases sharply by increasing k then it slows down quickly and continues linearly. Observing this common trend, we conduct a simple linear regression on various costs with respect to various k values. The regression line is expected to fit more through the higher ks where the costs have lower deviations. Thus, the optimal partitioning can be set to the first k where the grid cost deviated from the fitted line lower than the average.

On the other side, by increasing the size of grid the area of non-empty cells decreases. Thus, it is reasonable to assume this trend to continue with even smaller cells, but the descending trend slows down while decreasing cell sizes. Visualizations of the collected area reveals a common trend which is reverse to the previous one. The area starts at a maximum value, decreases very sharply at lower k and keeps decreasing at a lower gradient. In order to find the optimum value for k, we analogously fit a linear regression through the data set rejecting the low k values which deviate larger than average from the fitted line. The following steps summarize this procedure.

- Step 1: The grid is divided into $k \times k$ cells where the initial size for k is 1.
- Step 2: The grid cost as well as the area of non-empty cells are determined and the values are stored.
- Step 3: We iteratively increase k ranging from 1 to a max_k and repeat the previous steps
- Step 4: Now the optimum partitioning is determined employing two different criteria.

2.2 MDL-based Objective Function

Utilizing the Minimum Description Length (MDL) principle [10] we regard the clustering task as a data compression problem so that the best clustering is linked to the strongest data compression. Given the appropriate model corresponding to any attribute, MDL leads to an intuitive clustering result employing the compression cost as a clustering criterion. The better the model matches major characteristics of the data, the better the result is. Following the MDL principle, we encode not only the data but also the model itself and minimize the overall description length. Simultaneously, we avoid over-fitting since the MDL tends to a natural trade-off between model complexity and the goodness-of-fit. That is, for a given cluster C_i the corresponding compression cost is defined as:

$$MDL(C_i) = CodingCost(C_i) + ParamCost(C_i) + IDCost(C_i) \tag{5}$$

where *CodingCost* shows the cost of coding the data points in cluster C_i by means of a coding scheme. The next two terms illustrate the model complexity where the model itself needs to be encoded. In this paper we employ the Huffman coding scheme to encode the data considering an appropriate model. That is, given the corresponding *Probability Distribution Function* (PDF) to any attribute, the coding cost of any object x is determined by $-log_2 PDF(x)$. Any PDF would be applicable and using a specific model is not a restriction [4] for our algorithm. In this paper, we consider Gaussian PDF for simplicity. In the following we elaborate our objective function more concretely.

- **Objective Function:** The overall MDL-based objective function is the summation of the all compression costs with respect to various clusters. That is,

$$MDL(\mathcal{D}) = \sum_{C_i \in C} MDL(C_i) \tag{6}$$

where $\mathcal{D}$ is the entire data set and $C = \{C_1, ..., C_k\}$ is the set of all clusters.

- **Data Coding Cost:** Let $\mathcal{X} = \{X_1, ..., X_d\}$ denote the set of all attributes. For any object $x = (x_1, ..., x_d)$ the corresponding coding cost is the sum of encoding any attribute value x_i. Putting all together, the coding cost corresponding to cluster C_i is given by:

$$CodingCost(C_i) = -\sum_{X_j \in \mathcal{X}} \sum_{x \in C_i} \log_2 PDF_j(x) \qquad (7)$$

where $PDF_j(.)$ is the Gaussian model with respect to $j-th$ attribute X_j.

- **Model Complexity:** Without taking the model complexity into account, the best result will be a clustering consisting of singleton clusters. This result is completely useless in terms of the interpretation. In order to specify the associated cluster with any data object, we need to encode the cluster IDs. Thus, the IDCosts are required to balance the size of clusters and defined as:

$$IDCost(C_i) = |C_i|.log_2 \frac{|C_i|}{|\mathcal{D}|} \qquad (8)$$

Following the fundamental results from the information theory [10], for any attribute X_j the parameters corresponding to model employed to encode the data need to be encoded as well. That is, concerning any Gaussian distribution PDF_j with respect to the attribute X_j, the mean value and the standard deviation need to be encoded, i.e.

$$ParamCost(C_i) = \frac{1}{2}.(2|\mathcal{X}|).log_2|C_i| \qquad (9)$$

2.3 Algorithm

As mentioned, ITGC consists of two main building blocks. Algorithm 1 summarizes our grid-based algorithm ITGC. First, an optimal grid is constructed following the steps mentioned in Section 2.1, i.e. the procedure *FindOptimumGrid(.)*. Then, we start merging the cells if it pays off in terms of our objective function (Section 2.2). Initially every cell is considered as a cluster while empty cells are ignored. The cluster with the most number of data points is chosen in the sense that at the end the results are deterministic. We compute the coding cost with respect to the selected cluster MDL_{before} and merge this cluster with one of its neighbors and compute the cost after merging two clusters MDL_{after}. If the cost after merging is smaller than the cost before, we merge two clusters and continue the merging process. Otherwise, the visited cluster is marked. Finally the algorithm terminates if no unmarked non-empty cell exists.

3 EXPERIMENTS

In this section we assess the performance of ITGC comparing to other clustering algorithms in terms of *Normalized Mutual Information* (NMI) which is a common evaluation measure for clustering results [13]. NMI numerically evaluates pairwise mutual information between ground truth and resulted clusters scaling between zero and one.

We conducted several experiments evaluating our algorithm on synthetic and real-world data sets. In order to investigate the effectiveness of ITGC we generated various data sets and compared to the base-line clustering algorithms, i.e. k-means [7] and DBSCAN [6]. While the insensitivity of ITGC to the shape of clusters as well as its effectiveness is illustrated by synthetic experiments, we extended the comparison to the wider range of well-known clustering algorithms. Our algorithm is implemented in Java and the source code as well as the data sets are publicly available [1].

Algorithm 1: Information-theoretic grid-based clustering

```
ITGC ($\mathcal{D}$)
$\mathcal{G}$ = FindOptimumGrid($\mathcal{D}$);
$C = \{C_1, ..., C_k\}$        // Non-empty cells in $\mathcal{G}$
seeds := non-visited clusters;
while (seeds != empty) do
    $C_i$ := the cluster with the most data points in $C$
    $C_i$ is visited
    while ($MDL_{before} > MDL_{after}$) do
        $MDL_{before} = MDL(C_i)$
        $C_j$ := a random non-visited neighbor cell w.r.t $C_i$
        $C_m$ := the cluster after merging $C_i$ and $C_j$
        $MDL_{after} = MDL(C_m)$
        if $MDL_{before} > MDL_{after}$ then
            remove $C_j$ and $C_i$ from $C$ .
            add $C_m$ to $C$
        end if
    end while
    seeds := non-visited clusters;
end while
return ($C$)
```

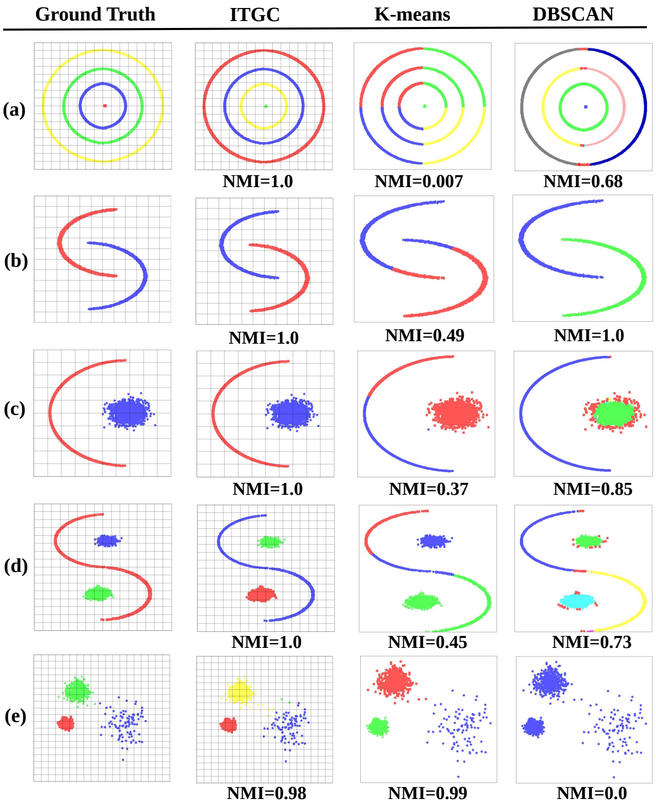

Figure 1: Comparison on various synthetic data sets.

3.1 Synthetic Experiments

In order to cover all aspects of ITGC, we investigate the performance of the algorithms considering various synthetic data sets including arbitrary shaped data sets as well as clusters with different densities. Then, we continue experiments by comparing all algorithms in terms of the scalability.

Performance: Most of the time any clustering algorithm is designed for a specific kind of data sets. For instance, k-means

User Knowledge	5/403	0.24	**0.27**	0.01	**0.27**	**0.27**	0.00	0.01

Table 1: Comparison on real data sets.

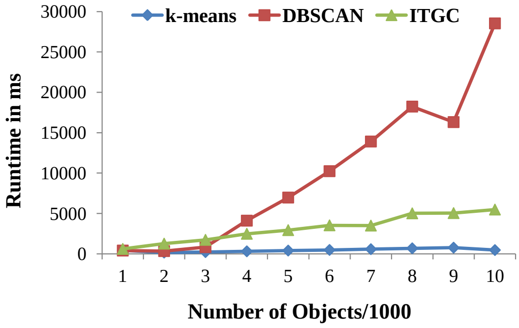

Figure 2: Scalability of the algorithms by increasing the number of objects.

appropriately deals with Gaussian shaped data sets and its performance dramatically decreases when the clusters have no specific shape. On the other hand density-based clustering algorithms are sensitive to different densities w.r.t. various clusters. In order to evaluate the performance of ITGC concerning various shapes of clusters, we synthetically generated arbitrary shaped clusters in a combination with some Gaussian clusters. Figure 1 shows the effectiveness and the insensitivity of ITGC considering various cases. As expected, k-means fails when the clusters are not Gaussian (Figure 1a,b,c,d). On the other hand, DBSCAN is not able to discover the clusters with various densities (Figure 1d,e)

Scalability: To evaluate the efficiency in terms of the runtime complexity we generated 5 dimensional synthetic data sets where we iteratively increased the number of data objects ranging from 1,000 to 10,000. Figure 2 shows the result of this experiment. As expected, k-means is the fastest algorithm while DBSCAN is the worse since its complexity highly depends on the number of objects. Although ITGC is not able to outperform k-means, its corresponding execution time is still reasonable and more efficient than DBSCAN.

3.2 Real Experiments

In this section we extend our experiments to the wider range of clustering algorithms including EM [5], Single link [12], spectral clustering [9] and CLIQUE [1] as the well-known representatives for any clustering approach. We evaluate clustering quality of ITGC on real-world data sets. We used *Iris*, *Occupancy Detection*, *User Knowledge* and *Breast Cancer* data sets from the UCI Repository [2]. Table 1 shows the characteristics of any data set and the results of applying various algorithms in terms of NMI. Concerning any data set the best NMI is high lighted and when getting "Out Of Memory" error we inserted "-" in the table. As Table 1 illustrates ITGC outperforms other algorithms considering the first 3 real-world data sets. Interestingly, in this experiment we outperform CLIQUE which is a well-known grid and density-based clustering algorithm (the results are similar on the *Occupancy* data set). Although some of the comparison methods perform slightly better than ITGC on *User Knowledge* data set, our result is still comparable and we outperform DBSCAN, CLIQUE and Single link.

4 CONCLUSION AND FUTURE WORKS

In this paper we propose an information-theoretic clustering algorithm, ITGC, utilizing the MDL-principle. Firstly, We employ the statistical characteristics of any data set to appropriately partition the data without any presumptions. Then, an MDL-based objective function is proposed to iteratively merge the neighbour clusters when it pays of in terms of the compression cost of the clusters. Our experiments on synthetic and real-world data sets show the advantages of our proposed algorithm compared to other well-known clustering algorithms. Similar to other grid-based clustering algorithms, our algorithm may lead to inefficiency when dealing with huge data sets in terms of the dimensionality. Thus, a possible future work would be to investigate the parallelization approaches in the sense that the required memory to store the grid information could be distributed. As another option for the further investigation could be to enhance the partitioning procedure in the sense that it results a sparse grid which is cheaper in terms of the memory.

ABSTRACT

Event-time based stream processing is concerned with analyzing data with respect to its generation time. In most of the cases, data gets delayed during its journey from the source(s) to the stream processing engine. This is known as *late* data arrival. Among the different approaches for out-of-order stream processing, low watermarks are proposed to inject *special* records within data streams, i.e., watermarks. A watermark is a timestamp which indicates that no data with a timestamp older than the watermark should be observed later on. Any element as such is considered a late arrival. Watermark generation is usually *periodic* and heuristic-based. The limitation of such watermark generation strategy is its rigidness regarding the frequency of data arrival as well as the delay that data may encounter. In this paper, we propose an adaptive watermark generation strategy. Our strategy decides adaptively when to generate watermarks and with what timestamp without a priori adjustment. We treat changes in data arrival frequency and changes in delays as concept drifts in stream data mining. We use an Adaptive Window (ADWIN) as our concept drift sensor for the change in the distribution of arrival rate and delay. We have implemented our approach on top of Apache Flink. We compare our approach with periodic watermark generation using two real-life data sets. Our results show that adaptive watermarks achieve a lower average latency by triggering windows earlier and a lower rate of dropped elements by delaying watermarks when out-of-order data is expected.

1 INTRODUCTION

Stream analytics is concerned with analyzing data on the move. Several stream processing engines (SPEs) have been developed that vary in their processing capabilities. One fundamental feature is the ability to process data with respect to their generation time rather than their arrival time at the SPE [2]. This is commonly known as event-time versus processing-time. For a data stream element e, we define $te(e)$ as a function that returns the timestamp of the event, i.e. the time it was created at the source, we also define $tp(e)$ to be the timestamp when it was first seen by the SPE. The event-time notion is more relevant in several applications. However, as the data sources are distributed and can be placed far away from SPEs, *delays* can occur until an element e reaches the SPE. This is known as *late arrival.* Moreover, a stream element can arrive *out-of-order.* For example, two stream elements e_1 and e_2 where e_1 was created before e_2, i.e., $te(e_1) < te(e_2)$ can arrive in the opposite order, i.e., $tp(e_2) < tp(e_1)$. This is known as out-of-order arrival.

Stream analytics jobs are usually defined by a sort of a window [4, 5, 7]. Windows are used to slice the infinite stream into finite chunks and apply the analytics computation, e.g. averaging, a.k.a window function, on the content of the window. Time windows are common types of windows that define stream element's membership to the window based on the elements timestamp w.r.t. window start and end times, when working in event time. The window function cannot be applied on the window content until the SPE decides that the window is closed. For system (processing) time mode, the decision is made when the internal clock (wall clock) of the SPE passes the window end. However, for event time processing, we need an external notion progress.

Low watermarks generation [1, 2] is a technique to account for the progress in event time. A watermark is a timestamp that *indicates* that there should be no future data older than the watermark to be seen. When a watermark is received by a window operator in a pipeline, it triggers executions of completed time windows whose closure completed at a time earlier than the watermark. A watermark is monotonic. That is, a new watermark cannot be less than the last generated watermark. Watermark progress affects two metrics in stream processing: latency and late arrival of data items and thus accuracy. Latency is hurt when too few watermarks are generated. Late arrival increases when too many watermarks are generated and thus accuracy decreases due to more elements being ignored (dropped).

Currently, watermark generation is either heuristic-based and periodic [1, 2] or punctuation-based [11]. The latter assumes knowledge about the content of the data. The former is inflexible with the change of the distribution of data arrival rate or the distribution of the delays in arrival. Those are unique properties of data streams. In this paper, we contribute an approach to watermark generation that is data-content-agnostic. We call our approach as adaptive watermarks. By treating the change in the skewness between stream elements event time and processing time as a concept drift, we employ a drift detection technique, the adaptive window (ADWIN) [3, 6], to decide when to generate a new watermark and with which value. Moreover, we provide another control, late arrival threshold, to decide about the watermark generation. We implement our approach on Apache Flink and compare it with a baseline periodic watermark generator using two real-life data sets. Our experiments empirically prove the superiority of adaptive watermarks with respect to a reduced latency and/or a reduced number of dropped elements.

2 ADAPTING TO DATA ARRIVAL RATES

2.1 Baseline: Periodic Watermark Generation

Periodic watermark generation is a heuristic-based approach. Heuristically, application developers determine a max allowed lateness m. With the arrival of a new event, the *maximum* timestamp seen is updated. Then, every s milliseconds, the SPE obtains the maximum timestamp t seen so far. The watermark value is $t - m$. New stream elements that arrive after the watermark are considered late. Depending on the configuration of the stream processing pipeline, such elements can still be included in the

Table 1: Parameters used for watermark generators

Parameter	Description
δ^*	Sensitivity to change $\in [0, 1]$. Default is 1.
l	Late arrival threshold, $l \in (0, 1]$. Default is 1.
m^*	Skewness between event time and ingestion time.
Δ_δ	Sensitivity change ratio, $\Delta_\delta \in (0, 1]$. Default is 1.
w	Warmup tuples used to initialize m.

Parameters with * are derived by the system

result or ignored. This approach is simple to implement. However, it is does not adapt to changes in 1) the arrival rate of data elements, 2) the lateness of elements.

2.2 Adaptive Watermark Generation

In practice, it would be desirable to learn both m, the lateness, and the period s for generating a new watermark and keep updating them as new elements arrive. Moreover, to account for high correctness, one would hold the generation of new watermarks if the ratio of late arrival elements to the total elements goes above a certain threshold l since the last generated watermark. In this situation, the period s at which a watermark is generated will change (adapt) according to the change in the distribution of data inter-arrival time. Similarly, m can be learned upon each change detection. The change of the inter-arrival time can be seen as a concept drift in data streams [10]. In our case, the drift to be detected is the change of events' inter-arrival time. To detect this drift, we employ the ADWIN algorithm [3].

ADWIN is an algorithm which detects concept drifts (e.g., changes in users opinions) and enables adapting machine learning models on data streams. It works by maintaining a window of data items over time. The size of the window changes over time based on the frequency of change detected in incoming data. The algorithm does not require a pre-determined period to trigger change detection. It checks for drifts on a per-tuple basis. The more change occurs, the smaller the size of the window as older items are considered irrelevant and dropped. The algorithm has a single parameter δ (Table 1) which controls the sensitivity to change. The higher the value of δ the more sensitive it will be to change. In our work, δ is by default set to 1 so that a change is detected as early as possible.

ADWIN works as follows: Upon the arrival of a tuple, it is added to the window. Then, the algorithm tries to detect a change by finding two sub-windows whose value distributions are *significantly different* with respect to δ. Here, ADWIN iterates over all possible combinations of sub-windows. As an optimization, ADWIN maintains histograms (buckets) of the sum and variance of the data rather than the data itself to have a better memory footprint. The histogram grows logarithmically to the number of data points. Grulich et al. [6] parallelize different parts of the original algorithm and reach two orders of magnitude enhancement of its throughput. Table 1 summarizes the parameters we use for the adaptive watermark generation technique.

Algorithm 1 describes how we employ change detection by ADWIN to adapt the generation of watermarks. At the arrival of a new element, that might be late, the *difference* between the new element's timestamp and its ingestion timestamp is inserted into ADWIN and a check is made for detection of a change (drift) (Line 12). Such a detection can be an indicator to generate a new watermark. It is not necessary that every change detection leads to the generation of a new watermark. We need to look at the second indicator which is the rate of late arrivals. A new watermark is generated only if this rate is less than the threshold l at the time of change detection (Line 15). This rate is reset each time a new watermark is generated.

Algorithm 1: Adaptive watermark generation

```
   Input: A data stream $S$
   Input: Sensitivity change rate $\Delta_\delta$
   Input: Late arrival threshold $l$
   Input: Warmup tuples count $w$
1  $warmup \leftarrow 0$; $m \leftarrow 0$; $watermark \leftarrow 0$;
2  $lateElements \leftarrow 0$; $totalElements \leftarrow 0$; $\delta \leftarrow 1$
3  $maxTimestamp = -\infty$
4  $adWin \leftarrow initializeAdWin(\delta)$
5  foreach $e \in S$ do
6      $maxTimestamp = max(te(e), maxTimestamp)$
7      if $warmup \leq w$ then
8          $m \leftarrow max(m, tp(e) - te(e))$
9          $warmup \leftarrow warmup + 1$
10     else
11         $totalElements \leftarrow totalElements + 1$
12         if $adWin.driftDetected((tp(e) - te(e))/m, \delta)$
            then
13             if $lateElements = 0$ then
14                 $\delta = increaseSensitivity(\Delta_\delta)$
15             if $lateElements/totalElements < l$ then
16                 $watermark = maxTimestamp - m$
17                 $emit(watermark)$
18                 $lateElements \leftarrow 0$
19                 $totalElements \leftarrow 0$
20             else
21                 $m \leftarrow updateSkewness()$
22                 $\delta = decreaseSensitivity(\Delta_\delta)$
23         else
24             if $te(e) < watermark$ then
25                 $lateElements \leftarrow lateElements + 1$
```

We call the elements collected between two successive watermarks a *chunk*. The value of m is the maximum difference between elements' ingestion and event time within the chunk (Line 21). The value of the new watermark is $maximum\ timestamp - m$ (Line 16). Upon the generation of a new watermark, all data about late arrival is reset (Lines 18 and 19). In case a chunk has no late arrivals, the sensitivity is increased (Line 14) to speedup change detection. However, upon crossing the late arrival threshold l, δ is adapted according to the δ_Δ parameter (Line 22).

As ADWIN is designed to work with values in the range $[0, 1]$, we need to normalize the deviation between element's event and ingestion times. For this, we use the first w tuples of the stream to learn about m (Line 7). That can be in the form of minimum, maximum, or average skewness observed between elements' event time and ingestion time.

For the adaptive watermark generation, the user needs to specify the late arrival threshold l, the sensitivity change ratio δ_Δ, and the warmup tuples w. The default values for these parameters are 1, 1, and 10000 tuples, respectively. The choice of a value of l is mainly driven by the accuracy expected by the application. The more accurate results expected, the lower the value of l should

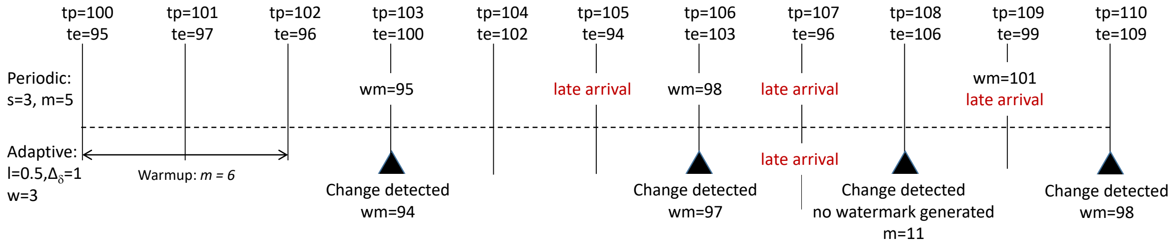

Figure 1: Example for adaptive watermark generation versus periodic generation.

be. If the source is stable and does not produce considerable late arrivals, the low value of l should not affect the latency of the results. Otherwise, lower values of l shall affect the latency, but this should be acceptable as the main concern is accuracy. Sensitivity to change δ_Δ is effective only in case that late arrivals rate is above l. In such case, δ is decreased and thus ADWIN will have to observe a larger number of elements before detecting a change. The value of w affects latency as for the first w tuples, no watermarks are generated and thus no window contents is processed. Larger value of w could be used with data sources with out-of-order arrivals. In Algorithm 1, we use the *maximum* skewness observed to update m. However, this can be changed to *average* or other measures.

Example: Figure 1 exemplifies how adaptive watermark generation works in comparison to the periodic one on a hypothetical stream. Vertical lines represent stream elements with their processing and event time respectively. The periodic generator is configured with $s = 3$ seconds and $m = 5$ seconds. The adaptive generator is configured with $l = 0.5$, $\Delta_\delta = 1$ and $w = 3$. The periodic generator will generate watermarks at $tp = 103$, $tp = 106$, and $tp = 109$ with values 95, 98, and 101, respectively. The elements arriving at $tp = 105$, $tp = 107$ and $tp = 109$ are late. For the adaptive generator, the first three tuples are used to initialize m; which is set to 6, as the max skewness observed between tp and te. At $tp = 103$, ADWIN detects a change. As there are no late arrivals, a watermark is generated with the value 94. At time $tp = 106$, another change is detected and a new watermark is generated with value 97. The next element at $tp = 107$ is late. ADWIN detects another change at time $tp = 108$. At this time, no watermark is generated as the late arrival ratio is equal to 0.5. Also, at this time, m is updated to 11, the skewness between $tp = 107$ and $te = 96$. At $tp = 110$, ADWIN detects another change. A watermark is generated as the late arrival ratio drops below 0.5.

3 EVALUATION

Setup: We have implemented adaptive watermark generation on top of Apache Flink v1.6.2, using the `Source` APIs to control the emission of watermarks. Our code base for the implementation and experimental evaluation can be found online[1]. We run our experiments on a standalone cluster with 6 *GB* of main memory and 4 cores at 2 *GHz*.

Data and query: For the comparison between adaptive and periodic watermark generation, we use two data sets from the *DEBS* grand challenges of 2012 [8] and 2015 [9] respectively. The *DEBS 2012* data set has 32,390,519 tuples and 1.5% of the elements arrive out-of-order with an average of 100 tuples per second. The *DEBS 2015* data set has 14,776,616 tuples and has 78.6% of its tuples arrive out-of-order. Moreover, the arrival rate of the data varies along the data set with an average of 6 tuples per second. For both of the data sets, we project the timestamps and create events with dummy content and the timestamps projected. We use a simple pipeline that applies a count function on the content of a time window. We report the window boundary, start and end, the number of elements in the window and the difference between window end and the watermark. The resulting tuples are of the form $\langle start, end, count, delay \rangle$. We use these values to construct the comparison metrics as we show next.

Table 2: Metrics for periodic watermark generation

Data-set	Allowed lateness	Period	Win. size	Dropped %	Avg. win. delay (ms)
DEBS 2012	1000	200	1000	1.24	9,452,454
			100	1.24	3,083,109
	100	10	1000	1.50	713,846
			100	1.50	175,497
DEBS 2015	1000	200	1000	98.72	644,046,759
			100	98.62	648,821,195
	100	10	1000	99.93	546,682,126
			100	99.97	392,904,397

Metrics: We measure two metrics: the percentage of dropped elements and the average delay between a window end and the watermark after which the window function was triggered. We call it the window delay and report it in milliseconds.

Parameters: For the periodic watermark generator, we set the value for the generation period $s \in \{10, 200\}$ *ms*. For the allowed lateness, $m \in \{100, 1000\}$ *ms*. For the adaptive watermark generator, we set w the number of tuples to initialize m to 10000, we set the late arrival threshold l and the sensitivity change rate Δ_δ to one of $\{1.0, 0.1, 0.01\}$, see Table 1 for descriptions of the parameters. For the size of the time window in the query, we vary it between 100 and 1000 milliseconds.

Results: For the data collected after running the pipeline for each unique combination of configuration parameters, to compute results we: 1) drop out result tuples for which the watermark is `Long.MAX_VALUE`. Flink generates a watermark with this value to flush any windows that were waiting for a watermark to trigger its computation, 2) count the number of tuples (*count* above) and subtract that from the total number of tuples we have in the respective data set to obtain the tuple drop percentage, and 3) average the delay over the computed windows remaining after step 1. Table 2 shows the results for the periodic generator and Table 3 shows the results for the adaptive one.

For the *DEBS 2012* data, the periodic generator provides lower delay for the shorter watermark generation period. But, with

8		0.1	1	100	1.49	16,796
9		0.1	0.1	1000	1.24	1,851,629
10		0.1	0.1	100	1.24	1,847,523
11		0.1	0.01	1000	1.17	2,472
12		0.1	0.01	100	1.17	2,471
13	DEBS	1	1	1000	79.60	72,863,504
14	2015	1	1	100	79.60	72,863,574
15		1	0.1	1000	44.14	33,826,576
16		1	0.1	100	44.14	33,827,281
17		1	0.01	1000	43.82	45,279,068
18		1	0.01	100	43.82	45,279,328
19		0.1	1	1000	85.52	51,965,257
20		0.1	1	100	85.52	51,965,876
21		0.1	0.1	1000	44.42	36,007,475
22		0.1	0.1	100	44.42	36,007,727
23		0.1	0.01	1000	41.64	92,672,393
24		0.1	0.01	100	41.64	92,673,050

higher drop rate. This is logical because of the trade off between tuple drop percentage and window delay. In the case of the adaptive watermark generator, with the default configuration (rows 1&2 in Table 3), it has almost the same tuple drop percentage as the periodic generator but with at least an order of magnitude improvement in window delay. Setting late arrival threshold $l = 0.1$, the tuple drop percentage is decreased but with two orders of magnitude higher window delay (rows 3&4). Yet, the delay is still below the delay of the periodic generator with the same tuple drop percentage. Setting $l = 0.01$ improves the tuple drop percentage by 0.07% and with very low window delay (row 5). This might look counterintuitive. But, by investigating the data for this configuration, we found that several windows were just fired by the termination of Flink's job. Thus, we had fewer windows that were processed due to the generated watermarks. This is logical as with a lower value of l, less number of watermarks is generated in general. Table 3 shows that changing the value of Δ_δ for the *DEBS 2012* data does not have much of an effect and the results are almost identical. The control is mainly driven by l.

For the *DEBS 2015* data set, we can see that the periodic generator drops almost all the tuples for the different configurations (Table 2). The window delay is very huge. Using the adaptive generator, with the default configuration (rows 13 and 14 in Table 3), we achieve a drop rate close to the percentage of the out-of-order tuples in the data set. However, the delay is an order of magnitude less than the periodic generator. Restricting the late arrival threshold to 0.1 reduces the tuple drop percentage and reduces the window delay by about 50% (rows 15 and 16). Pushing l to 0.01 reduces the tuple drop rate slightly but with an increase in window delay. The least tuple drop percentage is achieved when $\Delta_\delta = 0.1$ and $l = 0.01$ but with higher window delay (row 23). Figure 2 visualizes the tuple drop percentage and the average window delay for the different parameter values of the adaptive generator.

Our experimental results show the superiority of adaptive watermarks to baseline periodic ones. For both ordered and unordered streams, less tuple drop rate as well as several orders of magnitude saving in window delay.

4 CONCLUSION

In this paper, we have proposed an adaptive approach for generating low watermarks for event-time stream processing. It adapts to changes in data arrival frequency as well as to late arrival ratio. Compared to the baseline heuristic periodic watermark generation, and as indicated by application on data sets with different arrival frequency and delay characteristics, our approach strikes a balance between latency and accuracy of stream applications.

Currently, setting the late arrival threshold to very low percentage ceases the generation of the next watermark until the threshold is reached. This might be inconvenient and might cause high-latency. We intend to investigate an automated approach that automatically balances between latency and accuracy without having the user to specify threshold explicitly.

ABSTRACT

One of the applications of string similarity measures regards identifying the same entity within one or more corpora of data, also known as the problem of entity resolution. While a lot of methods have been introduced for assessing the similarity of two strings, there has not been yet a study to examine whether these methods are appropriate, in terms of effectiveness and fairness when applied to names of specific groups of individuals. In this paper, we provide extensive experimental results over a number of popular string measures which indicate that string comparison methods fall short when applied to specific groups, a fact leading to algorithmic bias against these groups. We also share some thoughts and guidelines on the way we envision, database practitioners should address such cases.

1 INTRODUCTION

Recently, the problem of algorithmic bias and fairness has drawn significant attention [8]. There is an increasing concern about the potential risks of data-driven approaches in decision making algorithms [2, 8, 15, 16, 18], raising a call for equal opportunities by design [9]. Biases can be introduced at different stages of the design, implementation, training and deployment of machine learning algorithms.

The problem has mainly been studied in the context of fairness in classification tasks, where individuals are classified in a positive or negative class. Example applications include, among others, hiring, school admission, crime risk factor estimation, and advertisement selection. There are two general approaches to defining fairness, namely *group* and *individual fairness* [6]. A common example of group fairness is *statistical parity*, where the proportion of members in a protected class that receive positive classification is asked to be identical to the proportion in the general population. Individual fairness requires that similar people are treated similarly.

In this paper, we draw attention to issues of bias in the task of entity resolution and, in particular, to string matching for name matching tasks. Approximate string matching forms the basis of a variety of algorithms in many applications where the ability to identify a word, despite of misspellings or typographical errors, is of crucial importance.

As such, there is a significant body of work on string comparison methods for name matching tasks [3, 7]. There has also been work on assessing the performance of these string matching algorithms [4, 17]. Amongst others, Lange and Naumann [11] consider different similarity measures for different frequencies of names in a database. Nevertheless, to the best of our knowledge, it is the first time that the problem of bias occurring in name matching is examined.

In this paper, we first provide a definition of bias in name matching tasks. Intuitively, we consider a matching algorithm to be negatively biased against a specific group of names, if the mismatches occurring for names in this group exceed those occurring on the average. Then, we examine a number of widely used string similarity measures in terms of bias.

We provide extensive experimental evidence that there is bias against certain race groups when applying string comparison algorithms for name matching tasks. This kind of biased behavior appears mainly against people with Asian origin, not intentionally, but as a consequence of the basic characteristic these names have, which is short length, compared to the names of people of other races. We then discuss approaches towards making methods for approximately matching names fair.

In brief, the contributions of this paper are outlined as follows:

- We identify the problem of bias in string comparison methods for name matching tasks.
- We propose a definition of bias for name matching tasks.
- We provide empirical evidence (in the form of extensive experimentation) of bias in a number of string similarity measures.
- We discuss how this problem may be addressed.

The rest of this paper is structured as follows. Section 2 introduces our measure for quantifying bias in name matching tasks, followed by a short description of the methods used in our assessment. Next, in Section 3, we present our experimental evaluation. Finally, we conclude in Section 4, summing up our findings, providing our vision on how bias cases for name matching tasks should be addressed by database practitioners and provide some thoughts for future work.

2 METHODOLOGY

In this section, we present our definition for bias in name matching tasks and a brief description of the string matching methods used in our evaluation.

2.1 Defining Bias

We need to quantitatively define the notion of bias in the context of record matching. In general, we want to capture the fact that for specific groups in the user population, there is unfair behavior. Let us use U to represent the general set of users. We assume that users are divided into m groups, G_i, $\cup_i G_i = U$, and $G_i \cap G_j = \emptyset$, for $i \neq j$, based on the value of some protected attribute, such as, for example, race, or gender.

Intuitively, we assume that there is bias against some specific user group G, if there are more errors in the results of matching when it comes to users in G than in the general population. There are two cases of errors, or *mismatches*. The first case is when two records are falsely reported as a match. This corresponds to a False Positive (FP). The second case is when two records that correspond to the same entity are not matched. This corresponds to a False Negative (FN). This is formalized in Definition 1.

Definition 1 (group mismatch). *The mismatch M for a user group G of size N is defined as $M(G) = \frac{\sum_{u \in G} FP(u)+FN(u)}{N}$, where $FP(u)$ and $FN(u)$ are the false positives and false negatives when matching names referring to user u in G.*

We determine whether a name matching method is biased towards a particular group by comparing its mismatch performance for this group with its mismatch performance for all groups of the general population U. To this end, we define

$$GM(U) = \frac{\sum_{G_i \in U} M(G_i)}{m} \tag{1}$$

Definition 2 (name matching bias). *The bias B of a string comparison method for a group population G is defined as:*

$$B(G) = \frac{GM(U) - M(G)}{GM(U)} \tag{2}$$

Let us now discuss the values of bias and their meanings. If G's mismatches are equal to the average number of mismatches of all groups, then its bias is equal to zero. On the other hand, if the mismatches of G are more than the average, then bias gets a negative value, and, in this case, we consider that the method examined is negatively biased against G. Finally, when the average number of mismatches is greater than that of G, then we assume that the method is biased in favor of G. Values close to 0 indicate low bias, while as the absolute value of bias increases, this is an indication of increased bias, either positive or negative.

In this paper, we consider string matching algorithms applied to names and race as the protected attribute.

2.2 Methods for Name Matching

Let us now briefly present some popular string comparison methods for name matching tasks that we use in our empirical evaluation. Let us consider two strings, which, in our case, represent names, S_1 and S_2.

Edit Distance. The edit distance between S_1 and S_2 is the minimum number of edit operations required to transform S_1 to S_2. We use the Levenshtein edit distance [12] where an edit operation is a character insertion, deletion or replacement, and each operation has cost equal to 1.

Jaro & Jaro-Winkler Similarities. The Jaro similarity [10] between two strings S_1 and S_2 is defined as:
$JS(S_1, S_2) = \begin{cases} 0, & \text{if m=0} \\ \frac{1}{3}\left(\frac{m}{|S_1|} + \frac{m}{|S_2|} + \frac{m-t}{m}\right), & \text{otherwise} \end{cases}$, where $|S_1|$, $|S_2|$ are respectively the lengths of S_1 and S_2, m is the number of matchings, and t is the number of transpositions defined as follows. Two characters are considered matching, if they are the same and within distance less than $\left\lfloor \frac{max(|S_1|, |S_2|)}{2} \right\rfloor - 1$. The number of transpositions is calculated as follows: The i-th common character in S_1 is compared with the i-th character in S_2. Each nonmatching character is a transposition.

Jaro - Winkler similarity [19] is based on Jaro similarity, favoring prefix matches, as they are considered of higher importance for name matching. It is defined as: $JWS(S_1, S_2) = JS(S_1, S_2) + l\,p(1 - JS(S_1, S_2))$, where l is the length of common prefixes of S_1, S_2, topping at four common characters and p a scaling parameter defaulting to 0.1.

Q-gram based methods. Q-grams are successive substrings of a string each of length Q. Each string is divided into a set of distinct Q-grams. Let N_1 and N_2 be the sets of Q-grams of strings S_1 and S_2 respectively. There are various set comparison measures [13]. In this paper, we use the Dice coefficient and Jaccard index, where the Dice coefficient is defined as $DC(S_1, S_2) = \frac{2|N_1 \cap N_2|}{|N_1|+|N_2|}$, and the Jaccard index as to $JI(S_1, S_2) = \frac{|N_1 \cap N_2|}{|N_1 \cup N_2|}$.

Table 1: Soundex mapping table.

a, e, h, i, o, u, w, y	→	0	*l*	→	4
b, f, p, v	→	1	*m, n*	→	5
c, g, j, k, q, s, x, z	→	2	*r*	→	6
d, t	→	3			

Soundex. Soundex, based on English language pronunciation, is the oldest (patented in 1918 [14]) and best known phonetic encoding algorithm. It keeps the first letter of a string and converts the rest into numbers according to Table 1. All zeros (vowels and 'h', 'w' and 'y') are then removed and sequences of the same number are merged to a single one. The final code is the original first letter and three numbers (longer codes are stripped off, and shorter codes are padded with zeros).

3 EXPERIMENTAL EVALUATION

In this section, we present the findings of our empirical assessment.

3.1 Experimental Setup

For our evaluation, we use data from the US Census Bureau[1], list of names. This list contains 162253 distinct names and the frequency of appearance of each of these names in several race groups in the agency's database. We selected three of the most popular of these race groups. These are the groups of names from people characterized as White, Afro-americans and those with Asian or Pacific origin. Since people of different races may have the same name, we keep only those names for which at least 90% of the people having these names belong to a single group. Then, we extracted the 50 most common names from each of these groups. The statistics of the dataset used in this study are depicted in Table 2.

Since our aim is to assess the effectiveness of string similarity methods for name matching tasks, we need alternative or erroneous versions of the names that we have extracted, for matching them with their original versions. For this purpose, we have employed the data corrupter from the German Record Linkage center [1]. This was configured to perform one random edit operation (insertion, deletion or replacement) in each of the names we have extracted, so as to produce 1 error for each of them, as it is rather unusual for a word to have more than one or two typographical errors [5].

Then, we perform record linkage between the original and the corrupted version of the datasets using each of the string comparison methods presented earlier. For each of these methods, we perform the same experiment 10 times. The matching thresholds used for each method are illustrated in Table 3.

For the Levenshtein distance, the minimum difference between two strings is equal to 1, meaning one modification. Jaro, Jaro-Winkler, Dice are Jaccard are similarity measures returning values between 0, for total dissimilarity, and 1 for absolute similarity. Finally, we desire codes produced by Soundex to totally coincide, since its representation contains approximation characteristics.

[1] Available at https://www.census.gov/topics/population/genealogy/data/2010_surnames.html

Table 2: Statistics of the dataset.

Race Group	Average occurrences per name in top-50	Average occurrences per name in group	Number of distinct names in group
Asian	68861.44	964.1	2897
Black	3027.06	272.52	2364
White	91959.86	681.72	100688

We built a testbed using Anaconda Python 3.5 and conducted our experiments on Ubuntu 18.04 LTS, powered by an Intel i5 processor with 8 GBs of RAM. The results of our assessment are illustrated in Figure 2. In all plots, the horizontal axis is used to display the various thresholds used in our evaluation, while the vertical axis represents bias. In each plot, the results for all races are illustrated using error bars, displaying the minimum, average and maximum measurement.

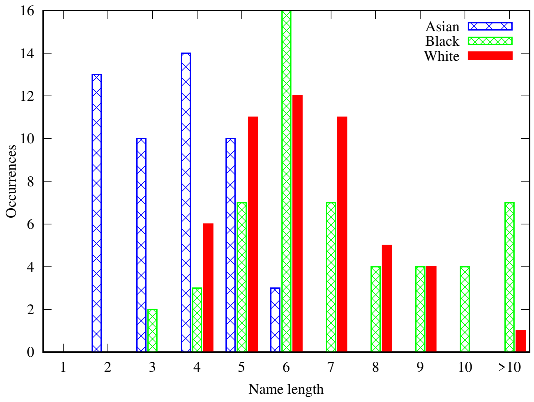

Figure 1: Length distributions for the top-50 names.

3.2 Discussion of the Results

Figure 2 indicates that all measures treat names from different groups differently, that is, all measures exhibit some form of bias. As a first step to interpret this bias, we seek to identify similar characteristics in each of the group of names. As such, we measure the lengths of the names in each group. These results are illustrated in Fig. 1. As we can see, the shortest names belong to people whose race is characterized as Asian.

We will now attempt to associate the length of these race groups with the behavior of the string comparison methods. As we can observe from Fig.2(a), the Levenshtein distance method performs worse for names with Asian origin than for names associated with people of White or African race. For the Asian group, the Levenshtein distance incurs negative bias lower than -1.67 when considering as matching names featuring an edit distance equal to 2, which is the lowest score in our evaluation. We speculate that, the reason for this behavior is the shorter length of the Asian names, as opposed to the other two groups, causing more ambiguous matches. The method seems to be slightly biased in favor of both the other two groups, with the White group receiving higher positive bias between the two.

As shown in Fig 2(b), Jaro also exhibits a continuous negative bias for the Asian group and a positive bias towards the African group. For the White names dataset, however, the situation is somewhat mixed. For matching threshold equal to 0.7, the bias is negative, then it becomes almost zero for threshold equal to 0.8 and it turns positive for a threshold equal to 0.9. This occurs because as we increase the threshold, the number of false positive matches drops, while the number of false negative matches remains merely unchanged. For Jaro-Winkler (Fig. 2(c)) the negative bias against Asian names is evident, again, as the positive bias in favor of African names. In this case, however, the method seems to also be negatively biased against White names as well.

Let us now consider the case of breaking names into sets of Q-grams. For the Dice coefficient 2(d), we observe that the bias for all groups tends to converge to zero, when we use a high matching thresholds equal to 0.9. This is because, there are zero matches in most cases. As such, the number of false negatives is almost the same for each case and the number of false positives is the factor affecting the bias for each method. Examining each group individually now, it is evident that, again, there is negative bias towards the Asian group. The other two groups exhibit similar behavior, with the African one receiving more positive bias. The use of the Jaccard index (Fig. 2(e)) results in a similar behavior. Again, the Asian dataset is far below average, while the other two are very close and slightly positive. In both cases, however, the incurred bias is much lower than in the previous methods.

Table 3: Comparison methods and threshold values used.

Method	Threshold values
Levenshtein	1, 2, 3
Jaro, Jaro-Winkler, Dice, Jaccard	0.7, 0.8, 0.9
Soundex	1

Finally, we consider the use of Soundex, which has been specifically designed for name matching tasks. In this case, a threshold is not used for matching, and there is a match when two phonetic codes coincide. The results for this case are illustrated in Figure 2(f). As we may see, again, the results are similar with the previous cases. The Asian names exhibit negative bias, exceeding -0.5, while African names score very close to +0.5. White names are very close to the average case, slightly positively biased, nevertheless. A reason for this behavior is that, Soundex does not consider vowels. As such, since Asian names are usually short having similar vowels, it is very easy for the algorithm to be led to false positives.

Summarizing, regardless of the string similarity measure used, there is significant evidence that there is negative bias when matching names of people belonging to the Asian race, while there is positive bias when matching names of people belonging to the African race. Depending on the method used, White names may be either positively or negatively biased, falling, in most situations, within the average case. Besides this general behavior, some of the string measures are better than others in terms of the volume of bias, with the Q-gram Jaccard method outperforming the others by exhibiting the smaller bias.

4 CONCLUSIONS, THOUGHTS AND FUTURE WORK

Bias of this or some other form may be present in different steps of entity resolution and a lot of work is needed to formalize, detect and remedy it in the many different algorithms and techniques around this important task.

Our preliminary studies have revealed that, even in the basic task of name matching, there may be bias, in the sense that the quality of the results varies based on the group an individual belongs to. In this case, bias is not malicious, but rather a side effect of the data values (names) of the attributes of individuals belonging to specific groups. For name matching, we believe that we provide some useful insight to database practitioners for handling such situations. To this end, considering a single threshold for matching names from all origins, does not yield correct results for the Asian names, therefore this is a factor of concern. A first measure to alleviate this issue would be to consider the lengths of the names, or race information, if available, in cases of name matching tasks and maybe perform this task separately for this class of names.

For the future, there are many additional steps to be taken, as our study focuses on a very specific task, namely string matching based on names. We aim at performing further experiments considering data from more distinct groups which are going to be addressed as hidden parameters and examining deeper the structures of the names of each case, in order to reveal more factors that cause algorithmic bias in name matching tasks.

ABSTRACT

In this work we present Rock, a method where the points **Ro**am to their **c**lusters using **k**-NN. Rock is a draft for an algorithm which is capable of detecting non-convex clusters of arbitrary dimension while delivering representatives for each cluster similar to, e.g., Mean Shift or k-Means. Applying Rock, points roam to the mean of their k-NN while k increments in every step. Like that, rather outlying points and noise move to their nearest cluster while the clusters themselves contract first to their skeletons and further to a representative point each. Our empirical results on synthetic and real data demonstrate that Rock is able to detect clusters on datasets where either mode seeking or density-based approaches do not succeed.

1 INTRODUCTION

Mode seeking clustering algorithms aim for detecting the modes of a probability density function (pdf) from a finite set of sample points. This type of clustering algorithm serves the purpose of detecting local maxima of density of a given distribution in the data set. In contrast density-based methods have the capability of detecting density-connected clusters of arbitrary shape. Rock positions itself between mode-seeking methods and density-based approaches. It is capable of detecting clusters of non-convex shapes *and* arbitrary densities at the same time. Plus it provides representatives for the detected clusters. Such an approach contributes additional expressiveness to the density-connected clusters. Further Rock provides the possibility to observe the directions of the data points roaming to the representatives. As an example, Figure 1 shows the path every point travels to its cluster representatives over time when Rock is applied. As Rock is not relying on any predefined density kernel it is able to detect non-convex clusters, which is a major advantage regarding other clustering methods.

The remainder of this paper is organized as follows: We provide a brief overview on the mode seeking method Mean Shift and other k-NN-based mode seeking algorithms. We then proceed explaining the Rock algorithm. Following to the elaboration on the algorithm we evaluate the performance of Rock against k-Means, Mean Shift and DBSCAN. Here the linking-role of Rock becomes clear, as our algorithm detects non-convex shaped areas where e.g., k-Means and Mean Shift fail and yet provides a representative of each detected cluster similar to the centroids in k-Means or modes in Mean Shift. We conclude this paper by providing an overview of the core features of our method and further elaborating on potential future work.

The main contributions of Rock are as follows:

- It finds non-convex shaped clusters of any density, which neither density based clustering methods nor mode or centroid based clustering methods are capable of
- The number of clusters does not have to be given by the user
- It provides a representative for every cluster

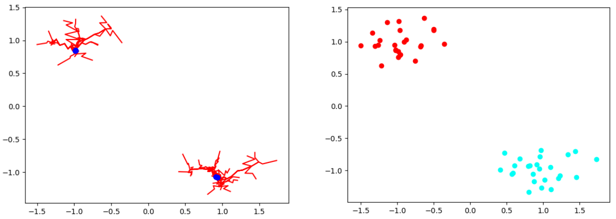

Figure 1: All points of a dataset with two clusters: overlapping final positions and the trajectories of all points on the left, initial positions and clustering on the right

2 RELATED WORK

The most popular related work is Mean Shift, which has been initially proposed in [5]. Its core idea is to regard the points in an area around each point and iteratively shift the center of this area to the mean of the points lying in the previously regarded area. The Mean Shift method became popular in the field of clustering by the work of [2]. The core concept of Mean Shift is to determine the maxima (referred to as modes) of a given density function. In contrast to Rock, Mean Shift requires a kernel function K by which the weights of the nearby points are determined in order to re-estimate the mean. Further the used kernel requires a size of the area to be regarded around each point, which is also referred to as bandwidth. The choice of the bandwidth is not trivial, additionally there can be the need of an adaptive bandwidth size.

Another algorithm for detecting modes is developed in [3]. In contrast to the Mean Shift approach they rely on k-Nearest Neighbors (k-NN). While Mean Shift relies on a kernel density estimate (KDE) the k-NN approach relies on a k-NN density estimate. The algorithm in [3] defines for each input point x_i a pointer to the point within the k-Nearest Neighbors with the highest k-NN density. The process is repeated until a pointer points to itself, which represents then the local mode of x_i. However, in contrast to Rock, this method also relies on a density definition, where the density of a point is defined as inversely proportional to the distance of the k-th nearest neighbor. In a more recent work, [8] proposed a k-NN clustering method relying on consensus clustering, in which results of several clustering trials are combined in order to get a better partition.

Regarding methods which generate a backbone of a cluster, in a more recent work named ABACUS [1] the authors propose a method which is specialized in identifying skeletons of clusters using k-NN. However ABACUS and Rock differ in two major aspects. First, Rock does not primarily aim for the skeletons of a cluster but for a representative for each detected cluster (body to representative). In contrast ABACUS is targeted to find first a

Figure 2: Actual positions of the points at the given time t. First “skeletons” of the clusters emerge, which then tighten to divisible clusters.

backbone of a cluster and then expand from the backbone until a border of a cluster is reached (backbone to body). Secondly, ABACUS uses a static k for the k-NN approach. In our work in progress, we provide a method where k changes over each iteration step.

In this paper we compare Rock with Mean Shift and k-Means [7]. K-Means is a partitioning clustering algorithm where the user provides the number of clusters k which shall be detected. The cluster model of k-Means provides as a result the cluster centroids μ and the assignment of the datapoints to their centroids. Finally we evaluate the performance of Rock compared to DBSCAN [4], which is a density based clustering method. We compare to density based clustering since it is in contrast to other types of clustering algorithms capable of detecting non-convex shaped clusters. DBSCAN requires an ε-range and a minimum number of points ($minPts$) which shall be located within this ε-range. Through these two parameters the user can control how dense the detected clusters have to be.

3 THE ALGORITHM

Rock implements the best of both worlds, partitioning and density-based clustering. It is able to detect non-convex clusters and clusters of highly different densities. Since we use the k-Nearest Neighbors as main indication for cluster membership the algorithm works for arbitrary numbers of dimensions. Given a query point p and a number of neighbors k, the k-Nearest Neighbors at timepoint t (we will explain that later) are defined as a set $kNN_t(p,k) \subseteq DB$ with exactly k objects, such that for all of these objects $\{o_1, o_2, ..., o_k\}$ the distance to the query point p is less or equal to the distance of any other data point o' to p in our data base DB:

$$\forall o \in kNN_t(p,k), \forall o' \in DB \setminus kNN_t(p,k) : d_t(p,o) \leq d_t(p,o')$$

t refers to the timepoint at which the data base DB is looked at, since each point will have a different position at different timepoints in our algorithm. Similarly we use $d_t(p,o)$ to describe the distance between points p and o for the status of the data base at timepoint t. For detecting the k-Nearest Neighbors, our implementation of Rock uses a Balltree [9] as index structure according to the sklearn reference.

The idea of Rock is, that every point moves gradually to the representative point ζ of its cluster by “wandering” into the center of its k-Nearest Neighbors in every step. So Rock does not need any other information than where the k-NN of each point are located at time step t, which makes it easily parallelizable. Equation 1 gives us the position ζ of a point p at a time t using $k(t)$ as the number of regarded neighbors: we get the new position $\zeta(p,k,t)$ of p by calculating the mean position of all objects $o \in kNN_{t-1}(p,k(t))$, i.e. of all k-NN of this point p *at the previous time step.*

$$\zeta(p,k,t) = \sum_{o \in kNN_{t-1}(p,k(t))} \frac{\zeta(o,k,t-1)}{k(t)} \qquad (1)$$
$$\zeta(p,k,0) = initialPosition(p)$$

We increase k linearly over time and stop if the algorithm converged or a given maximal time $tmax$ is reached. Of course we do not only store the actual position at a time of each point p but also its initial position $initialPosition(p)$. With that we are in the end able to put all points which have almost the same actual position into one cluster. This is when the distance is smaller than ε, which is described in equation 2. Therefore we regard the 1-NN-distances of all points, which is the distance to the first nearest neighbor each, and use half of the average 1-NN distances of all points as ε:

$$\varepsilon = \frac{\sum_{p \in DB} \left(\sum_{o \in kNN(p,1)} dist(p,o) \right)}{2 \cdot |DB|} \qquad (2)$$

We choose this ε since it delivers an intuitively good measure for how close two points have to be to be "mergeable" in regards to their initial distribution.
In summary the algorithm looks like follows:

Algorithm 1 Rock(pointset, tmax)

```
changed= true
t=0
while changed and t < tmax do
    k=k(t)
    changed=false
    for p in pointset do
        oldPosition= p.getOldPosition()
        newPosition= meanOfKNN(pointset, p, k, t)
        p.setActualPosition(newPosition)
        if distance(oldPosition, newPosition)<$\varepsilon$ then
            changed=true
    t++
```

Note that $tmax$ is not mandatory a hyperparameter and can be set beforehand to the same value for various experiments as we will show in section 4. If we took a static k, most of the points would only shrink together with their exact k-Nearest Neighbors. Thus, we increase k over time, to receive stable clusters. The minimal value with which we will also start should be $k = 3$, since observing less nearest neighbors (including the point itself) would not lead to anything. The highest useful value for k is $\frac{n}{2}$ for a dataset of n points since if more neighbors would be regarded, it would lead to only one big cluster. We want to reach that highest value at the maximal number of iterations $tmax$, thus we obtain for linear increase:

$$k(t) = \frac{0.5n - 3}{tmax} \cdot t + 3$$

In order that k actually increases in every step the slope of $k(t)$ should be at least 1. Therefore $tmax$ should be chosen such that $tmax < 0.5n - 3$. Choosing $tmax$ significantly too low would mean to early regard a high number k of nearest neighbors, which potentially belong to other clusters, and therefore merging several clusters into one. Vice versa, a significantly too high $tmax$ could result in clusters splitting up.

Figure 2 shows the positions of all points at expressive points in time t while clustering the two moons dataset, which is further described in section 4.1. Regarding that, we already note an additional advantage: The skeleton which emerges already in early steps for each cluster could be used for anytime results or elimination of outliers, which we plan to examine further in future work.

3.1 Complexity

Having described our algorithm, we now elaborate on the runtime complexity of Rock and compare it on a theoretical basis to k-means and MeanShift. Focusing first on the used index structure, according to [9] the runtime complexity of a Ball tree is $O(d \log(N))$ where d denotes the dimensionality and N the number of data points. The runtime complexity of MeanShift is $O(iN^2)$ where i denotes the number of iterations. k-Means has a runtime complexity of $O(Nkid)$ where k refers to the number of clusters which shall be found. For Rock, using the Balltree structure, we get a runtime complexity of $O(kNd \log(N))$ where k denotes here the number of k-NN. Conclusively it can be stated that our method performs with regards to its time complexity between the performance of k-means and MeanShift. Since this is a work in progress, it may be viable to consider query-strategies which rely on different structures, such as e.g., Locality-Sensitive-Hashing (LSH) as used in [10].

4 EVALUATION

We tested Rock on several datasets and compared our results to the ones obtained by DBSCAN, k-Means and Mean Shift, since Rock positions itself between them: it finds non-convex shaped clusters as DBSCAN, but as well finds clusters of different densities with according representatives as k-Means and Mean Shift. As quality measures we use the Normalized Mutual Information (NMI) and the Adjusted Rand Index (ARI) in regards to the ground truth. All experiments were executed with $tmax = 15$, which is an empirically determined good value for the normalized data we use (i.e. removing the mean and scaling to unit variance). For all comparative methods the best parameters have been determined by iterating over a parameter range [1] and choosing those parameters which yield the best NMI resp. the best ARI for each of the methods. This shows again the simplicity of choosing the one hyperparameter Rock requires in comparison to the several parameters of our competitors, as Rock is not too sensitive to $tmax$, as we will show in future work due to the lack of space.

4.1 Two Moons

The dataset as shown in Figure 3 is a classical and well known dataset consisting of two moon-shaped clusters. For Mean Shift a bandwidth of 0.6 yielded the best NMI and a bandwidth of 1.2 yielded the best ARI. For DBSCAN $\varepsilon = 0.3$ and $minPts = 2$ yielded an NMI and ARI of 1 and for k-Means we chose $k = 2$. We tested the dataset with 250 datapoints and 5% noise, obtaining the optimal result with Rock as well as with DBSCAN. The non-density based methods k-Means and Mean Shift assigned a part of each moon to the false cluster as shown in Figure 3. As that, k-Means reaches an NMI of 0.36 and an ARI of 0.46. Mean Shift performed slightly better with an NMI of 0.53 (bandwidth 0.6) and an ARI of 0.50 (bandwidth 1.2). It may seem unintuitively first why Rock finds such shaped clusters even though regarding "only" the k-NN, but it makes sense considering that we slowly increase k. Figure 2 shows the development of the points' positions: First, the noise gets eliminated and the skeleton of the two clusters emerges. Then the ends of the clusters shrink up more and more into the middle of the clusters each. When the algorithm finishes at $tmax = 15$, there are only the two representatives of the clusters left as Figure 2d implies already.

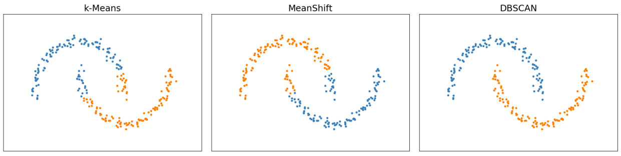

Figure 3: The clustering of two moons as received by k-Means, Mean Shift and DBSCAN (in this order)

4.2 Mouse

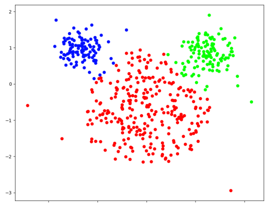

Figure 4: Result Rock returns for the mouse dataset

	NMI	ARI
k-Means	0.58	0.53
Mean Shift	0.67	0.66
DBSCAN	0.71	0.68
Rock	0.81	0.86

Table 1: Performances of the algorithms on the mouse dataset

To show how Rock deals with colliding clusters, we chose the mouse dataset. It consists of three round clusters of different densities which blend into each other at two points, where the "ears" of the mouse touch the "head". We conducted the experiment with Mean Shift using a bandwidth of 0.9, with DBSCAN using an ε-range of 0.2 and $minPts = 4$, and k-Means with $k = 3$. While Rock is able to distinguish the three clusters without a problem, the other algorithms cannot, as Figures 4.2 and 5 show: DBSCAN does not find the correct dividing line between head and right ear, k-Means puts a lot of the points from the head to the ears, and Mean Shift performs only slightly better than k-Means. The exact values of the resulting NMI and ARI can be seen in table 1.

4.3 Iris

Iris [6] may be the most famous dataset and one of the most challenging ones, since two of the three clusters are very difficult

[1] We tested ε with steps of 0.1 in a range of $[0.1, 2.0]$, $minPts$ with steps of 1 in a range of $[2, 10]$ and the bandwidth with steps of 0.1 in a range of $[0.1, 2.0]$

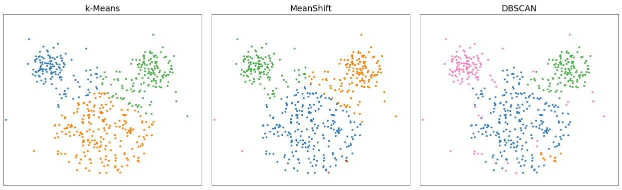

Figure 5: Clustering of the mouse dataset as obtained by the comparative methods k-Means, Mean Shift and DBSCAN (in this order).

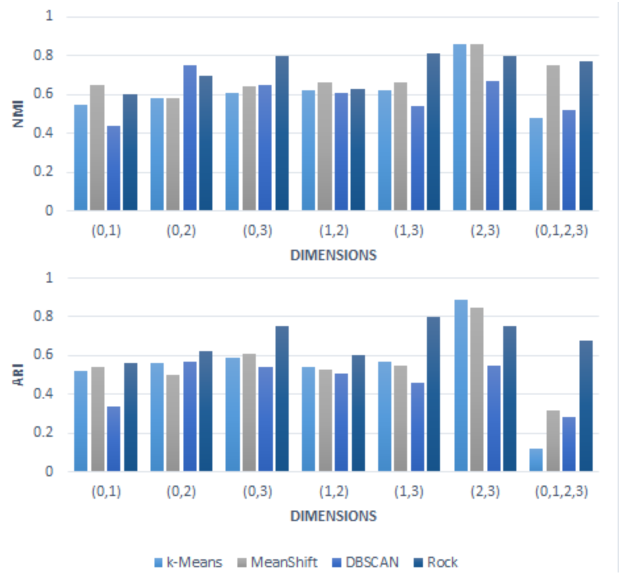

Figure 6: The NMIs (top) and ARIs (bottom) reached by the comparative methods and Rock, using different combinations of dimensions of the Iris dataset respectively.

to separate for they are overlapping in virtually every dimension. Nevertheless, even here Rock delivers good results: depending on which two of the four given dimensions it regards, we receive an NMI between 0.6 and 0.8 and an ARI between 0.56 and 0.8. These results are very good in comparison to the other methods, as Figure 6 shows: regarding the NMI we achieve at least the second best value, but most of the times the very best, no matter which two dimensions of the dataset are regarded. Concerning the ARI we mostly surpass the other algorithms, partially by far, as for example by using dimensions 1 and 3 (which is also reflected in the NMI). Since we claimed in Section 3 that Rock works with higher number of dimensions, we conducted an experiment on the full four-dimensional Iris dataset. Here our method yields the best results compared to its competitors, especially with regards to the computed ARI as can be seen in the rightmost case in Figure 6. The exact parameters for the comparative methods are shown in table 2 in the appendix.

5 CONCLUSION

In conclusion we developed an algorithm which is able to autonomously find clusters of various kind. Due to the successive increase of neighbors being decisive to a point, we are able to find non-convex shaped clusters. Without this successive increase Rock would be equivalent to a simple k-Means, but with the increase we only obtain the advantages of k-Means: being simple and providing kind of a cluster centroid which gives us even more information about the found clusters than DBSCAN provides. With the right use of index structures Rock is not only effective but also efficient. We showed that Rock surpasses good methods like Mean Shift, DBSCAN and k-Means in regards to non-convex shaped clusters, colliding clusters of different densities and even overlapping clusters like in the Iris dataset. Since it regards k-NN and no other distance measures it works on high dimensional datasets as well as on two dimensional ones. The rate of increase of k will be treated in future work, as a logarithmic or hyperbolic increase could lead to interesting results. Moreover we are also curious to know the impact of using reverse k-Nearest Neighbors instead of the k-NN, as well as using the median or mode of the k-NN instead of the mean. The influence of the parameter $tmax$ was also not yet analyzed thoroughly. And, last but not least, the feature of Rock to create skeletons of the clusters before reducing them further to representatives could be used to detect advanced structures, eliminate noise, or deliver anytime results.

A APPENDIX

Dimensions	Mean Shift	DBSCAN		k-Means
	bandwidth	minPts	ε	k
(0, 1)	0.9	2, 8	0.4, 0.5	3
(0, 2)	0.8, 0.6	2	0.5	3
(0, 3)	0.7, 0.8	2	0.5	3
(1, 2)	1.0	2	0.59	3
(1, 3)	0.8	2	0.7	3

ABSTRACT

The discrete Fréchet distance (DFD) is widely used to measure the similarity between two trajectories. Trajectory range query has been extensively studied in trajectory analytical applications, e.g., outlier detection, movement pattern analysis. With the discrete Fréchet distance, the above applications are computation bound rather than disk I/O bound. In this work, we propose new lower and upper bound functions to speedup the evaluation of trajectory range queries. Experimental studies on three real datasets demonstrate the superiority of our proposal.

1 INTRODUCTION

The range query problem on trajectory dataset is a core subroutine in trajectory analytical applications, e.g., anomaly monitoring [3], traffic analysis [4]. In particular, given a query trajectory q and trajectory database T, the trajectory range query problem returns a subset $S \subseteq T$ such that for each $t \in S$, the distance between t and q is within given threshold θ, i.e., $dist(t, q) \leq \theta$. Specifically, we use the discrete Fréchet distance (DFD) d_F, a widely used trajectory similarity measure [1, 5]. Given two trajectories $t = \langle t[1], t[2], \cdots, t[n] \rangle$ and $q = \langle q[1], q[2], \cdots, q[m] \rangle$, a coupling L between t and q is a sequence $\langle (t[a_1], q[b_1]), (t[a_2], q[b_2]), \cdots, (t[a_l], q[b_l]) \rangle$, where $a_1 = 1, b_1 = 1, a_l = n, b_l = m$, and for all $i = 1, \cdots, l$, we have $a_{i+1} = a_i$ or $a_{i+1} = a_i + 1$, and $b_{i+1} = b_i$ or $b_{i+1} = b_i + 1$. The discrete Fréchet distance between t and q is defined as

$$d_F(t, q) = \min_{L \in \Omega} \max_{(t[a_i], q[b_i]) \in L} ||t[a_i] - q[b_i]||,$$

where Ω is the set of all possible couplings between t and q.

Figure 1(a) illustrates the discrete Fréchet distance (DFD) between two trajectories t and q. Computing discrete Fréchet distance between t and q is equivalent to find a path from $(t[1], q[1])$ to $(t[n], q[m])$ in a free space diagram such that (i) the path travels along non-decreasing positions, and (ii) the maximum $||t[a_i] - q[b_i]||$ along the path is minimized [5]. For instance, the value of $d_F(t, q)$ in Figure 1 is determined by the gray path in Figure 1(b). Since it can be computed via dynamic programming, the time complexity of DFD computation is $O(mn)$.

In the literature, several lower and upper bounds have been proposed for DFD [2, 5]. We will introduce these bounds in Section 2. Nevertheless, the trajectory range query problem is still a computationally intensive problem, taking $O(|T|mn)$ time, where $|T|$ is the cardinality of trajectory dataset. To improve the query performance, we devise new lower and upper bound functions in this paper. Our experimental studies on real datasets reveal that our proposal improves the range query performance on DFD by up to an order of magnitude when compared to a baseline approach based on existing techniques.

The remainder of this paper is organized as follows. Section 2 formulates trajectory range query problem and presents the baseline solution adapted from existing works. We present our novel techniques in Section 3. Section 4 demonstrates the efficiency of our proposal with experiments on real datasets. Finally, we conclude the paper in Section 5.

2 PRELIMINARIES

In this section, we first define the trajectory range query problem in Section 2.1, then we present the baseline solution for it by adapting existing techniques in Section 2.2.

2.1 Problem Definition

Definition 2.1 (Trajectory Range Query Problem). Given a query trajectory q, and a trajectory dataset T and distance threshold θ, the trajectory range query returns a subset $S \subseteq T$ such that for each trajectory $t \in S$, the discrete Fréchet distance (DFD) between t and q is at most θ, i.e., $d_F(t, q) \leq \theta$.

A straightforward approach for this problem (cf. Definition 2.1) is to compute the exact discrete Fréchet distance (DFD) between each trajectory $t \in D$ and the query trajectory q. Its time complexity is $O(|T|mn)$, rendering it impractical for a large trajectory dataset.

2.2 Baseline Solution

In this section, we briefly introduce a baseline approach for the trajectory range query problem (cf. Definition 2.1) which employs existing techniques in the literature. It follows the filter-and-refinement paradigm. Let $LB(t, q)$ and $UB(t, q)$ denote the lower and upper bounds of $d_F(t, q)$ respectively, i.e., $LB(t, q) \leq d_F(t, q) \leq UB(t, q)$. A candidate t cannot be a result if $LB(t, q) > \theta$. A candidate t is definitely a result if $UB(t, q) \leq \theta$. In these two cases, we save an expensive exact DFD computation.

(a) Group-based trajectory (b) Group-based bounds

Figure 2: Group-based DFD illustration and computation

We introduce existing lower and upper bounds as follows.

Cell-based lower bound LB_{cell} (from [5]): The cell-based lower bound is defined as

$$LB_{cell}(t, q) = \max(||t[1] - q[1]||, ||t[n] - q[m]||).$$

The idea of LB_{cell} is that any coupling L between q and t must start from $(1, 1)$ and end at (n, m). Its computation cost is $O(1)$.

Row-based lower bounds LB_{row} and LB_{cross} (from [5]): The row-based and column-based lower bounds are defined as follows:

$$LB_{row}(t, q) = \min_{b_i \in [1,m]} (||t[2] - q[b_i]||).$$

$$LB_{col}(t, q) = \min_{a_i \in [1,n]} (||t[a_i] - q[2||).$$

The path leading to DFD pass through the second column and row certainly contribute these two bounds. Both of them have $O(n)$ time complexity.

For example, the row-based and column-based lower bounds for trajectory t and q are $LB_{row}(t, q) = \min\{2, 4, 1, 4, 7, 7\} = 1$ and $LB_{col}(t, q) = \min\{7, 6, 7, 5, 4, 3\} = 3$, respectively.

By combining row-based and column-based lower bounds, we obtain a cross-based lower bound as follows.

$$LB_{cross}(t, q) = \max(LB_{row}(t, q), LB_{col}(t, q)).$$

Group-based bounds LB_g and UB_g (from [5]): The idea is to partition a trajectory t (in Figure 1(a)) to a grouped trajectory $gt = \{gt[1], gt[2], gt[3]\}$ (in Figure 2(a)), which can be represented by a sequence of minimum bounding rectangles (MBRs). The length of group-based trajectory is denoted as τ. The minimum and maximum distance between $gt[a_i]$ and $gq[b_i]$ (two MBRs) are denoted as $d_G^{lb}(gt[a_i], gq[b_i])$ and $d_G^{ub}(gt[a_i], gq[b_i])$.

They can be derived in $O(1)$ cost. For example, in Figure 2 $d_G^{lb}(gt[2], gq[2])$ and $d_G^{ub}(gt[2], gq[2])$ are 1 and 4, respectively.

The DFD computing procedure with group-based trajectory adopts the minimum or maximum distances between MBRs leads a lower or upper bound of $d_F(t, q)$, as follows:

$$LB_g(t, q) = \min_{L \in g\Omega} \max_{(gt[a_i], gq[b_i]) \in L} d_G^{lb}(gt[a_i], gq[b_i]),$$

$$UB_g(t, q) = \min_{L \in g\Omega} \max_{(gt[a_i], gq[b_i]) \in L} d_G^{ub}(gt[a_i], gq[b_i])$$

As shown in Figure 2(b), the lower and upper bound DFD distance between group-based trajectory gt and gq are $LB_g(t, q) = 2$ and $UB_g(t, q) = 6$, respectively. It reduces computation cost as $O(\tau^2) < O(mn)$.

Greedy-based upper bound UB_{greedy} (from [2]): In addition to the above bounds, [2] proposed a greedy algorithm to compute an upper bound for $d_F(t, q)$ with $O(n)$ cost.

The idea of greedy algorithm is simple, e.g., the discrete Fréchet distance (DFD) goes as follows: in every step, make the move that minimizes the current distance, where a "move" is a step in either one sequence or in both of them. The greedy algorithm guarantees $2^{\Theta(n)}$-approximation of the discrete Fréchet distance with linear time cost $O(n)$. As shown in Figure 1(b), the greedy algorithm produces the path shown as the circled numbers.

Figure 4: Running example

Baseline approach: We construct the baseline approach by exploiting existing techniques. It applies a filter-and-refinement framework, as shown in Figure 3. It computes exact DFD distance for a candidate t only if it cannot be dismissed by lower bounds (i.e., LB_{cell}, LB_{cross}, LB_g) or upper bounds. Specifically, the computation cost of employed bounds are in an order from quick-but-dirty one to slow-but-accurate one.

3 PROPOSED OPTIMIZATIONS

To improve the performance of trajectory range query (cf. Definition 2.1), we propose several novel optimizations in this section.

3.1 Group-based border bounds

The lower bound distance between two grouped trajectories gt and gq is $LB_g(t, q) = \min_{L \in g\Omega} \max_{(gt[a_i], gq[b_i]) \in L} d_G^{lb}(gt[a_i], gq[b_i])$, where $d_G^{lb}(gt[a_i], gq[b_i])$ is the lower bound of ground distance between $gt[a_i]$ and $gq[b_i]$, shown as the dashed line with the label 1 in Figure 2(a). The effectiveness of the group-based lower bound pruning depends on term $LB_g(t, q)$.

Group-based border lower bound. Instead of using $d_G^{lb}(gt[a_i], gq[b_i])$ in baseline approach, we devise a tighter lower bound for ground distance between two groups $(gt[a_i], gq[b_i])$ by the crucial observation as follows. Consider $(gt[2], gq[2])$ in Figure 4, the minimum distance of $(gt[2], gq[2])$ is determined by the gray cells, as if the DFD path of trajectory t and q passes though the group pair $(gt[2], gq[2])$, $d_F(t, q)$ must be larger than

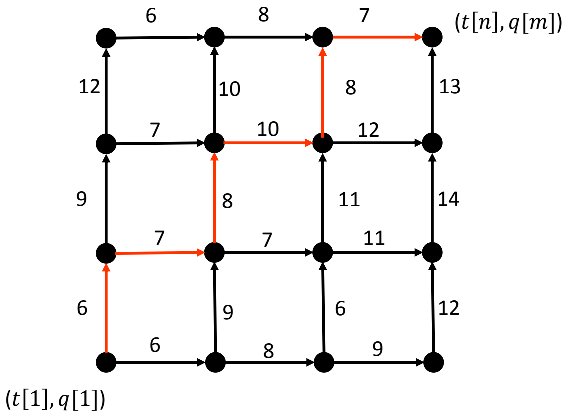

Figure 5: Group-based border upper bound

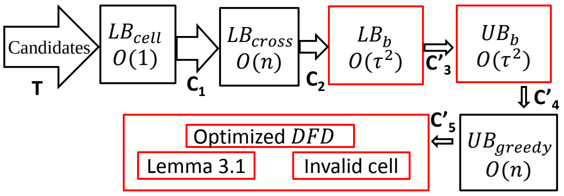

Figure 6: Advanced approach for trajectory range query

or equal to the minimum value in entrance cells (red rectangles) and exit cells (blue rectangles).

In particular, the minimum value of entrance cells and exit cells in given pair $(gt[a_i], gq[b_i])$ is defined as $d^{en}_{min}(gt[a_i], gq[b_i])$ and $d^{ex}_{min}(gt[a_i], gq[b_i])$, respectively. Thus, the entrance and exit cell based lower bound of ground distance of group pair $(gt[a_i], gt[b_i])$ is

$$d^{lb}_{ee}(gt[a_i], gq[b_i]) = \max\{d^{en}_{min}(gt[a_i], gq[b_i]), d^{ex}_{min}(gt[a_i], gq[b_i])\}.$$

Consequently, we have a tighter lower bound $LB_b(t, q)$ by

$$LB_b(t, q) = \min_{L \in g\Omega} \max_{(gt[a_i], gq[b_i]) \in L} d^{lb}_{ee}(gt[a_i], gq[b_i]).$$

There is a trade-off between the tightness of $d^{en}_{min}(gt[a_i], gt[b_i])$ (the same as $d^{ex}_{min}(gt[a_i], gt[b_i])$) and its computation cost. The quick-and-loose one is taking the smaller distance of $t[\frac{a_i n}{\tau}]$ with the MBR of $gq[b_i]$ and the MBR of $gt[a_i]$ with $q[\frac{b_i m}{\tau}]$. The slow-and-tight one is computing the smallest distance of $t[\frac{a_i n}{\tau}]$ with all points (i.e., 3, 7, 5, 6 in red rectangle) in $gq[b_i]$ and all points in $gt[a_i]$ with $q[\frac{b_i m}{\tau}]$ (i.e., 3, 5, 4, 6 in red rectangle). In terms of time complexity, the former one is $O(\tau^2)$ and the later one is $O(\tau n)$ for every group pairs in gt and gq.

Group-based border upper bound. As shown in Figure 5, the upper bound of ground distance between $t[\frac{a_i n}{\tau}]$ with the MBR of $gq[b_i]$ and the MBR of $gt[a_i]$ with $q[\frac{b_i m}{\tau}]$ for each $(gt[a_i], gq[b_i])$ pair are computed with $O(\tau^2)$ cost. The upper bound of the DFD path from $(t[1], q[1])$ to $(t[n], q[m])$ is equivalent to find a path from left-bottom corner to right-top corner, where the maximum value in that path is minimized, as the red path shown.

We denote that DFD upper bound as $UB_b(t, q)$, it is 10 in the example of Figure 5.

3.2 DFD path transfer directions

Take $(gt[1], gq[1])$ in Figure 4 as an example, the minimum distance between $gt[1]$ and $gq[1]$ is $\max\{\min\{3, 4\}, \min\{4, 6\}\} = 4$. Computing $LB_g(t, q)$ is equivalent to find a DFD path from $(gt[1], gq[1])$ to $(gt[\tau], gq[\tau])$ among the minimum distances of each group pairs, i.e., $d^{lb}_G(gt[a_i], gq[b_i])$. Even the minimum distance of each group pair is improved by entrance and exit cell bounds as above, it still can be optimized by exploiting the path transfer direction. For example, as shown in Figure 4, if the path is from $(gt[1], gq[1])$ to $(gt[1], gq[2])$, the lower bound contributes from $(gt[1], gq[1])$ is the minimum value among the magenta cells and yellow cells. Similarly, The path from $(gt[1], gq[1])$ to $(gt[2], gq[2])$ must pass the yellow cell. Obviously, the minimum value from $(gt[1], gq[1])$ to $(gt[1], gq[2])$, and from $(gt[1], gq[1])$ to $(gt[2], gq[2])$ are 6 and 7, which is larger than 4, i.e., the distance between $gt[1]$ and $gq[1]$ by entrance and exit cells bound. In summary, the transfer-based minimum values are used to tight the group-based DFD lower bound (i.e., $LB_b(t, q)$) during the DFD computation on grouped trajectories gq and gt.

3.3 DFD computation acceleration

As illustrated in Figure 3, for these candidate trajectories cannot be pruned by its lower bound or be detected as true results, it will incur expensive DFD computation $O(mn)$. Specifically, it computes the distance between any two points among t and q, i.e., each cell in Figure 4, then computes the $d_F(t, q)$ via dynamic programming. In the subsequential section, we devise two novel techniques, namely early termination and invalid cell ignoring, to reduce the DFD computation cost.

Early termination. We define $layer_{i,j}$ among trajectory t and q (cf. Figure 4) as either $t[i]$ or $q[j]$ are considered in that cells. Formally, the lower bound of $layer_{i,j}$ is defined as:

$$LB^{i,j}_{layer}(t, q) = \min\{\min_{k \in [1,j]}\{||t[i]-q[k]||\}, \min_{k \in [1,i]}\{||t[k]-q[j]||\}\}.$$

Lemma 3.1. $LB^{i,j}_{layer}(t, q) \leq d_F(t, q)$

Proof. The proof is trivial as the path from $(t[1], q[1])$ to $(t[n], q[m])$ must pass through the at least one cell of $layer_{i,j}$, thus, $d_F(t, q)$ is not smaller than the minimum value in $layer_{i,j}$. □

Thus, we terminate DFD computation if $LB^{i,j}_{layer}(t, q) \geq \theta$ with Lemma 3.1. Suppose the distance threshold $\theta = 2$, consider the $layer_{3,3}$ in Figure 4, $LB^{3,3}_{layer}(t, q) = \min\{3, 3, 4, 3, 4\} = 3$. We terminate the exact DFD computation earlier as $LB^{3,3}_{layer}(t, q) > \theta$. It improves computation cost by ignoring a lot of ground distance pair computation and the exact DFD computation.

Invalid cell ignoring. Consider the example in Figure 4, suppose the distance threshold $\theta = 7$. Given cell $(t[i], q[j])$ its distance computation can be avoided if $||t[i], q[j-1]||$, $||t[i-1], q[j]||$, and $||t[i-1], q[j-1]||$ are larger than θ. We define such kind of cells as invalid cells, set their distances as ∞, as shown in Figure 4 without incurring expensive distance computation.

Put all it together: We present the framework of our advanced approach (AA) for trajectory range query (with discrete Fréchet distance) in Figure 6. Our proposed techniques are enclosed by red rectangles, e.g., $LB_b(t, q)$, $UB_b(t, q)$, and optimized exact DFD computation.

(c) **OSM-FULL**

Figure 7: Response time vs. distance threshold θ

4 EXPERIMENTAL EVALUATION

We evaluate the performance of the baseline approach (BB, cf. Section 2) and our advanced approach (AA, cf. Section 3) for trajectory range queries. In our experiments, we report the average measurements over 10 different query trajectories.

Dataset: We used three real world trajectory datasets with diverse geographical coverage and scales of sizes.

GeoLife.[1] The GeoLife project in Microsoft Research Asia collected this dataset from 182 users over five years (April 2007-August 2012). It has 18,655 trajectories and 24.9 million GPS points.

OSM-FULL.[2] This dataset contains 7.5 years of OpenStreetMap trajectory data around the world. It includes total 2.4 million trajectories constructed by 2.7 billion GPS points.

OSM-DE. It is a subset of **OSM-FULL**. We extracted trajectories that are located in Germany. **OSM-DE** has the highest data density among all regions in **OSM-FULL** [6]. It has 0.5 million trajectories and 0.5 billion GPS points in total.

We used C++ for the implementation and conducted all experiments (with single thread) on a machine with AMD A10-7850K 3.70GHz processor and 16GB main memory.

Overall performance evaluation: We compare the performance of BB and AA for trajectory range query problem on all three real world datasets by varying distance threshold in Figure 7. AA is faster than BB by 2.42 to 50.1 times. In addition, the performance gap between AA and BB becomes large with the rise of distance threshold θ. It also confirms AA is scalable. The trajectories in **GeoLife** are much denser than other two datasets, and that is the reason why range queries perform slower though **OSM-FULL** and **OSM-DE** have large sizes.

Effect of optimizations: We then evaluate the effectiveness of our proposed optimization techniques, e.g., group border-based bound, path transfer direction-aware bound, etc. Due to space limitation, we omit the experiment results on **OSM-DE** and **OSM-FULL** as they are similar to **GeoLife**. The group-size τ is 8 in all the experiments.

Table 1 illustrates the number of DFD executions (per query) of BB and AA with regard to distance threshold θ, respectively. Obviously, our advanced approach outperforms baseline approach.

We then investigate the effectiveness of DFD lower and upper bounds. Our proposed LB_b is much better than LB_g while both with $O(\tau^2)$ cost. In addition LB_b with $O(\tau n)$ cost is slightly better than with $O(mn)$, as shown in Figure 8(a). UB_b is better than UB_{greedy} and UB_g as illustrated in Figure 8(b).

Table 1: DFD **executions on GeoLife dataset**

θ	0.1 km	0.5 km	1km	5 km
BB	6.60	48.97	125.33	550.01
AA	**1.87**	**21.15**	**19.32**	**88.1**

5 CONCLUSION

In this paper, we propose several novel techniques (e.g., group border-based bound, DFD computation acceleration) to speedup the trajectory range query problem on discrete Fréchet distance. Our advanced approach is up to 50 times faster than the baseline solution we construct from the literature. A promising direction for future work is to devise error-guaranteed approximate solutions for the trajectory range query problem.

Repairing of Record Linkage: Turning Errors into Insight[*]

Quyen Bui-Nguyen, Qing Wang, Jingyu Shao, Dinusha Vatsalan

ABSTRACT

Linking records from different data sources, referred to as record linkage, is a longstanding but not yet satisfactorily resolved question in many fields of science. For practitioners, it is difficult to ensure the quality of linkage at the time of applying linkage techniques in real world applications. Instead, linkage errors are often detected later on, mostly by users of the applications. This not only requires us to repair errors, but also provides us with opportunities to observe the linkage quality and uncover why such errors occur. In viewing that record linkage is a complex and evolving process, we study how to acquire insights from linkage errors for achieving high-quality linkage. We propose a generic repairing framework which allows us to start with imperfect linkage models, and dynamically repair linkage models and errors for improved linkage quality. We have evaluated our repairing framework over three real-world datasets and the experimental results show that the performance of the proposed tree-structured classifier SVM-tree outperforms the baseline methods.

1 INTRODUCTION

Determining which records from one or more datasets correspond to the same real-world entities, referred to as *record linkage*, is a fundamental problem arising in many fields of computer science, e-commerce, health and social sciences [4]. Current research on record linkage mainly focuses on developing accurate and efficient linkage techniques, which are constrained by a number of factors (e.g., concerns about quality of data, ambiguity of domain knowledge and unavailability of training labels) and fails to capture the full variety of record linkage [8, 11]. Therefore, it is generally difficult to guarantee linkage quality at the time when record linkage techniques are applied.

One question that often arises is how to handle linkage errors which cannot be detected at the time of applying linkage techniques, but are reported later on, particularly by users of the record linkage based applications. Since data may be enriched with additional information over time, we can find linkage errors that are hidden in the linkage process. Essentially, record linkage is not a static and one-off task, but rather a complex, continuous and evolving process. Based on the insight acquired from linkage errors we may build a repairing framework to improve linkage quality through repairing errors.

Nevertheless, building such a repairing framework is challenging. Can we generalise errors into insight and leverage such insight into improving linkage models? Not all errors are equally useful for finding insight. Some errors may be outliers and generalising such errors may even deteriorate the performance of linkage models. Thus, we need a means for assessing the genericity of linkage errors - to what extent a linkage error can act as being a representative example of similar linkage errors. In this paper, we propose a dynamic repairing framework, which aims to turn errors into insight for improved linkage models and results. The central idea is to leverage detected errors to derive similar and relevant errors for maximally repairing an “imperfect" linkage model. Figure 1 presents a high-level overview of our repairing framework which incorporates a tree-structured classifier and an error analyser for supporting an iterative repairing process. More specifically, linkage errors such as false matches or non-matches may be detected by a user or governed by integrity rules and sent to an error analyser. The error analyser uses an error normality measure to determine whether an error can be generalised for improving the linkage model. Then qualified linkage errors are sent to the tree-structured classifier, and through refining the tree structure of the classifier, the linkage quality can be improved.

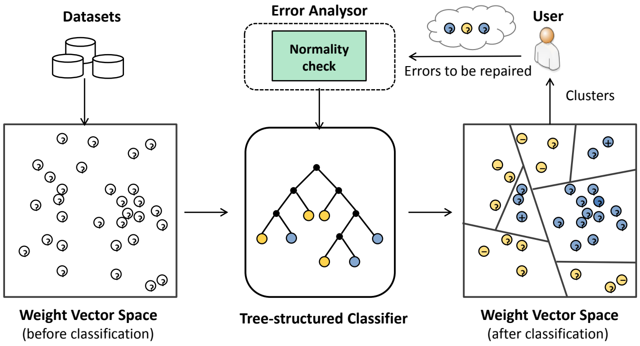

Figure 1: Proposed repairing framework, where each circled question mark represents an unlabeled weight vector, and each weight vector labeled as matches is shown with a blue $\oplus$, and non-matches with a yellow $\ominus$.

Our contributions are as follows: (1) We develop a generic repairing framework which allows us to start with imperfect linkage models and actively repair linkage models and errors for improved linkage quality. (2) We design a novel measure to assess the genericity of an linkage error, which indicates the probability of generalising errors into insight. (3) We have experimentally validated the effectiveness of the proposed repairing framework using several real-world datasets.

2 RELATED WORK

Record Linkage (RL) has long been central to the study of data integration and data cleaning [2, 5, 13]. Previous research has studied various aspects of the RL process such as: blocking, similarity comparison, classification, evaluation, active learning, and training data selection [6, 7, 9, 10, 12]. Nonetheless, these works primarily focused on preventing rather than repairing errors in linkage results.

In this paper, instead of only repairing detected errors, we also study the problem of repairing linkage models through detected linkage errors, i.e., linkage errors are leveraged to improve the performance of linkage models. It is worthy to note that,

[*] Produces the permission block, and copyright information

10.5441/002/edbt.2019.75

different from database repair [1, 3], we do not stipulate a minimal change requirement on our repairs. Existing approaches of database repair mostly deal with data errors either by obtaining consistent answers to queries [1] or by developing automated methods to find a repair that satisfies required constraints and also "minimally" differs from the original database [3]. These approaches are often computationally expensive and not applicable to repairing linkage models in real-world applications.

3 PROBLEM STATEMENT

Let R be a finite, non-empty set of records from one or more data sets. We assume that a set $F = \{f_1, \ldots, f_n\}$ of features is selected for performing record linkage tasks and each record $r \in R$ has a number of feature values $(v_1, \ldots, v_n)$ over F. Accordingly, each pair of records (r_i, r_j) over R is associated with a n-dimensional *weight vector* $\mathbf{x_{ij}} = (x_1, \ldots, x_n) \in [0,1]^n$ where each x_k represents the similarity between the feature values of f_k in r_i and r_j. For example, a pair of records (r_1, r_2) may have three features $\{\mathit{fname}, \mathit{sname}, \mathit{age}\}$ with $r_1.\mathit{fname} = \mathit{Rob}$, $r_1.\mathit{sname} = \mathit{Smith}$, $r_1.\mathit{age} = 30$, $r_2.\mathit{fname} = \mathit{Robert}$, $r_2.\mathit{sname} = \mathit{Smith}$ and $r_2.\mathit{age} = 31$, and correspond to a 3-dimensional weight vector $(0.5, 1, 0.5)$.

Let X consist of the weight vectors to which all pairs of records in R. Some blocking technique may also be applied for efficiency [9, 11]. In viewing that weight vectors are a set of data points in X, a *weight vector space* (X, δ) can be defined for X together with a *similarity metric* $\delta : X \times X \mapsto [0,1]$ that satisfies the non-negativity, identity, symmetry and triangle inequality properties as defined in [14]. Thus, the higher two data points $\mathbf{x_1}$ and $\mathbf{x_2}$ are similar, the larger the value $\delta(\mathbf{x_1}, \mathbf{x_2})$ is. A *partition* of X is a set $\{X_1, \ldots, X_q\}$ of pairwise disjoint subsets with $\bigcup_{1 \le i \le m} X_i = X$. We call each (X_i, δ) $(i \in [1, q])$ a *weight vector subspace* of (X, δ).

The label of a weight vector $\mathbf{x} \in X$ is denoted as $y(\mathbf{x})$ and $y(\mathbf{x}) \in \{1, -1\}$, where 1 refers to a true match and -1 refers to a true non-match. In this paper, we consider a linkage model as a binary classifier $c : X \longrightarrow \{-1, 1\}$, which can classify a weight vector $\mathbf{x}$ either as 1 or as -1. Thus, two kinds of errors may occur in record linkage: (1) false positives (i.e. false matches) and (2) false negatives (i.e. false non-matches):

- $fp(c) = \{\mathbf{x} \in X | c(\mathbf{x}) = -1 \wedge y(\mathbf{x}) = 1\}$;
- $fn(c) = \{\mathbf{x} \in X | c(\mathbf{x}) = 1 \wedge y(\mathbf{x}) = -1\}$.

Definition 3.1. (RL repair problem) Let c be a linkage model and E be a set of detected errors. Then the *RL repair problem* is to find a linkage model c^* such that the following objective function is minimised:

$$\operatorname*{argmin}_{c} \frac{fp(c^*) + fn(c^*)}{fp(c) + fn(c)} \tag{1}$$

The focus of the RL repair problem is on maximally repairing linkage models through detected errors, i.e., gain maximum insights from errors, rather than repairing only detected errors.

4 REPAIRING FRAMEWORK

We propose a novel framework for solving the RL repair problem.

4.1 Error Analyser

Generally, linkage errors may be caused by various reasons, e.g., poor data quality, biased classifiers and insufficient training data. Although it is desirable to repair all errors, linkage errors are not equally informative for improving a linkage model. For instance, repairing a linkage model based on errors that are indeed outliers often leads to the overfitting problem. On the other hand, errors that repeatedly occur under certain similar conditions may suggest a pattern of these errors which is more informative for repairing a linkage model. To quantify the informativeness of errors, we thus develop the notion of error normality to measure the degree errors can be generalised from specific cases to more structured ones.

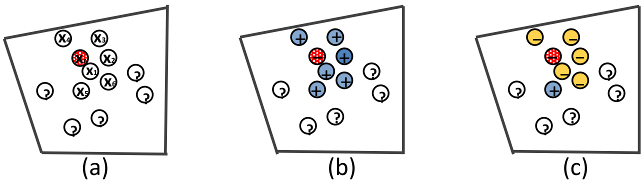

Figure 2: A false match, denoted as $\mathbf{x_r}$ and highlighted as being red, is detected in a weight vector subspace X_i.

Definition 4.1. Let (X, δ) be a weight vector subspace, $\mathbf{x} \in X$, and $N(\mathbf{x}, X)$ refer to the set of k nearest neighbours of $\mathbf{x}$ in (X, δ). Then the *normality* of $\mathbf{x}$ in X, denoted as $\rho(\mathbf{x})$, is defined as:

$$\rho(\mathbf{x}) = y(\mathbf{x}) \cdot \frac{\sum\limits_{\mathbf{x}' \in N(\mathbf{x}, X)} \delta(\mathbf{x}, \mathbf{x}') \cdot y(\mathbf{x}')}{\sum\limits_{\mathbf{x}' \in N(\mathbf{x}, X)} \delta(\mathbf{x}, \mathbf{x}')} \tag{2}$$

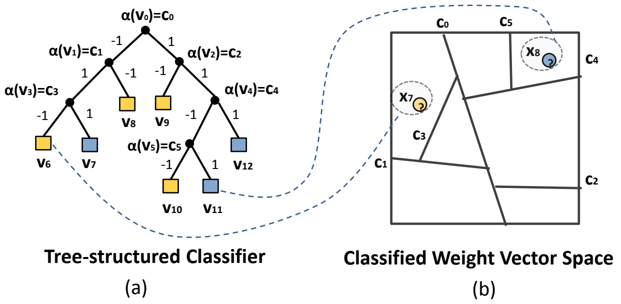
The values of normality range from -1 to 1, indicating the possibility of generalising an error $\mathbf{x}$ into improving a linkage model: (1) $\rho(\mathbf{x}) = -1$ means that all the nearest neighbours in $N(\mathbf{x}, X)$ have the opposite label to $\mathbf{x}$; (2) $\rho(\mathbf{x}) = 1$ means that all the nearest neighbours in $N(\mathbf{x}, X)$ have the same label as $\mathbf{x}$. In addition to the labels, the distances of $\mathbf{x}$ and its nearest neighbours are also taken into account by the normality. For each neighbour in $N(\mathbf{x}, X)$, the close its distance is to $\mathbf{x}$, the more influence it has on $\rho(\mathbf{x})$. Intuitively, the normality of an error $\mathbf{x}$ is measured by a weighted majority vote of their nearest neighbours, i.e., the margin between strength of voting on the same label $y(\mathbf{x})$ and strength of voting on the opposite label $-1 \cdot y(\mathbf{x})$.

Example 4.2. Suppose that, for the detected error $\mathbf{x_r}$ in Figure 2, we have $N(\mathbf{x_r}, X_i) = \{\mathbf{x_1}, \ldots, \mathbf{x_6}\}$, and $\delta(\mathbf{x_r}, \mathbf{x_i})$ is 0.9, 0.8, 0.8, 0.8, 0.7 and 0.7 for $i = 1, 2, 3, 4, 5, 6$, respectively. Then $\rho(\mathbf{x_r}) = 1$ in Figure 2.b and $\rho(\mathbf{x_r}) = (0.9 + 0.8 + 0.8 + 0.8 + 0.7 - 0.7)/(0.9 + 0.8 + 0.8 + 0.8 + 0.7 + 0.7) = 0.7$ in Figure 2.c.

4.2 Tree-structured Classifiers

To repair linkage models effectively, the repairing framework needs to offer great flexibility and expressive power in refining linkage models. We thus propose to use a tree-based structure for repairing classifiers. A tree-structured classifier can be formalised as a tuple (T, C, α, β), where T is a binary tree, C is a set of binary classifiers, α is a labeling function that assigns a classifier $c_i \in C$ to each internal vertex v_i of T, i.e., $\alpha(v_i) = c_i$, and β assigns a label in $\{-1, 1\}$ to each edge (v_i, v_j) of T, i.e., $\beta(v_i, v_j) \in \{-1, 1\}$. Therefore, given a weight vector $\mathbf{x} \in X$, a tree-structured classifier $h = (T, C, \alpha, \beta)$ classifies $\mathbf{x}$ using the following condition: $h(\mathbf{x}) = \beta(v_{n-1}, v_n)$ if there exists a path $\langle v_0, v_1, \ldots, v_n \rangle$ in T starting from the root vertex v_0 of T and ending at a leaf vertex v_n such that $\alpha(v_k) = c_k$ and $\bigwedge_{k \in [0, n-1]} c_k(\mathbf{x}) = \beta(v_k, v_{k+1})$.

Example 4.3. Consider two weight vectors $\mathbf{x_7}$ and $\mathbf{x_8}$ from the weight vector space depicted in Figure 3.b. The tree-structured classifier in Figure 3.a has classified this weight vector space into many smaller weight vector subspaces, each being assigned a



Tree-structured Classifier

(a)

Classified Weight Vector Space

(b)

Figure 3: A schematic layout of a tree-structured classifier and the corresponding classified weight vector space.

label of either −1 (highlighted by a yellow square) or 1 (highlighted by a blue square). We have $h(\mathbf{x}_7) = -1$ due to a path $\langle v_0, v_1, v_3, v_6\rangle$ with $c_0(\mathbf{x}_7) = -1, c_1(\mathbf{x}_7) = 1$ and $c_3(\mathbf{x}_7) = -1$. Similarly, we have $h(\mathbf{x}_8) = 1$ because there is a path $\langle v_0, v_2, v_4, v_5, v_{11}\rangle$ with $c_0(\mathbf{x}_8) = 1$, $c_2(\mathbf{x}_8) = 1$, $c_4(\mathbf{x}_8) = -1$, and $c_5(\mathbf{x}_8) = 1$.

Initially, the binary tree T in a tree-structured classifier only has one internal vertex as the root, which represents the initial classifier c_0, and two leaf vertices that represent two weight vector subspaces X_1 and X_2 of the given weight vector space X classified by the initial classifier c_0 such that $\forall \mathbf{x}_1 \in X_1(c_0(\mathbf{x}_1) = 1)$ and $\mathbf{x}_2 \in X_2(c_0(\mathbf{x}_2) = -1)$. Then when a linkage error $\mathbf{x}$ is detected, c can be repaired by extending T to T' such that one of the leaf vertices of T (say v_t) is replaced by an internal vertex with two leaf vertices. Accordingly, the weight vector subspace associated with v_t is divided into two smaller weight vector subspaces (one with the label 1 and the other with the label -1). This process is iteratively conducted when repairing errors.

As a result, an important property of tree-structured classifiers is to support *bounded repairs*, i.e., only weight vectors in a specified subspace are affected by a repair. This property can reduce the risk of incorrect repairs and lead to convergence on quality of a linkage model after a finite number of repairing iterations.

4.3 Repairing Algorithm

Our repairing algorithm is provided in Figure 4. Given a weight vector space X which is partitioned into $\{X_1, \ldots, X_n\}$ by an initial classifier c_0, the algorithm iteratively leverages errors to repair a tree-structured classifier until the labelling budget is used up or no more errors are detected (Line 2).

In this algorithm, E_h refers to detected errors of h, q keeps record of the number of labels requested from the human oracle, $\textsc{select\_error}(E_h)$ randomly selects an error e from E_h, and $\textsc{find\_subspace}(\mathbf{X}, e)$ searches for a subspace X_{cur} of X which contains e (Lines 3-4). If $|X_{cur}|$ is greater than S_{min} (Line 5), then $\textsc{nn\_select}(e, X_{cur}, k)$ finds k nearest neighbours of e in X_{cur}, and their labels are requested (Lines 6-7). If the normality $\rho(e)$ of e is greater than the threshold t (Line 9), $\textsc{fn\_select}(e, X_{cur}, k)$ finds k farthest neighbours of e and their labels are requested (Lines 10-11). If the purity of X_{cur} is lower than the threshold p (Line 13), the classifier c_{q+1} is trained and extends c_q by classifying X_{cur} into two subspaces X^M_{cur} (for matches) and X^N_{cur} (for non-matches) (Lines 14-16). Then accordingly, the tree-structured classifier h is repaired by adding c_{q+1} (Line 17). We consider errors whose normality values are lower than the threshold them as outliers. The algorithm returns a tree-structured classifier h with improved linkage quality (Line 23).

```
Input: initial classifier: $c_0$, normality threshold: $t \in [-1.1]$,
       human oracle for labelling: $\textsc{oracle}()$, budget limit: $b$,
       number of nearest neighbours: $k$, purity threshold $p$,
       minimum size of weight vector subspaces: $s_{min}$
Output: a tree-structured classifier $h$
1:  $\mathbf{X} \leftarrow \{X_1, \ldots, X_n\}$, $q \leftarrow 1$, $h \leftarrow c_0$
2:  while $q \le b$ and $|E_h| > 0$ do:
3:      $e \leftarrow \textsc{select\_error}(E_h)$
4:      $X_{cur} \leftarrow \textsc{find\_subspace}(\mathbf{X}, e)$
5:      if $|X_{cur}| \ge s_{min}$ then:
6:          $V_{nn} \leftarrow \textsc{nn\_select}(e, X_{cur}, k)$
7:          $V^L_{nn} \leftarrow \textsc{oracle}(V_{nn})$
8:              $V^L \leftarrow V^L \cup V^L_{nn}$
9:          if $\rho(e) \ge t$ then:
10:             $V_{fn} \leftarrow \textsc{fn\_select}(e, X_{cur}, k)$
11:             $V^L_{fn} \leftarrow \textsc{oracle}(V_{fn})$
12:             $V^L \leftarrow V^L \cup V^L_{fn}$
13:             if $purity(X_{cur}) < p$ then
14:                 $c_{q+1} \leftarrow \textsc{train}(c_q, X_{cur}, V^L)$
15:                 $X^M_{cur}, X^N_{cur} \leftarrow c_{q+1}.\textsc{classify}(X_{cur})$
16:                 $\mathbf{X} \leftarrow \mathbf{X} - \{X_{cur}\} \cup \{X^M_{cur}, X^N_{cur}\}$
17:                 $h = \textsc{repair\_classifier}(h, c_{q+1})$
18:             endif:
19:         endif:
20:     endif:
21:     $q \leftarrow q + 1$
22: endwhile:
23: return $h$
```

Figure 4: Repairing Algorithm

5 EXPERIMENTS

We have implemented the repairing framework to experimentally validate its effectiveness on three real-world datasets.

Baseline methods. We have used support vector machines (SVM) with three different kernels: linear, polynomial, and Gaussian (RBF) and a decision tree as the baseline methods. For our tree-structured classifier, we used SVMs with linear kernel as binary classifiers for its internal vertices, called SVM-tree. We also used the following parameters: $s_{min} = 25$, $p = 0.97$, and $k = 50$.

Sampling methods. We use KNN+FNN to refer to the k nearest and farthest neighbours sampling method described in the repairing algorithm in Figure 4. To evaluate its effectiveness, we compared it with three other sampling methods: (1) KNN, (2) FNN, and (3) random, in which k nearest, k farthest, and k random neighbours of an error are sampled, respectively.

Datasets. We have used three datasets: (1) Cora, which contains 1,295 publication records and is publicly available [1], (2) DBLP_ACM, which contains 4910 bibliographic records from the DBLP and ACM websites [8], and (3) NCVR, using two datasets with 1048576 and 613767 records respectively from the North Carolina Voter Registration (NCVR) database[2]. We did not apply any blocking on Cora but used *publication year* and the 1st char of *title* for DBLP_ACM, and *last_name* and *first_name* for NCVR.

Performance of classifiers. Figure 5 shows the performance of SVM-tree in comparison to the baseline methods. SVM-tree

[1] Available from: http://secondstring.sourceforge.net

[2] Available from: ftp://alt.ncsbe.gov/data/

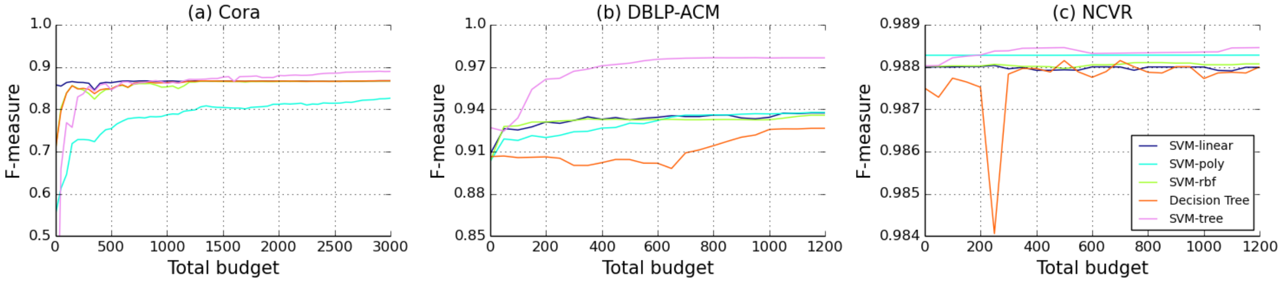


Figure 5: Comparison to the baseline methods, where the sampling method is KNN+FNN and normality threshold is -0.6.

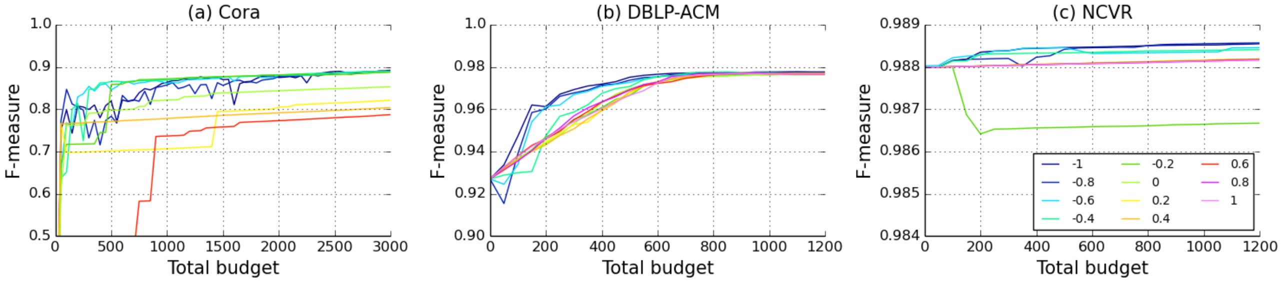

Figure 6: SVM-tree with different normality thresholds, where the sampling method is KNN+FNN.

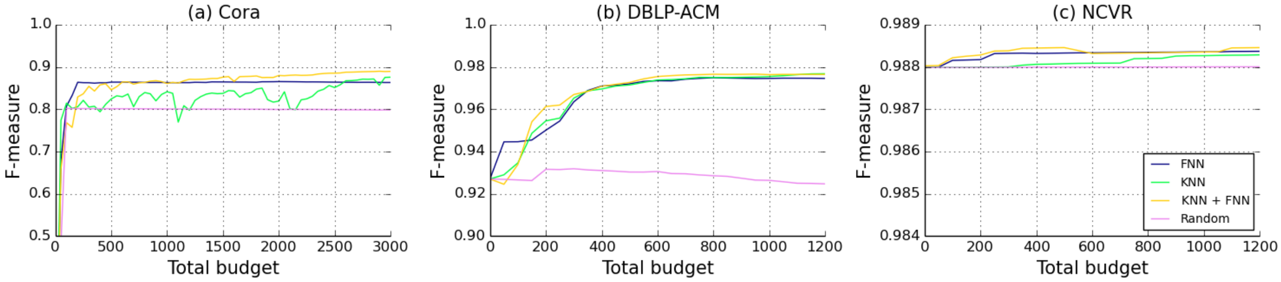

Figure 7: SVM-tree with different sampling methods, where the normality threshold is -0.6.

generally performs better than the other methods for all datasets. For Cora, SVM-tree performs increasingly better when more errors are detected. For DBLP_ACM, it has a significant increase in performance. For NCVR, it is a clean dataset that produces high quality results (around 0.988 f-measure) for all methods; nonetheless, SVM-tree is still marginally better.

Effect of normality. Figure 6 presents the experimental results for classification using SVM-tree with varying thresholds. The KNN+FNN sampling method is used in this experiment. A normality threshold of -0.4 to -1 produces the best performance for all datasets. The threshold of -0.6 produces consistently stable good results over all datasets.

Performance of sampling. Figure 7 shows the performance of SVM-tree using different sampling methods and the normality threshold is set to -0.6. KNN+FNN generally produces the best and most stable results among all the sampling methods, particularly over the datasets Cora and DBLP_ACM. When the budget is low, the performance of FNN is comparable to KNN+FNN. The performance of KNN is not stable on Cora. The random sampling has the worst performance among all the methods.

ABSTRACT

Streaming join is an essential operation in many real-time applications. A lot of research has been devoted to the study of distributed streaming join algorithms. However, existing solutions rely on heuristics and cannot handle data skew optimally. On non-streaming, static data, the HyperCube algorithm ensures a balanced load across all processors in an optimal way. In this paper, we extend this algorithm to the streaming setting, which can adapt the HyperCube configuration depending on the current data distribution. Some preliminary experimental results are provided to demonstrate the efficiency our algorithm.

1 INTRODUCTION

The prevalence of applications in financial trading, sensor networks, traffic analysis and web data management has brought attention to query processing over data streams. Various Distributed Stream Processing Systems (DSPSs) have emerged such as Flink [1], Spark Streaming [2] and Apache Storm [3]. As one of the most critical operations in database management systems, join has been extensively studied in the literature both in static models [5–8, 14, 16] and streaming models [11, 12, 17, 18].

Low latency and high throughput are two essentials for an efficient streaming join algorithm. In a massively distributed system, a key to achieving these goals is to ensure a good load balance among the workers. Over static data, the HyperCube algorithm [6] and its extensions [8] achieve an optimal load balance. However, this algorithm crucially depends on the data statistics, in particular, the set of heavy hitters and their frequencies. In a dynamic setting like streaming data, these statistics are changing all the time, which renders the HyperCube algorithm inapplicable.

In this paper, we propose Streaming HyperCube (SHC), an adaption of the HyperCube algorithm to the streaming setting. A key challenge in designing SHC is how to adaptively change the HyperCube configuration as the data statistics change over time. On the one hand, we want to keep the configuration as close as possible to the optimal setting the HyperCube uses for static data. On the other hand, we also want to avoid too frequent configuration changes, since each configuration change requires migration of states, which introduces communication overhead and stalls streaming processing. The SHC algorithm supports both full-stream joins as well as joins over a sliding window.

Below, we first review the related work in Section 2, in particular the static HyperCube algorithm. In Section 3 we describe the Streaming HyperCube algorithm. We have implemented the algorithm in Flink. In Section 4 we describe its implementation and show some preliminary experimental results comparing with some state-of-the-art stream join algorithms.

2 RELATED WORK

2.1 Parallel Hash Join

The Parallel Hash Join (PHJ) algorithm is the default join algorithm used in many state-of-the-art DSPSs [2, 3, 10, 19], including Flink. Consider a (natural) join $R(A,B) \bowtie S(B,C)$. Let p be the number of workers in the system, numbered $1, 2, \dots, p$. The algorithm utilizes a random hash function $h : B \rightarrow [p] = \{1, \dots, p\}$ to assign tuples $(a,b) \in R$ and $(b,c) \in S$ to worker $h(b)$. Each worker is responsible for producing the join results on all tuples assigned to it. More precisely, it maintains two hash tables built on attribute B, one for tuples from R, one for tuples from S. Upon the arrival of a tuple $(a,b) \in R$, it inserts it to the hash table on R, and probes the hash table on S with key b to find all tuples in S that can join with (a,b).

When there is no skew, this algorithm performs relatively well. However, when there are heavy hitters, namely, many tuples in R or S share the same value on attribute B, the load may no longer be balanced, since all tuples with the same b value must be sent to the same worker. In the worst case, if all tuples have the same value on b, the join degenerates into a Cartesian product, and one worker will be doing all the work while the other $p-1$ workers are idle.

2.2 HyperCube

The worst case scenario of the aforementioned PHJ algorithm happens when there is only a single value $b \in B$. In this case, the join degenerates into a Cartesian product. This problem was solved in [6] by the following HyperCube algorithm.

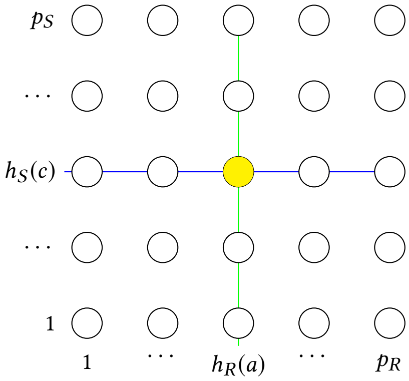

Figure 1: The HyperCube algorithm. Tuple (a,b) is sent to all workers in the column $h_R(a)$, and the tuple (b,c) is sent to all workers in the row $h_S(c)$. The worker at coordinate $(h_R(a), h_S(c))$ produces the join result (a,b,c).

The p workers are organized into a $p_R \times p_S$ grid (see Figure 1), where $p_R = |R|\sqrt{\frac{p}{|R|\cdot|S|}}$, $p_S = |S|\sqrt{\frac{p}{|R|\cdot|S|}}$. Two hash functions $h_R : A \rightarrow [p_R]$, $h_S : C \rightarrow [p_S]$ are used. Each tuple $(a,b) \in R$ is sent to all workers with coordinates $(h_R(a), *)$ and each $(b,c) \in S$

Series ISSN: 2367-2005

10.5441/002/edbt.2019.76

is sent to all workers $(*, h_S(c))$. As figure 1 shows, each output tuple is handled by exactly one worker. With high probability, each worker receives

$$\tilde{O}\left(\frac{|R|}{p_R} + \frac{|S|}{p_S}\right) = \tilde{O}\left(\sqrt{\frac{OUT}{p}}\right)$$

tuples, where the output size $OUT = |R| \cdot |S|$ for Cartesian product. Assuming $|R| = |S|$, this is better than the $O(|R|)$ load of the PHJ algorithm by an $O(\sqrt{p})$ factor.

Beame et al. [8] have generalized this algorithm to general joins. Let $R(b) = \sigma_{B=b}R$, and similarly define $S(b)$. The idea is to first partition the join attribute B into heavy hitters B^H and light hitters B^L. Let N denote the total number of tuples:

$$B^H = \left\{ b \in B \;\middle|\; |R(b)| > \frac{N}{p} \text{ or } |S(b)| > \frac{N}{p} \right\}$$

and B^L is the remaining attribute values. The light hitters B^L will be handled by the PHJ algorithm. Since there is no skew in the light hitters, the load is bounded by $\tilde{O}(N/p)$ for any worker. For each heavy value $b \in B^H$, $p_{(b)}$ workers are allocated to handle it using the *shares* algorithm, where

$$p_{(b)} = \frac{OUT(b)}{OUT^H} \cdot p = \frac{|R(b)| \cdot |S(b)|}{OUT^H} \cdot p$$

and $OUT^H = \sum_{b \in B^H} OUT(b)$ denotes the output size generated by all heavy hitters. The load of each worker for handling heavy hitters is upper bounded by $\tilde{O}(\sqrt{OUT/p})$. Therefore, the total load is $\tilde{O}\left(\frac{N}{p} + \sqrt{\frac{OUT}{p}}\right)$, which has been shown to be optimal.

However, this algorithm does not work in the streaming model, because it needs all the heavy hitter information to decide the configuration of each cube, namely how to set $p(b)$ for all the b's, and how to set the dimensions of each cube. Furthermore, the heavy hitter set may change throughout stream processing, which requires the HyperCube configuration to change correspondingly. These will be solved by our algorithm described in section 3.

2.3 BiStream Join

Lin et al. [17] proposed the Join-Biclique (JB) algorithm for computing joins over distributed streaming data. Their BiStream system divides the join into two stages, a routing stage for storage and a joining stage for producing outputs. Their work outperforms existing systems [11] in terms of memory consumption, scalability, latency and throughput. However, the algorithm relies on heuristics and does not work well on highly skewed data. We will compare SHC with a Flink implementation of the Join-Biclique algorithm in Section 4.

2.4 Cell Join

Cell Join presented by Gedik et al. [12] solves the windowed streaming join problem specifically on Cell processors. Following the three-step procedure described by Kang et al. [15], the algorithm parallelizes the scan task of streams over available workers to achieve high performance. However, since re-partition is needed whenever a new tuple arrives, this algorithm suffers from scalability issues. Although it supports band joins and can be extended to multi-way joins, its framework is solely designed for the IBM's cell processor.

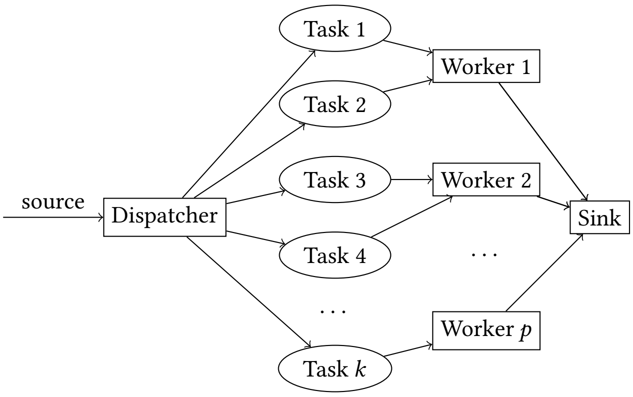

Figure 2: System Architecture.

2.5 Handshake Join

Roy et al. [18] presented a highly parallelizable handshake join for window streams. Hardware acceleration was implemented to achieve high data throughput. The algorithm uses similar window semantics to the ones in [15] by dividing the window into subwindows. The two streams flow in opposite directions so that each pair of subwindows has a handshake. This algorithm adopts the batch-processing model and may introduce disorder in the output tuple sequence, meaning it is not suitable for applications requiring instant outputs.

3 STREAMING HYPERCUBE

3.1 System Architecture

Figure 2 describes the architecture of our system. There are p workers along with a dispatcher and a sink. The dispatcher preprocesses input tuples after receiving them. The tuples are partitioned into *tasks*, which are then dynamically allocated to physical workers at runtime. The workers compute join results on-the-fly and pass them to the sink. Our system adopts the event-triggered model of Flink, where the output is updated immediately after the arrival of each tuple to ensure low latency.

3.2 Algorithm

The dispatcher runs an approximate heavy hitters tracking algorithm [9] to keep track of the heavy hitters and their approximate frequencies. Specifically, it classifies a join value $b \in B$ to be heavy hitter if $N(b) = |R(b)| + |S(b)| > \frac{N}{p}$ and light hitter if $N(b) < (\frac{1}{p} - \epsilon)N$, N is the current stream length (for full stream joins) or window length (for sliding window joins), and ϵ is some small constant. A value with frequency in between may be either heavy or light. As long as $\epsilon \leq \frac{1}{2p}$, there are at most $2p$ heavy hitters. Note that the heavy hitter tracking algorithm also maintains approximated frequencies $|R(b)|$ and $|S(b)|$ for each heavy hitter b, each with at most ϵN additive error. Therefore the corresponding output size $OUT(b) = |R(b)| \cdot |S(b)|$ can be estimated with at most $2\epsilon N$ additive error. Summing over all the heavy values, we obtain an estimate of OUT^H, the output size of all heavy hitters, with no more than $2p\epsilon N$ additive error.

Similar to the HyperCube algorithm, the dispatcher treats heavy and light hitters differently. The light hitters are handled by the PHJ algorithm using p tasks and an associated hash function

$h^L : B \longrightarrow [p]$.[1] Each heavy value b occupies $p_{(b)}$ tasks organized into a $p_{R(b)} \times p_{S(b)}$ grid. Two hash functions $h_{R(b)} : A \longrightarrow [p_{R(b)}]$ and $h_{S(b)} : C \longrightarrow [p_{S(b)}]$ are involved.

Suppose a tuple $(a, b) \in R$ arrives at time t. The dispatcher first reflects the update to the heavy-hitter tracking algorithm, so that the heavy hitter set and its statics are still valid approximations. If b is a light hitter, it is sent to task $h^L(b)$ for light hitters and the assigned worker produces the output. If b is a heavy hitter, it is sent to all tasks labeled $(h_{R(b)}(a), *)$ in the $p_{R(b)} \times p_{S(b)}$ grid allocated to b.

A key difference between SHC and the static HyperCube algorithm is that the number of tasks allocated to each heavy hitter, as well as the grid dimensions, may change over time. This is done by a *state migration* between tasks. To see why this is necessary, consider a value b, which starts light but continuously receives tuples over time. If only a single task is allocated to handle it, that worker will have a huge load. For efficient state migration, the dispatcher stores the current number of tasks $p_{R(b)} \times p_{S(b)}$ allocated for each heavy hitter b. According to the estimated statistics, it can also calculate a *desired* number of tasks for b, namely

$$p^d_{R(b)} = \frac{|R(b)|}{\sqrt{OUT^H}}\sqrt{p}, \text{ and } p^d_{S(b)} = \frac{|S(b)|}{\sqrt{OUT^H}}\sqrt{p}$$

When the estimates of OUT^H, $|R(b)|$, and $|S(b)|$ change over time, the dispatcher will compare the currently assigned grid dimension with the desired one. If $p_{R(b)} > 2p^d_{R(b)}$, we reduce $p_{R(b)}$ to half. Specifically, each task

$$(x, y), x = \frac{1}{2}p_{R(b)} + 1, \ldots, p_{R(b)}, y = 1 \ldots, p_{S(b)}$$

sends all its tuples in $R(b)$ to task $(x - \frac{1}{2}p_{R(b)}, y)$ and then gets released. If $p_{R(b)} < \frac{1}{2}p^d_{R(b)}$, double $p_{R(b)}$. Specifically, create $p_{(b)}$ new tasks and extend the grid to $2p_{R(b)} \times p_{S(b)}$. Each task

$$(x, y), x = 1, \ldots, p_{R(b)}, y = 1 \ldots, p_{S(b)}$$

sends all its tuples in $S(b)$ to $(x + p_{R(b)}, y)$. For each tuple $(a', b) \in R(b)$ in the task, apply a new hash function $h' : A \longrightarrow \{0, 1\}$ to it, where 0 means that the tuple stays, and 1 means the tuple gets sent to task $(x + p_{R(b)}, y)$. The new hash function associated with $p_{R(b)}$ is $h_{R(b)} + p_{R(b)} \cdot h' : A \longrightarrow 2p_{R(b)}$. It is similar for $p_{S(b)}$.

Finally, the dispatcher manages assignment of tasks to workers. Since the tasks are almost balanced, the dispatcher keeps a count on the total number of tasks each worker is currently handling. When a new task is created, it will be sent to the worker with the minimum number of tasks. When a task is released, the dispatcher decreases the count of the corresponding worker by 1. Note that some tasks may be assigned to the same worker, so that they are only logically separated, but the communication between them can be easily achieved. The worker nodes receiving tasks compute join results, and send it to the sink.

3.3 A Running Example

Figure 3 gives a running example of state migration. Suppose at some point of the algorithm, 500 tuples have been received, where 200 tuples contain b_1 and 250 tuples contain b_2. There are 50 other tuples of light hitters. The output size from heavy hitters is

$$OUT^H = |R(b_1)| \cdot |S(b_1)| + |R(b_2)| \cdot |S(b_2)| = 20k$$

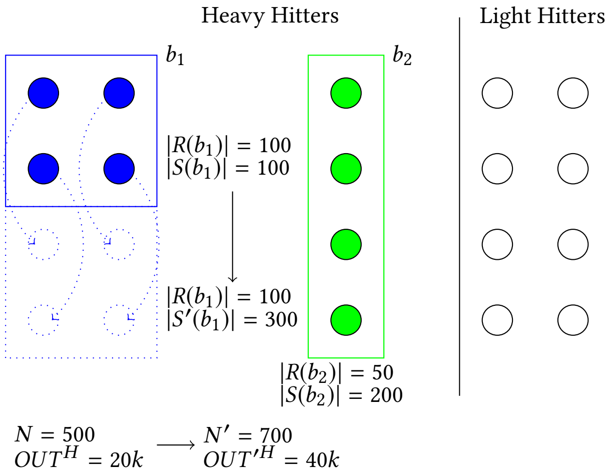

Figure 3: Example task allocation for $p = 8$. There are 8 tasks for light hitters. 2 heavy values b_1 and b_2 each occupies 4 tasks. The dotted circles represents the new tasks created in state migration.

Also assume task allocation is optimal at this time. Indeed, $p_{R(b_1)} = 2, p_{S(b_1)} = 2, p_{R(b_2)} = 1, p_{S(b_2)} = 4$. Note that the task layouts are different between two heavy hitters because they have different internal skew.

Suppose after this state, we received 300 more tuples from $S(b_1)$ and no other tuples. Consider b_1, the dispatcher calculates the new desired number of tasks as:

$$\begin{aligned} p^d_{R(b_1)} &= \frac{|R(b_1)|}{\sqrt{OUT^H}}\sqrt{p} \\ &= \frac{100}{\sqrt{40,000}}\sqrt{8} = 1.414 \end{aligned}$$

Since $2 = p_{R(b_1)} \leq 2p^d_{R(b_1)}$, state migration does not need to be performed for $p_R(b_1)$. However,

$$\begin{aligned} p^d_{S(b_1)} &= \frac{|S(b_1)|}{\sqrt{OUT^H}}\sqrt{p} \\ &= \frac{300}{\sqrt{40,000}}\sqrt{8} = 4.243 \end{aligned}$$

indicates that $2 = p_{S(b_1)} < \frac{1}{2}p^d_{S(b_1)}$. The dispatcher decides $p_S(b_1)$ should be doubled, and creates 4 more tasks to handle it. As Figure 3 illustrates, the 2×2 grid is extended to a 2×4 one, where arrows denote the flow of tuples.

For b_2, the desired numbers are 0.707 and 2.828 respectively. No migration is needed since the original 1×4 grid is sill an optimal configuration, up to a factor of 2.

4 EVALUATION

In this section, we discuss implementation details and provide comparative evaluations of our algorithm with the widely implemented PHJ algorithm and state-of-the-art Join-Biclique (JB) [17] algorithm.

4.1 Implementation

In the current implementation of our SHC algorithm, we maintain a copy of each stream in the dispatcher node in the form of a hash table. The dispatcher is responsible for redistributing

[1] $[p] = \{1, \ldots, p\}$

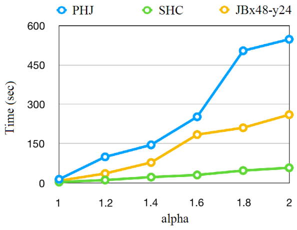

Figure 4: Zipf, varying α.

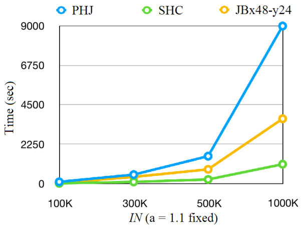

Figure 5: Zipf, varying IN.

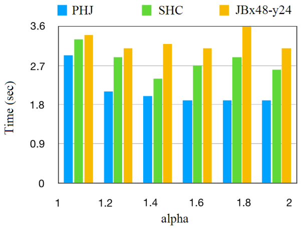

Figure 6: TPC-H, varying α.

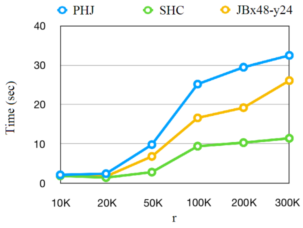

Figure 7: COREL, varying r.

certain parts of the state hashtables to the join processing workers according to state migration policies. In addition, the dispatcher may invalidate the state of certain heavy hitters from specific workers.

4.2 Experimental Setup

Environment. We conduct all experiments on an Intel(R) Xeon(R) CPU E5-2650 v4 @ 2.20GHz server that has 12 cores with 4 threads each and runs Red Hat 4.8.5. The server has 256 GB of memory, which suffices for maintaining all raw and intermediate data even if all tuples are sent to one processor only. Flink 1.4.2 is installed on the server and the implemented algorithms have maximum parallelism of $p = 48$ processing units.

Data sets. Our preliminary experiments focus on full-stream joins. We use two synthetic and one real data sets to evaluate our algorithm.

The first synthetic data set is generated from the Zipf distribution with varying value for α, which controls the level of the skewness. The second synthetic data set is the TPC-H benchmark [4]. Specifically, we choose to experiment on the Q5.

For the real data set, we use the same COREL dataset as in [13] for applying SRHC on similarity joins. The data set contains a set of 15,000 points with dimentionality 64. Each point corresponds to a histogram of a unique color image collected from the COREL repository. Based on a provided similarity threshold we apply a locality-sensitive hash function on every point, and afterwards we perform a self-join on the produced hash codes.

4.3 Performance Analysis

4.3.1 Zipf Distribution. Figure 4 and 5 demonstrates the performance of three algorithms on the generated Zipf data set, with respect to varying skewness and input size. For the JB algorithm, we present the performance of the best setting, namely JBx48-y24. The y parameter determines the number of groups that the processing units are organized into. SHC clearly outperforms both existing methods in terms of execution time.

4.3.2 TPC-H Benchmark. All TPC-H queries consists of *primary key-foreign key* joins, i.e., the join key is not skewed in one side of each join. Under this scenario, SHC will only assign a $1 \times p_{(b)}$ grid for each heavy value, which is simply broadcasting the primary key tuple to all allocations of the other stream. For JB, we observe that the more groups used, the less efficient the algorithm is. PHJ seems to yield the best performance. We stress that SHC algorithm is better on many-many joins, where skewness exists in both relations.

4.3.3 COREL data set. We perform self similarity join on this high dimensional data set utilizing a $(r, 10r, 0.9, 0.1)$-sensitive family of hash functions, i.e. points within r distance are hashed to the same bucket with at least 0.9 probability and points with more than $10r$ distance have only 0.1 probability to be hashed to the same bucket. This similarity join is a many-many join. Again, SHC algorithm outperforms the other two in terms of execution time. It is better especially when r is large, meaning a higher skewness.

5 CONCLUDING REMARKS

In this paper, we proposed the Streaming HyperCube algorithm that extends the static HyperCube algorithm to the streaming setting. The algorithm continuously maintains an approximation (up to a factor of 2) of the optimal HyperCube configuration, while inuring small state migration overhead. In the future, we plan to conduct a more thorough theoretical analysis and extend it to multi-way joins.

ABSTRACT

We study fairness of ranking in online job marketplaces. We focus on group fairness and aim to algorithmically explore how a scoring function, through which individuals are ranked for jobs, treats different demographic groups. Previous work on group-level fairness has focused on the case where groups are pre-defined or where they are defined using a single protected attribute (e.g., Caucasian vs Asian). In this paper, we argue for the need to examine fairness for groups of people defined with any combination of protected attributes. To do this, we formulate an optimization problem to find a partitioning of individuals on their protected attributes that exhibits the highest unfairness with respect to the scoring function. The scoring function yields one histogram of score distributions per partition and we rely on Earth Mover's Distance, a measure that is commonly used to compare histograms, to quantify unfairness. Since the number of ways to partition individuals is exponential in the number of their protected attribute values, we propose two heuristic algorithms to navigate the space of all possible partitionings to identify the one with the highest unfairness. We evaluate our algorithms using a simulation of a crowdsourcing platform and show that they can effectively quantify unfairness of various scoring functions.

INTRODUCTION AND POSITIONING

Online job marketplaces are gaining popularity as mediums to hire people to perform certain tasks. Examples include freelancing platforms such as Qapa and MisterTemp' in France, and TaskRabbit and Fiverr in the USA. On those platforms, workers can find temporary jobs in the physical world (e.g., looking for a plumber), or in the form of virtual "micro-gigs" such as "help with HTML, JavaScript, CSS, and JQuery". A person who needs to hire someone for a job can formulate a query and is shown a ranked list of people. The resulting ranking naturally poses the question of fairness. Algorithmic fairness has recently received great attention from the data mining, information retrieval and machine learning communities (See for instance [3, 5, 8, 10]). The most common definition of fairness was introduced in [1, 11] as *demographic parity*, that is the unfair treatment of a person based on *belonging to a certain group of people*. Groups are defined using protected attributes such as gender, age, ethnicity or location. We carry these definitions in our work and define unfairness in online marketplaces as the unequal treatment of people by a scoring function based on their protected attributes. This definition is inline with what is also commonly referred to as *group unfairness* [2].

Most previous work on group-level fairness have either assumed that groups are pre-defined [8] or that they are defined using a single protected attribute (e.g., Caucasian vs Asian) [4]. In this work, we consider groups of people defined with any combination of protected attributes (the so-called *subgroup fairness* [5]). The scoring function yields one histogram per demographic group as score distributions. We use the Earth Mover's Distance (EMD) [7], a measure that is commonly used to compare histograms, to quantify distances between groups. Our intuition is that if score distributions between groups are significantly different, the scoring function does not treat the individuals in these groups equally. For instance, consider two groups only, namely young males and females living in France. Unfairness can be computed as the distance between the score distributions of those two groups.

Since we do not want to focus only on pre-defined groups, we must exhaust all possible ways of partitioning individuals on their protected attributes to quantify unfairness. For example, a scoring function might treat both men and women equally but might be unfair towards older Asian Americans compared to younger White Americans. We define an optimization problem as finding a partitioning of the ranking space, i.e., individuals and their scores, that exhibits the highest average EMD between its partitions. Exhaustively enumerating all possible partitionings is exponential in the number of values of protected attributes. Therefore, we propose two heuristic algorithms, BALANCED that generates a balanced tree of partitions, and UNBALANCED that generates an unbalanced tree of partitions. At each step, our algorithms greedily split individuals on the worst attribute, i.e., the one that results in the partitioning with the highest EMD between score distributions. This local decision is akin to the one made in decision trees using gain functions [6]. The algorithms stop when there are no further attributes left to split on or when the current partitioning of individuals exhibits more unfairness than it would if its partitions were split further.

PROBLEM DEFINITION

To quantify unfairness in online job marketplaces, we model the problem as computing the highest average distance between the score distributions of all possible partitions of individuals. Unlike previous work where partitions were defined or known a priori (e.g., [4]), we explore the space of all possible groups defined by a combination of values of the individuals' protected attributes. The goal becomes finding an unfair partitioning of individuals under the scoring function. We cast this goal as an optimization problem as follows.

DEFINITION 1 (MOST UNFAIR PARTITIONING PROBLEM). *We are given a set of individuals W, where each individual is associated with a set of protected attributes $A = \{a_1, a_2, ..., a_n\}$ and observed attributes $B = \{b_1, b_2, \ldots, b_m\}$. The protected attributes are inherent properties of the individuals such as gender, age, ethnicity, origin, etc. The observed attributes represent the skills of individuals for jobs and could include, for instance, the reputation and writing skills of an individual. We are also given a scoring function $f : W \to [0, 1]$, which is defined using observed attributes*

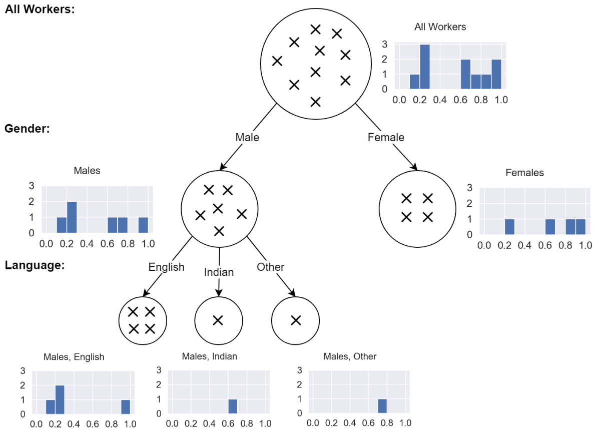

Figure 1: Optimum Partitioning of the Toy Example Data

as follows: $f(w) = \sum_{i=1}^{m} \alpha_i b_i$, *where* α_i *is a user-defined weight for observed attribute* b_i. *A weight of zero indicates that the corresponding attribute is not relevant for the user in ranking the individuals. Our goal is to* fully *partition the individuals in* W *into* k disjoint *partitions* $P = \{p_1, p_2, \ldots, p_k\}$ *based on their protected attributes in* A *using the following optimization objective:*

$$\begin{aligned} &\underset{P}{\text{argmax}} && \textit{unfairness}(P, f) \\ &\textit{subject to} && \forall i, j \; p_i \bigcap p_j = \phi \\ & && \bigcup_{i=1}^{k} p_i = W \end{aligned}$$

We now define how to compute the amount of unfairness of a function f for a partitioning P, or *unfairness*(P, f) in the above optimization problem.

Definition 2 (Average Pairwise Unfairness). *For a set of individuals* W, *a full-disjoint partitioning of the individuals* $P = \{p_1, p_2, \ldots, p_k\}$ *and a scoring function* f, *unfairness of* f *for the partitioning* P *is quantified as the average pairwise Earth Mover's Distance (EMD) between the distribution of scores in the different partitions of* P, *which is computed as follows:*

$$\textit{unfairness}(P, f) = \underset{i,j}{\text{avg}} \quad \textit{EMD}(h(p_i, f), h(p_j, f))$$

where $h(p_i, f)$ *is a histogram of the scores of individuals in* p_i *using* f.

Figure 1 shows a toy example of the optimum partitioning of 10 workers in a freelancing platform, which are ranked based on their qualification for some task using a scoring function f. The optimum partitioning is the one resulting from splitting the workers based on Gender first, and then splitting only the Male partition based on Language to get the following partitioning of workers: *Male - English, Male - Indian, Male - Other,* and *Female.* To arrive to this partitioning, one must exhaust all possible *full disjoint* partitionings of workers based on the protected attributes A and for each possible partitioning compute the average EMD between any two partitions. To do that, we generate a histogram for each partition as indicated in Figure 1 based on the function scores by creating equal bins over the range of f and counting the number of workers whose function values $f(w)$ fall in each bin.

Algorithm 1 Balanced (W: a set of individuals, f: a scoring function, A: a set of attributes)

```
$a = worstAttribute(W, f, A)$
$A = A - a$
$current = split(W, a)$
$currentAvg = averageEMD(current, f)$
while $A \neq \emptyset$ do
    $a = worstAttribute(current, f, A)$
    $A = A - a$
    $children = split(current, a)$
    $childrenAvg = averageEMD(children, f)$
    if $currentAvg \geq childrenAvg$ then
        break
    else
        $current = children$
        $currentAvg = childrenAvg$
    end if
end while
Add $current$ to $output$
```

Once the partitioning with highest average pairwise unfairness has been identified, it is up to the user, requester or platform developer, to decide on the right subsequent action.

ALGORITHMS

Our optimization problem for finding the most unfair partitioning is hard since there are is an exponential number of possible partitionings P. For this reason, we propose heuristics-based algorithms to identify a partitioning of individuals with respect to our optimization objective within reasonable time.

We first propose Balanced (Algorithm 1), an algorithm that generates a partitioning of the individuals in a greedy manner using the EMD of the partitions. Balanced is based on decision trees with EMD as utility [6]. It starts by splitting the individuals on the *worst* attribute with respect to EMD. This is done by trying out all possible attributes one at a time, and associating to each attribute-value partition, one histogram of the scores of all the individuals it contains. For each candidate attribute, Balanced computes the average pairwise EMD over histograms associated to the partitions obtained with the values of that attribute. It then returns the attribute with the highest average pairwise EMD and splits on that attribute. In the subsequent splitting steps, Balanced iteratively partitions the individuals using the other attributes in the same manner and only stops when the average pairwise EMD of the current partitioning is greater than that of the next candidate partitioning.

Balanced results in a partitioning of all the individuals using the same set of attributes (i.e., a balanced partitioning tree) since each splitting uses the same attribute over all current partitions. We also developed Unbalanced (Algorithm 2), another algorithm that partitions the individuals in a non-homogenous manner by locally deciding for each partition whether to further split it or not (i.e., resulting in an unbalanced partitioning tree).

Unbalanced is a *recursive* algorithm that decides to split a given partition by comparing the average EMD of that partition with its siblings to that of its children with its siblings. The intuition behind this is that it assesses what would happen to unfairness as measured by the average EMD if the partition was replaced by its children. It only splits a partition if its average pairwise EMD with its siblings is less than the average pairwise

Algorithm 2 UNBALANCED (*current*: a partition, *siblings*: a set of partitions, f: a scoring function, A: a set of attributes)

```
if $A = \emptyset$ then
    Add current to output
else
    $currentAvg = averageEMD(current, siblings, f)$
    $a = worstAttribute(current, f, A)$
    $A = A - a$
    $children = split(current, a)$
    $childrenAvg = averageEMD(children, siblings, f)$
    if $currentAvg \geq childrenAvg$ then
        Add current to output
    else
        for each partition $p \in children$ do
            UNBALANCED $(\{p\}, children - \{p\}, f, A)$
        end for
    end if
end if
```

EMD of its potential children with the partition's siblings. To invoke the algorithm, we first split the given set of individuals using the worst attribute as in the case of BALANCED and then the algorithm UNBALANCED is called once for each resulting partition. After all recursive calls of the algorithm terminate, the output is returned as the final partitioning of the individuals.

EVALUATION

To evaluate the effectiveness of our approach in quantifying unfairness, we run a simulation of a crowdsourcing platform using two sets of *active* workers and various scoring functions that rank those workers based on their qualification for tasks.

Setting. We generate two sets of active workers $\mathcal{W}$ of different sizes: 500 and 7300 (the estimated number of Amazon Mechanical Turk workers who are active at any time [9]). Each w in $\mathcal{W}$ has 6 protected attributes: Gender = {Male, Female}, Country = {America, India, Other}, Year of Birth = [1950, 2009], Language = {English, Indian, Other}, Ethnicity = {White, African-American , Indian, Other}, and Years of Experience = [0,30], and two observed attributes: LanguageTest = [25,100] and ApprovalRate = [25,100].

The values of those attributes are populated randomly so as to avoid injecting any bias in the data ourselves. Moreover, we define 5 different task qualification functions of the form $f = \alpha b_1 + (1 - \alpha)b_2$, where b_1 = Language Test and b_2 = Approval Rate and $\alpha \in \{0, 0.3, 0.5, 0.7, 1\}$.

We compare our two proposed algorithms UNBALANCED and BALANCED to a set of baselines. The first two baselines, which we refer to as R-BALANCED and R-UNBALANCED, are copies of our two algorithms BALANCED and UNBALANCED that use a random attribute instead of the worst attribute to split the workers at each step. The third baseline, which we refer to as ALL-ATTRIBUTES, is an algorithm that splits the workers based on *all* their protected attributes resulting in a full partitioning. Note that we also implemented an exhaustive algorithm that solves our optimization problem exactly by generating all possible partitionings in a brute-force manner and then returning the one with the highest average EMD. However, this algorithm failed to terminate after running for two days with only 6 attributes as in our simulation, even when each attribute had only a maximum of 5 values.

Simulation Results. Our first observation from Tables 1 and 2 is that for both datasets, functions f_4 and f_5 exhibit the highest unfairness as measured by the average pairwise EMD for all the partitionings retrieved by all the algorithms. Recall that these two functions are the ones that rely on one observed attribute only (LanguageTest in case of f_4 and ApprovalRate in case of f_5). *This indicates that if the scoring function uses fewer observed attributes, the chance of unfairness increases. In our simulation, since the attribute values were generated at random, there is a higher chance that the function scores correlate with a single protected attribute.*

Second, we observe that our two algorithms UNBALANCED and BALANCED consistently outperform or do as good as all other baselines for all datasets and functions. For the case of 500 workers, the UNBALANCED outperforms all other algorithms for the last three functions f_3, f_4 and f_5. On the contrary, the BALANCED returns the partitioning with the highest average EMD in the case of f_1. In the case of f_2, both BALANCED and R-BALANCED return the highest average EMD over the partitionings they find. *This allows us to validate the stopping condition used in our algorithms.*

Finally, in the case of 7300 workers, all the algorithms behave similarly, with the BALANCED and ALL-ATTRIBUTES returning the partitionings with slightly higher average EMD compared to all other algorithms. Upon investigating the returned partitioning by the different algorithms, we observed that in most cases all the algorithms returned the full partitioning tree, i.e., using all protected attributes, which is the same as the partitioning returned by the ALL-ATTRIBUTES algorithm. *We conjecture that it is due to the random values of all attributes.*

In terms of efficiency, the BALANCED algorithm took the most time to terminate compared to all other algorithms. In addition, the larger the dataset, the more time it took for all algorithms to finish. This is very intuitive given that the larger the dataset, the larger the individual histograms and the more time it takes to compute the pairwise EMD between them. Moreover, the deeper the partitioning tree, the larger the number of histograms that need to be compared. Finally, our two algorithms, BALANCED and UNBALANCED incur additional time since at each splitting step, they need to examine all remaining attributes to determine the worst one (i.e., the one which might result in the highest average EMD). All these factors contributed to the increased time to execute the BALANCED compared to all others. It is worth noting nonetheless that BALANCED terminates in less than 1.6 hours in the worst case (for the case of 7300 workers).

Qualitative Results. In addition to our simulation where we used a set of *random* task qualification functions, we also ran our algorithms on the following set of carefully-constructed functions, which are *unfair* by design:

- f_6: this function discriminates against females by setting the task qualification of workers as follows: $f_6(w) > 0.8$ if w is male and $f_6(w) < 0.2$ if w is female.
- f_7: this function sets the qualification of workers in a biased manner based on their gender and nationality as follows: $f_7(w) > 0.8$ if w is male and American, $f_7(w) < 0.2$ if w is female and American, $0.5 < f_7(w) < 0.7$ if w is Indian, either male or female, $f_7(w) > 0.8$ if w is female with any other nationality, and $f_7(w) < 0.2$ if w is male with any other nationality.
- f_8 designed as follows: $f_8(w) > 0.8$ if w is female and American, $0.5 < f_8(w) < 0.8$ if w is female and Indian and $f_8(w) < 0.2$ if w is female with another nationality.

Table 1: Average EMD and runtime for 500 workers and random functions

Algorithm	Average EMD					time (in secs)				
	f_1	f_2	f_3	f_4	f_5	f_1	f_2	f_3	f_4	f_5
UNBALANCED	0.195	0.191	**0.179**	**0.247**	**0.257**	20.987	23.715	22.823	29.504	28.845

BALANCED	**0.196**	**0.194**	0.177	0.246	0.253	**311.17**	**323.16**	**326.68**	**330.61**	**327.22**
R-BALANCED	0.195	**0.194**	0.177	0.246	0.253	131.87	122.49	119.97	127.06	124.46
ALL-ATTRIBUTES	0.195	0.193	0.177	0.246	0.253	42.708	42.494	42.597	42.235	42.337

Table 2: Average EMD and runtime for 7300 workers and random functions

Algorithm	Average EMD					time (in secs)				
	f_1	f_2	f_3	f_4	f_5	f_1	f_2	f_3	f_4	f_5
UNBALANCED	0.161	0.162	**0.151**	0.208	0.209	1169.224	1246.651	1205.963	1292.506	1245.037
R-UNBALANCED	0.162	**0.163**	**0.151**	0.208	0.209	1401.36	1391.541	1358.795	1290.977	1397.894
BALANCED	**0.163**	**0.163**	**0.151**	**0.210**	**0.211**	**5733.528**	**5745.611**	**5693.681**	**5840.131**	**5808.715**
R-BALANCED	**0.163**	**0.163**	0.122	**0.210**	**0.211**	3174.327	3240.727	2358.744	3115.123	3120.553
ALL-ATTRIBUTES	**0.163**	**0.163**	**0.151**	**0.210**	**0.211**	1453.626	1449.466	1450.712	469.839	1467.606

Table 3: Average EMD for 7300 workers & biased functions

Algorithm	Average EMD			
	f_6	f_7	f_8	f_9
UNBALANCED	0.040	0.164	**0.460**	0.317
R-UNBALANCED	0.399	0.362	0.322	0.350
BALANCED	**0.800**	**0.427**	**0.460**	**0.359**
R-BALANCED	0.496	0.368	0.330	0.301
ALL-ATTRIBUTES	0.420	0.368	0.337	**0.359**

- f_9 correlates with protected attributes ethnicity, language and year of birth similarly to previous ones.

As can be seen from Table 3, BALANCED retrieves the partitionings with the highest possible average EMD compared to all other algorithms. In addition, the resulting partitionings are the ones expected, i.e., using the attributes for which the functions were designed to correlate with. For example, for f_6, BALANCED partitions the workers on only gender for all datasets. Similarly, for f_7, it partitions the workers on both gender and country. We show only the results in the case of 7300 workers due to space limitation. Finally, we observe that *overall for all functions and algorithms, the average EMD is much higher compared to the functions used in our simulation experiment, which indicates that our optimization problem is indeed effective in capturing unfairness of the scoring functions as conjectured.* The only exception was for UNBALANCED in the case of f_6 and f_7, where the algorithm ended up splitting the workers further than it should because of the local nature of its stopping condition. In fact, since the function scores were generated at random within the specified range, various runs of the experiments resulted in different behavior, where in some cases, UNBALANCED performed as well as BALANCED.

SUMMARY AND FUTURE WORK

We set out to examine fairness of ranking in online job marketplaces. To do this, we defined an optimization problem to find a partitioning of the individuals based on their protected attributes that exhibits the highest unfairness by a given scoring function. We used Earth Mover's Distance between score distributions as a measure of unfairness. Unlike previous work, we did not assume a pre-defined partitioning of individuals and instead proposed two heuristic algorithms, BALANCED and UNBALANCED, that efficiently partition the individuals without exploring the full space of partitionings. Our immediate plan is to test our algorithms on real datasets from Qapa and TaskRabbit. We are also investigating other formulations and metrics for fairness instead of the Earth Mover's Distance. We are also studying ways of "repairing" bias in the context of ranking in online job marketplaces.

ABSTRACT

Transactional database systems and data stream management systems have been thoroughly investigated over the past decades. While both systems follow completely different data processing models, the combined concept of transactional stream processing promises to be the future data processing model. So far, however, it has not been investigated how well-known concepts found in DBMS or DSMS regarding multi-user support can be transferred to this model or how they need to be redesigned. In this paper, we propose a transaction model combining streaming and stored data as well as continuous and ad-hoc queries. Based on this, we present appropriate protocols for concurrency control of such queries guaranteeing snapshot isolation as well as for consistency of transactions comprising several shared states. In our evaluation, we show that our protocols represent a resilient and scalable solution meeting all requirements for such a model.

1 INTRODUCTION

Emerging application domains such as cyber-physical systems, IoT, and healthcare have fostered the convergence of stream and batch processing in data management. This can be observed not only by market trends such as real-time warehousing but also by architectural patterns like the lambda architecture aiming at combining batch and online processing on Big Data platforms.

This convergence means that the input to the system is treated as a continuous stream of data elements whose processing is implemented as a stream processing pipeline (query) with one or more persistent states/tables as sinks. Updates on these tables trigger further processing implemented again as stream processing pipeline. In addition, tables can be also queried in an ad-hoc fashion, e. g., for snapshot reports. Hence, the query part of an application is a mix of stream and ad-hoc queries while the data objects are streams and tables. However, concurrency and the need for providing fault tolerance require transaction support: at least stream queries writing to or reading from a table should run within a transaction context with ACID guarantees. This is necessary for recovery in case of failures and to provide a consistent view on (persistent) subsets of the stream (such as a window). Here, we refer to this processing style as *transactional stream processing* [2, 13] meaning that (a) a stream query writing to tables represents a sequence of transactions and (b) stream or batch queries on such tables require transaction isolation. Supporting such *queryable states* raises several requirements:

① state representations (tables) have to be queryable at all,
② the isolation property for concurrently running stream queries updating the state and ad-hoc queries on these states has to be guaranteed, and
③ consistency among multiple states of the same stream query is required even in the case of transaction aborts.

Figure 1 sketches a possible smart metering scenario which could benefit from transactional stream processing. Here, it is getting data from private households and the global infrastructure which is checked against respective specifications. It consists of three continuous and one ad-hoc query accessing various (shared) states whose semantic we explain in more detail in Section 3.

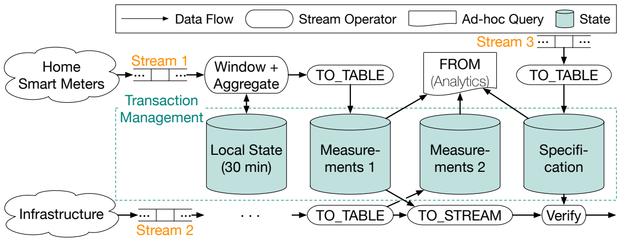

Figure 1: Possible smart metering use case.

In this paper, we present techniques to address the requirements above. Based on the work introduced in [2, 13], we propose a data-centric transaction model for data streams, discuss why and how to realize snapshot isolation on queryable states together with a consistency protocol. With the help of a micro benchmark, we show the suitability and scalability of our approach.

2 RELATED WORK

The first major investigation of a possible combination of relational and stream processing took place in the STREAM project [14]. However, when designing the system the team focused only on continuous queries instead of a hybrid query set of continuous and single point in time queries. To model the transformations of streams and relations, STREAM provides operations based on the whole relation (*RStream*), inserts (*IStream*), or deletes (*DStream*).

A more recent development of a system supporting transactions and data streaming is S-Store [13] which is built upon the main memory OLTP system H-Store [9]. S-Store inherits the ACID properties of H-Store by implementing data streaming concepts like windows and streams as time-varying H-Store tables with a timestamp as ordering property. Continuously running stream queries are implemented as stored procedures. Together with an input batch, which is the unit of a stream with the same timestamp, the execution of the stored procedure over such a batch forms a transaction over stream data.

Transactional Stream Processing [2] is a different notion to combine streaming and pure transaction processing. Their approach defines a unified transaction model which assigns a timestamp to each transaction and transforms continuous queries into a series of one-time queries, where each one-time query reads all required data before writing the result set. Transactional Stream Processing is based on a storage manager which transfers data processing into a producer-store-consumer scenario and identifies different properties to provide the proper storage for a producer-consumer combination.

In the context of scalable data stream processing platforms, Apache Flink Streaming is one of the most advanced approaches to consistent states and fault tolerance [3]. Their mechanism is based on distributed snapshots where stream barriers are moving along with the data through the dataflow. At operator level, the flow is aligned until all barriers with the same ID arrive and subsequently the current state is persisted in the state backend (e. g., HDFS). Whenever a failure occurs, the last complete snapshot is used for restoring a consistent state per streaming pipeline.

In [15] the authors present a platform combining OLTP, OLAP, and stream processing in a single system. For that, they merge Apache Spark with an in-memory transactional store and enhance it by additional features such as approximate processing.

MVCC is one of the most widely used concurrency control protocols and has been implemented in, e. g., Postgres [18], HyPer [10], Hekaton [5], and SAP HANA [12]. No precise standard exists that describes how MVCC should be implemented. There are several possibilities and adjustments that strongly depend on the expected workload. In [20] the authors present an extensive study of key design decisions when implementing MVCC in an in-memory DBMS. In particular, these are concurrency control protocol, version storage, garbage collection, and index management. We have used the findings of this study to design our own MVCC approach (see Section 4).

3 TRANSACTION MODEL

Addressing the scenario and requirements described in Section 1 requires to distinguish two basic concepts: *tables* for representing states and *streams*. Tables represent a finite collection of data structured in rows and columns, as known from relational DBMS. Streams define a potentially infinite sequence of tuples of data, where tuples carry an implicit or explicit ordering. While a table requires a physical storage representation, streams are volatile.

Linking operators. As already proposed in the query language for STREAM [1], two classes of query operators are required to link these objects: stream-to-table and table-to-stream. Here, we call them TO_TABLE and TO_STREAM.

- TO_TABLE inserts, deletes, or updates tuples from a stream in a table, e. g., to update an operator state, and
- TO_STREAM produces a stream of tuples from a table.

Whether a stream tuple is inserted or updated in a table depends on the presence of a table tuple with the same key. A delete occurs if the tuple is outdated (e. g., from a window) or explicitly removed by a *delete tuple*. TO_STREAM unifies the two cases, where stream tuples are just incrementally processed and, on the other hand, table wide operations are executed before new tuples can be emitted. Whenever a certain condition on a table is fulfilled, TO_STREAM is executed and emits a new (set of) tuple(s) to a stream. In addition to these operators, a standard ad-hoc query operator FROM is required to either attach to a stream, i. e., read all tuples of the stream starting at the point of attachment, or to read data of a table. Figure 2 illustrates these operators.

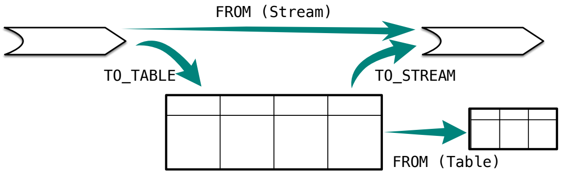

Figure 2: Linking operators.

Transaction boundaries. A first question is how to define transaction boundaries for data streams. Apart from the rather trivial case where each stream element represents its own transaction (aka "auto-commit"), two basic approaches can be distinguished. In the *data-centric* approach, transaction boundaries (BOT, COMMIT, ROLLBACK) are marked by dedicated stream elements, whereas the other stream elements are interpreted as insert or update operations. *Punctuations* [19] or *control tuples* are useful concepts for this purpose. This way each transaction can be defined over a consecutive number of stream tuples. Thereby, a transaction span can range from the length of an entire stream to the length of a sub-stream or each tuple is considered a single transaction. An alternative strategy is the traditional *query-centric* approach meaning that transaction boundaries are specified as part of the query or dataflow program. Obviously, this approach is better suited for ad-hoc and not for stream queries.

Unified tables for queryable states. For our system model, we rely on a unified table model taken from the DBMS world to cover all relevant aspects needed for transactional stream processing. However, stateful stream operators such as windows or aggregates also require structures for maintaining operator related data. Such operators exploit tables as internal structures to publish their state as a table allowing to share their content with other queries or to query the content. Besides sharing operator states, this approach also provides the advantage of re-using persistence and recovery mechanisms.

Transactional semantics. Inserts, deletes, or updates on states/tables need to run in a transactional context to guarantee atomicity for writes to a table and isolation for reads. The only way to modify a table in our model is provided by using the TO_TABLE operator which has to guarantee atomicity based on the transaction boundaries. Because a single stream query might contain multiple operators maintaining a persistent state, consistency among multiple states is a further requirement. This means that all states updated within the same stream query should be updated atomically with each commit, i. e., another query reading these states should see updates from the same (most recent) committed transaction. For reads of the FROM operator, we have to consider isolation properties. This also applies if FROM provides access to a data stream: here different isolation levels should provide different levels of visibility. For reads in TO_STREAM, we have to consider the trigger policy in addition to the isolation property. Trigger policy means the condition when a stream element is produced (TO_STREAM) or modifications in form of one or more transactions are generated into a back-to-the-table-directed stream. Here, possible policies are to consider each tuple modification or to rely on transaction commits.

4 TRANSACTIONAL STATE MANAGEMENT

From the transactional semantics described in Section 3, the following requirements can be derived that correspond to the ACID principle applied to the transactional stream processing model. First, there is atomicity, which occurs in several aspects. As mentioned before, the scope of a transaction that should be executed atomically must be marked via certain transaction boundaries. In addition, the individual operations must also be performed atomically in order to ensure both fault tolerance and consistency in case of concurrent access. This leads directly to the next two requirements: persistence and isolation. The latter property must ensure that both continuous and ad-hoc queries do not influence each other in terms of correctness and consistency. Furthermore, consistency must be ensured even if a query accesses multiple states, also in the event of transaction aborts. The persistence requirement means that the results of successfully committed transactions are still available after a system restart or crash. This goes hand in hand with recoverability, which must ensure that the states are brought back or always stay in a consistent form. Taking these requirements into consideration, we have realized a snapshot isolation approach comprising three components:

- multi-versioned data structures for queryable states,
- a transaction protocol to access these states, and
- a protocol guaranteeing consistency among multiple states.

These components are prototypically implemented as part of our data stream processing framework PipeFabric[1]. We opted for an MVCC approach as it has proven to be the most scalable and widely used concurrency control protocol in the literature for DBMSs [4, 16, 20]. We expect it to behave similarly in a transactional stream processing environment. However, this still has to be revealed, which we will pursue in the following sections.

4.1 Data Structures

As transactional state representation, we have designed a table wrapper as shown in Figure 3. For the base table, any existing backend structure with a key-value mapping can be used. Therefore, every state type can use a suitable underlying structure making our design extremely versatile. Here, each key is mapped to an MVCC object. An entry in this object corresponds to the typical structure for MVCC [17, 20] $(\equiv\ <[cts, dts], value>)$. The commit and deletion timestamp (CTS/DTS) indicate the lifetime of the value version. With the help of a bit vector (UsedSlots) the available free version slots are managed.

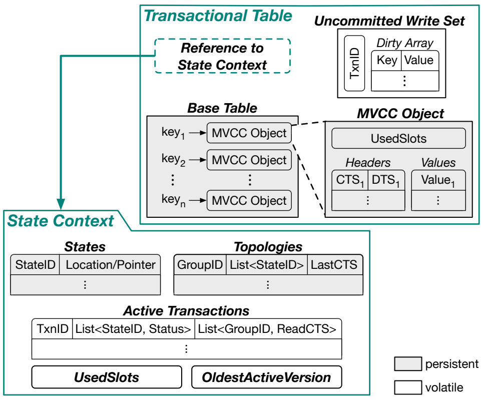

Figure 3: Transaction components.

Before new versions become visible to readers the changes are transiently stored as Uncommitted Write Set. This enables simple and fast aborts and also prevents the mixing of committed and uncommitted versions. Furthermore, the transactional table has a reference to the global context which contains all necessary runtime information. It consists of metadata about the states, topologies, and active transactions. For the states it contains general information such as their ID and physical location (e. g., file system path). In PipeFabric a query is written by defining a so-called *Topology*. It can be seen as graph where each node is an operator and the edges represent their subscribed streams. Each state is part of at least one topology for which we track the states that must be written together atomically. This is necessary for the correct application of the consistency protocol (see Section 4.3) for which the last committed transaction (LastCTS) per group is recorded. For recovery purposes, this information needs to be persistent. At the beginning of each transaction, it is assigned a unique timestamp (TxnID). All timestamps are logical and generated by a global atomic counter. For currently running transactions, we save a list of accessed states containing their ID and status (Active, Abort, or Commit) as well as the global commit timestamp at the time of reading for each topology. Again, we use a bit vector[2] to atomically manage the available slots. For garbage collection, we clean up old versions on demand (using OldestActiveVersion), i. e., if a new version has to be created and no space is available in the version array. The state context of the transaction management is completely latch-free and solely uses atomic instructions.

4.2 Concurrency Protocol

Before considering global consistency, we look at the basic operations required, namely *read*, *write*, *commit*, and *abort*. For a better separation of the protocols, we first assume that only a single state needs to be accessed consistently at a time. We further assume a beginning punctuation to signal the start of a transaction that assigns a timestamp and registers it in the context. To synchronize the actual access of MVCC blocks a lightweight locking strategy with read-write locks (latches) can be used.

The *read* operation starts by checking whether the accessing transaction has already written a new value (Uncommitted Write Set) and returns it. Otherwise, the latest visible version will be looked up using the commit and deletion timestamps. To achieve snapshot isolation, the first read version timestamp of this transaction must be transiently stored and used for subsequent reads (readCTS). The found value is finally returned to the caller.

When a transaction wants to *write* a new value, it is merely appended to its write set (Dirty Array). In case of a single writer, no exclusive locks are required and writes never block. For multiple writers, it could be checked if write sets overlap and then prematurely abort/restart the later transaction. Alternatively, this could be done only at commit time to prevent slower writes.

As all uncommitted changes are stored transiently together, it is enough for the *abort* operation to simply clear the corresponding write set and release the memory. The *commit* operation, on the other hand, is a bit more complex since all changes must be applied atomically and isolated from other readers. For each modification the MVCC object is loaded, the position of the new value is determined, and the position of the current value is looked up. The changes are then applied in memory. If no free insert position could be found, the garbage collection is performed at this point. Subsequently, the changes are populated atomically and isolated into the base table. As a final step, the global commit timestamp of the table is changed to the committing transaction's ID. By atomically setting this timestamp, the protocol can guarantee that the changes of a transaction are either visible completely or not at all. In the case of multiple writers, additional write locks are introduced and the order of the commits must be checked. If the current version is greater than the timestamp of the transaction, it must abort (First-Committer-Wins rule).

The way we designed our operations eliminates the need for undo operations within the actual table. In addition, read operations are generally not blocked by write operations and vice versa. Only during the commit time, a short synchronization is required. Therefore, we expect the performance to remain stable even for high contention situations.

4.3 Consistency Protocol

If now a continuous query needs to update multiple states, they must become visible together to maintain consistency. Assume a simplified case where a data stream query writes two states and

[1] PipeFabric: https://github.com/dbis-ilm/pipefabric

[2] In fact, it is a 64-bit integer, which is updated by CAS operations.

a second (ad-hoc) query reads from both states. We coordinate the operators with the help of the state context (see Figure 3). Whenever a commit arrives the corresponding status flag for this transaction and state is set to `Commit`. The modifications are not persisted until all states registered for this transaction are ready for commit. The operator that sets the last status flag to `Commit` becomes the coordinator and is responsible for the global commit. In addition, a transaction must be aborted globally as soon as `Abort` has been flagged for at least one state. In this respect, this is a modified version of the 2-Phase-Commit protocol [11] relying on proven concepts which adds almost no overhead in our case.

Readers can see the last completed transaction using `LastCTS` for each topology which is set at the end of a commit (instead of the transaction ID as described before). They must also check in the context which states are written together. For these, the version must be the same, otherwise, a commit has been executed in the meantime. Therefore, the read version is noted within the context (`ReadCTS`) and is only set at the first read per topology. Thus, every operation reads from the same snapshot and interleaved commits do not pose a problem. If there is an overlap when reading multiple topologies with different versions (`LastCTS`), the older version must be read to guarantee consistency.

5 EVALUATION

In this section, we present a micro benchmark to substantiate the suitability and scalability of our approach. For this, we evaluate our MVCC protocol against a simple strict two-phase locking (S2PL) [6] and a backward-oriented optimistic concurrency control (BOCC) [8] protocol. We have made every effort to implement optimized versions of each protocol. All concurrency control protocols use fundamentally the same consistency protocol for multiple states as described in Section 4.3.

5.1 Setup and Workloads

The experiments were run on a 2-socket Intel Xeon E5-2630 each 6 cores à 2 threads, 128 GB DDR3, Linux kernel 4.15, and GCC 7.3. As a base table, we use a persistent key-value store, namely RocksDB[3]. It has a log-structured merge-tree (LSM) design and provides many configuration options for a wide range of requirements. We kept the default configuration and only set the *sync* option to true to guarantee failure atomicity. As a benchmark, we use a scenario having one stream continuously writing to two states and multiple ad-hoc queries reading from these states. Both are initialized with a table size of one million key-value pairs (4 Byte key, 20 Byte value). During the experiments, we vary the number of parallel ad-hoc queries and the contention rate using a Zipfian distribution ($\theta = 2.9 \mathrel{\hat{=}} 82\%$ the same key) [7].

5.2 Performance Study

In the following, we compare the performance of all concurrency control protocols for transactions of medium length (10 operations each). An excerpt of our measurements is shown in Figure 4. Due to the synchronous writing, the readers (mostly only accessing memory) contribute almost exclusively to the total throughput. While the other two protocols are dropping, the MVCC protocol provides consistently a good performance. Interestingly, the BOCC protocol is slightly faster (~5%) than MVCC with little contention and many concurrent ad-hoc queries. However, this is logical as it is designed for scenarios with few conflicts. If the number of threads and the contention increases, it brings the S2PL and BOCC to their knees relatively quickly. It is noticeable that at least for MVCC caching effects are visible with a higher contention. Overall, it shows that our MVCC approach combined with the consistency protocol is highly scalable and resilient, making it well suited for transactional state management.

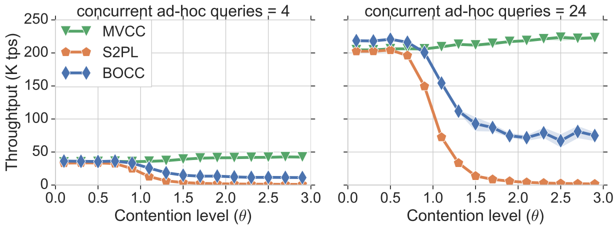

Figure 4: Contention and scalability check with persistent synchronous writes and medium-sized transactions.

6 CONCLUSION

Transactional stream processing systems itself offer a wide range of research opportunities. In this paper, we presented a data-centric transaction model and investigated concurrency and consistency aspects within this model. We have found that our snapshot isolation approach meets all our initial requirements. We designed a versatile state representation which is queryable by both continuous and ad-hoc queries. Even under high parallelism and contention, the ACID properties could always be maintained with great performance even when involving multiple states.

ABSTRACT

Prediction of human intent during a user interaction session with the database received a significant amount of attention in the recent past [1, 8]. State-of-the-art intent detection approaches such as [5] insist that the human intent is dynamic and is constantly changing throughout the user session. While the usage of classifiers like SVMs and decision trees have been proposed to capture static user intent [2], such models become ineffective in predicting dynamic or ever-changing human intent. Recurrent Neural Networks (RNNs) are powerful temporal predictors and have recently been prominent in the database research community for tasks such as entity matching [3, 6]. In this work, we discuss the application of RNNs to the problem of dynamic user intent prediction during a human-database interaction. We propose two variants of SQL-specific embedding vectors for RNNs. We also propose *active learning* strategies for RNNs which consume a fraction of the held-out training data to produce competitive prediction quality as full training or *supervised learning*. Our experiments on real user sessions upon the NYCTaxiTrip dataset [9] evaluate the effectiveness of vanilla, LSTM and GRU based RNNs.

1 INTRODUCTION

Prediction of user intent during a Human-Database Interaction (HDI) session helps prefetching the results of the anticipated queries [4] thus making the interaction seamless. Existing works such as [1, 2] define the user intent as the last (target) query asked by a user in an interaction session and the prediction of user intent as a binary classification problem. The test data at hand is classified as interesting or not by using a decision tree or a Support Vector Machine (SVM) based on the training the classifier has undergone. The positive class predictions are evaluated against the results of the target SQL query held as ground truth. This line of work assumes that the user intent is static, contrary to which [5] emphasizes that the user can refine and adapt her needs constantly until the termination of an HDI session i.e., the target query changes continuously. Capturing dynamic multi-user intent using [1, 2] requires a binary classifier for each user session. Instead, we can model dynamic intent discovery as a temporal prediction task using a single Recurrent Neural Network (RNN) for all the user sessions because of its ability to train on and predict several sequences of data.

For a query qu_i issued by the user at timestep i, we not only retrieve the results of qu_i but also predict the intent vector of the subsequent query at timestep $i + 1$. We use RNN as the intent prediction middleware between the user and the database as illustrated in Figure 1. A prior embedding layer can convert raw text either into real-valued embeddings or *one-hot* vectors or words in a *vocabulary* which are fed to the RNNs as intent vectors.

Figure 1: Intent Prediction Pipeline using RNNs

The performance of an RNN is dependent on the granularity at which these embeddings and the corresponding vocabulary are created. For instance, either an entire SQL query or each distinct substring or character in the query can be considered as a word in the vocabulary. In the latter case, external libraries such as word2vec (https://code.google.com/archive/p/word2vec/) or GloVe (https://nlp.stanford.edu/projects/glove/) can be used to borrow pre-trained real-valued embeddings [6].

We create two variants of SQL-specific binary embeddings for dynamic intent vector representation customized to relational databases rather than relying on external libraries which are SQL-agnostic. In the first variant of query embedding, we use a one-hot vector which is a bitmap of 1s and 0s to represent each query intent. It only has a single dimension set to 1 that corresponds to a specific query among the collective set of queries issued by the users until a given point of time. The second variant of operator-based embedding breaks down a SQL query into several smaller bitmaps each corresponding to a distinct family of SQL operators. A concatenation of all the operator-specific bitmaps produces an operator embedding as the user intent for that query.

RNNs are known to consume a lot of training data and time. To reduce the amount of training data, we use active learning on RNN to empirically test if it can make effective predictions with limited user sessions. Active learning selectively includes *ambiguous* (hard-to-classify) examples into the training data and incrementally refines the classifier based on the additional training data. Our approach differs from active learning for static intent in [2] as we select query sequences that is more scalable than labeling tuples. To minimize the training time and enhance interactivity, we propose using an incrementally trained RNN. We present our results on 139 sessions we collected from real user interactions on the NYCTaxiTrip [9] dataset. The remaining paper is organized as follows: we first present the details of the experimental dataset and the construction of the embedding vectors followed by the application of supervised learning and active learning on RNN for dynamic intent prediction. We conclude the paper with a discussion on the experimental results.

2 DATASET AND SYSTEM OVERVIEW

We collected 139 user sessions from 30 real world users with 4 to 5 average sessions per user. Each of them interacted with a sample of 100,000 trips loaded from a total of 10M taxi trips that span over 5 weeks in June and July 2016. We used the visual interface of Tableau [7] connected to the database engine of PostgreSQL 9.5.10. The reason for sampling is to increase the interactivity between the user and the database without overloading the Tableau interface. The visual interactions are translated into SQL queries and stored in logs by Tableau. We obtained a total of 1958 SQL queries with 1190 distinct queries from the user interactions. Our offline vocabulary creation step ensures that the embedding vectors of all the queries have the same pre-fixed dimensionality. We do not have to handle "UNK"(unknown) tokens as RNNs conventionally do for out-of-vocabulary strings, because of the offline step.

Query Embedding: Query-based intent uses the actual query for intent representation. Each query is thus assigned a specific dimension within the entire vocabulary space of 1190 distinct SQL queries in the dataset. A bitmap of 1190 bits is created for each query of which a single bit is set to 1 specific to the query.

Operator Embedding: The NYCTaxiTrips dataset is stored as a single table and hence each SQL query intent vector is a composite bit vector of all possible operators allowed over a single relation and can be written as $vec(qu_{Aggr})$ = π_{vec} $Aggr_{vec}$ σ_{vec} $GROUP\ BY_{vec}$ $ORDER\ BY_{vec}$ $HAVING_{vec}$ $LIMIT_{vec}$. Each query vector $vec(qu_{Aggr})$ is a concatenation of bit vectors for operators such as PROJECT, AGGREGATE, GROUP BY, ORDER BY, HAVING and LIMIT. Every single operator out of these six has a dimensionality equal to the number of attributes $|Attr|$ in the database schema (indicating the columns that the operator can be associated with) except AGGREGATE and LIMIT. $Aggr_{vec}$ is a concatenation of five most common aggregate operators - AVG, MIN, MAX, SUM and COUNT and thus has a dimensionality of $|Attr| * 5$ bits. LIMIT operator contributes only to a single bit in the operator vector as it is not associated with any attribute and is more like a Boolean recording its presence in the query. The total dimensionality of an operator embedding bitmap is thus $|Attr|$x10+1 which is 18x10+1=181 for the NYC taxi trip dataset.

Operator	**Operator sub-vector**	**#Dimensions**
π_{vec}	000000000000100000	#Columns = 18
$Aggr_{vec}$	0...0111111111111111111	#Columns x 5 = 90
σ_{vec}	0000..0	#Columns = 18
$GROUP\ BY_{vec}$	000000000000100000	#Columns = 18
$ORDER\ BY_{vec}$	0000..0	#Columns = 18
$HAVING_{vec}$	0000..0	#Columns = 18
$LIMIT_{vec}$	0	1

The above table lists the operator (sub-)vectors for each expected category of SQL operators for the example query qu_{i+1} from Figure 1, qu_{Aggr}: *SELECT COUNT(*), taxi_fare FROM nyc_yellow_tripdata GROUP BY taxi_fare*. Let taxi_fare be the 13^{th} attribute among the list of 18 possible attributes. We can see the corresponding bit position set to 1 in the 18-bit operator sub-vector for the projection and group by operator while setting all the attributes for the count operator to 1.

2.1 Supervised Learning

In this section, we describe how RNNs are trained and tested for dynamic intent prediction. We use Keras API (https://keras.io/) with TensorFlow library (https://www.tensorflow.org/) for RNNs. Figure 2 illustrates RNN for two consecutive timesteps T_i and T_{i+1} in intent prediction. We use a "many-to-one" sequential RNN with an input layer, a hidden layer and an output layer. The input layer is fed with the sequence of query/operator embedding vectors until the current timestep in the session to get a temporal prediction of the intent for the next timestep. The output layer emits a probability vector with same dimensionality as the intent vector. The value of each dimension indicates the probability of that dimension being a 1. For example, in Figure 2, the output vector $< 0.6, 0.4, 0.01, 0.01, 0.9 >$ at T_i denotes the probabilities of each of its five dimensions being 1.

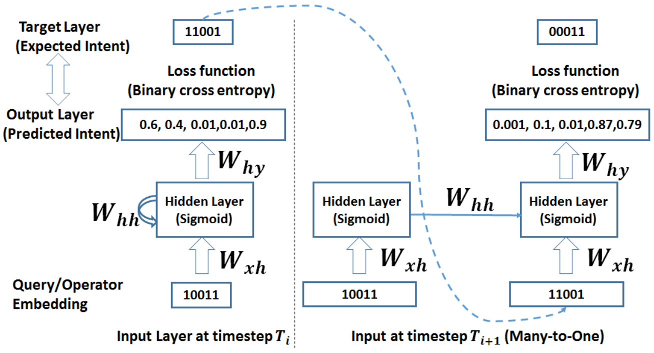

Figure 2: Recurrent Neural Network for Intent Prediction

During the training phase, the predicted probabilistic output vector is compared to the target query which is the successor query from the next timestep or the expected intent vector output (of 11001 at T_i in the figure) using a loss function. The hidden layer weights (w_{xh}, w_{hh}, w_{hy}) are updated using backpropagation either by fitting the model simultaneously on the sequences across all the timesteps so far ($fully\ trained$) or updating the model obtained thus far by fitting it only on the latest sequence ($incrementally\ trained$). We limit the number of learning epochs to 10 during training for interactivity. We append the target vector of timestep T_i to the session sequence as input to the RNN at the subsequent timestep T_{i+1}. We empirically choose sigmoid activation function for hidden layer and binary cross entropy as the loss function at the output layer. During the test phase, instead of predicting the most likely intent vector, we predict the top-K candidate output intent vectors having the highest cosine similarity to the probabilistic output vector. These top-K vectors are picked from the historical sessions that the RNN has been trained on, and this ensures that arbitrary bitmaps which may not correspond to a meaningful SQL query are not predicted.

2.2 Active Learning

Active learning can be applied to RNN to test if it can perform well with limited training data. Instead of learning the RNN upon all the training session queries, the training set can be divided into two parts - session query sequences which are made available to the RNN, and query sequences held out from the RNN. By training the RNN upon the available query sequences and selecting informative sequences from the held-out data for inclusion into the training set, the RNN is incrementally refined to verify if it achieves high F1-scores on the test set without exhausting the entire training set. It should be noted that by query qu_i, we refer to its intent vector throughout this section.

For a given user session with queries qu_1, qu_2 and qu_3, the temporal sequences constructed are $qu_1 \longrightarrow qu_2$ and $qu_1, qu_2 \longrightarrow qu_3$ as shown in Figure 3. A held-out session means that the antecedent (e.g., qu_1, qu_2 in $qu_1, qu_2 \longrightarrow qu_3$) of a temporal sequence dependency is available while keeping the consequent (e.g, qu_3 in $qu_1, qu_2 \longrightarrow qu_3$) invisible. Thus, the trained RNN is supposed to predict the consequent of each temporal dependency given its

Algorithm 1: Active Learning for intent prediction

3      $C_i \leftarrow$ learnClassifier(L, $Tr_A$)
4      $seq_{ambig} \leftarrow$ pickAmbiguousQuerySequence(L,$Tr_H$)
5      $seq_{labeled} \leftarrow$ obtainSuccessors($seq_{ambig}$)
6      $Tr_H \leftarrow Tr_H - seq_{labeled}$
7      $Tr_A \leftarrow seq_{labeled} \cup Tr_A$
8      $qu_{predicted} \leftarrow$ predictSuccessors($Test$, $C_i$)
9      $Test_{F1} \leftarrow$ computeF1($Test$, $qu_{predicted}$)
10     $i \leftarrow i + 1$
11 $C^* \leftarrow C_{i-1}$
12 return $C^*$, $qu_{predicted}$
```

antecedent. Among all such held-out sequences, if the RNN finds a particular sequence to be the hardest to predict the successor for, it is deemed to be an ambiguous sequence for RNN. The consequent or the successor query of that particular temporal sequence is made available to the RNN and is included into the available training set. In Figure 3, $qu_{11}, qu_{12}, ..., qu_{20} \longrightarrow qu_{21}$ is the hardest held-out temporal sequence and hence, it is included into the training set.

Figure 3: Active learning for RNNs

Algorithm 1 describes the active learning based intent prediction algorithm using RNN. Tr_A and Tr_H are the available and held-out training datasets. In each active learning iteration, the most ambiguous query sequence is picked from Tr_H for which the successor query is the hardest to predict and the corresponding successor query is made available to RNN (lines 4 and 5). The query sequence is removed out of Tr_H and is added to Tr_A (lines 6 and 7). At the end of each iteration, the RNN learned thus far is evaluated on the fold test data until the held-out training set is exhausted. The purpose of using active learning algorithm is to verify if all the training set needs to be completely exhausted during learning to achieve a significantly high enough test F-measure. While ambiguous sequence selection is time consuming, if it helps active learning reach an early convergence to high F-measures, it is a trade-off worth considering.

2.2.1 Ambiguous Example Selection Strategy (Minimax). We have described in section 2.1 that the output layer of the RNN emits a probability vector. We compute the cosine similarity between the probability vector and the intent vectors of all the historical session queries that the RNN has learned from until then, and select the top-K intent vectors with the highest cosine similarity as the predicted intents. Hence, we can use the value of the maximum cosine similarity as the confidence measure and the inverse of the confidence value denotes the ambiguity. Among several temporal held-out sequences $seq_1, seq_2, ..., seq_n$, the one for which predicting the successor query is the hardest is inferred based on the value of the highest cosine similarity between the weight vector and the historical intent vectors. If the corresponding values of the highest cosine similarities are $maxSim_1, maxSim_2, ..., maxSim_n$, the most ambiguous query sequence is seq_i if i=$arg\ min_{i=1}^{n}$ $\{maxSim_i\}$, i.e., it has the least maximum cosine similarity (minimax) among all the sequences.

3 EXPERIMENTS

All our experiments were conducted on a Mac machine with a 4-core 2.8 GHz Intel Core i5 processor, 16GB RAM and 1.02 TB hard disk. Our experiments for supervised learning were conducted on queries arriving in an interleaved order from concurrent user sessions. Active learning experiments were conducted on 10-fold splits of the data into 10 different training and test set pairs with 90% and 10% of the user session queries respectively. We compute the precision and recall as follows:

$Precision = \frac{\#\{PredDim_i=1 \cap ActualDim_i=1\}}{\#\{PredDim_i=1\}}$

$Recall = \frac{\#\{PredDim_i=1 \cap ActualDim_i=1\}}{\#\{ActualDim_i=1\}}$

Each dimension $PredDim_i$ in the predicted intent vector is compared to the corresponding dimension $ActualDim_i$ in the actual vector, and the hits and misses are measured based on the fraction of 1s predicted accurately. We report F1-scores in our results.

Concurrent User Sessions: The queries arrive in batches of 10 and hence the 1958 queries from the NYCTaxiTrip dataset are divided across 196 learning episodes. While the RNN gets updated at the end of each learning episode with additional training data obtained from the queries during the episode, it is tested throughout the episode with the arrival of new query. For each new query, its embedding (query or operator) vector is fed to the RNN, which predicts the top-K intent vectors for the next query. K is set to 3 and we report the maximum F-measure among the top-3 predictions by averaging it across all the queries in each episode. Response time is the sum of the intent vector creation and execution times for the current query added to the intent vector prediction time for the next query. It is heavily dominated by the RNN prediction time which also includes its cumulative training time based on all the queries seen thus far. For incrementally trained vanilla (simple backpropagation) RNN, the training time depends only on the batch of queries from the latest episode.

LSTM (Long Short Term Memory) and GRU (Gated Recurrent Unit) perform same as vanilla RNN on the operator embedding intent vector (Figure 5) but GRUs perform slightly better than LSTM and vanilla on query embedding (Figure 4) vectors. The reason for this is that the average user session length is ≈18 queries per session which is not lengthy enough for advanced RNN variants to exploit the long short term dependencies. On an average, vanilla RNN seems to give competitive F-measures while also consuming lesser response time than LSTM and GRU (Figure 6). Incrementally trained RNN sacrifices test F-measures on query embedding but produces comparable quality as fully trained RNNs on operator embedding while incurring very low response times. Time charts on query embedding demonstrate similar patterns as operator embedding for both supervised and active learning which is why we omitted them for brevity.

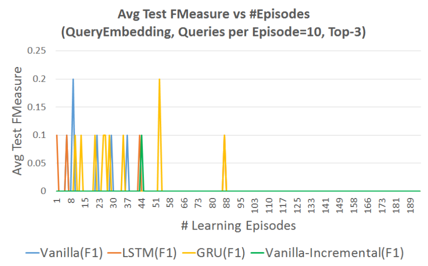

Figure 4: Concurrent Sessions (Query)

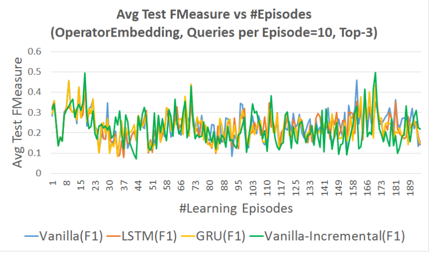

Figure 5: Concurrent Sessions (Operator)

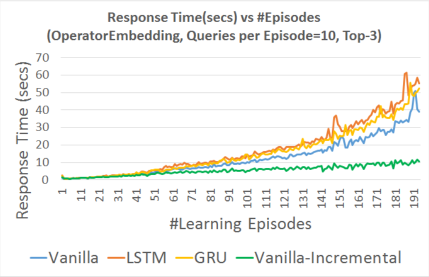

Figure 6: Response Times (Operator)

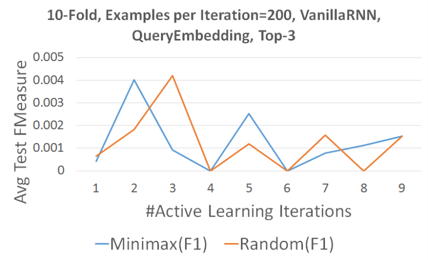

Figure 7: Active Learning (Query)

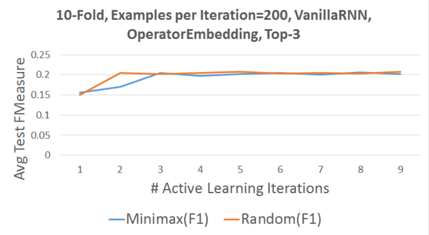

Figure 8: Active Learning (Operator)

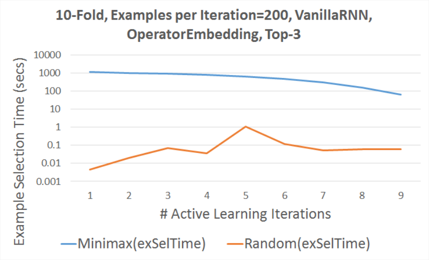

Figure 9: Selection Times (Operator)

A general observation is that operator embedding is more expressive and produces better F-measures than query embedding because predicting SQL operators in a query is easier than predicting the query in its entirety. We can also notice that the initial queries in concurrent sessions are easier to predict than the later ones. In the real world sessions we collected, each user arrives at a distinct goal by the end of the exploratory session. The first few queries may be similar across users, but each session becomes specialized with unique queries towards the end, thus inducing little overlap across sessions. This in turn makes workload prediction harder as the sessions progress concurrently.

Active Learning: Our 10-fold active learning experiments were upon the fully trained vanilla version of RNN using standard backpropagation algorithm. There were ≈1648 examples (temporal query sequence dependencies) in the training set and ≈190 test examples. We started with a seed available training set of 30 randomly chosen training examples and 1618 held-out training examples. We selected 200 examples in each iteration from the hold-out set and added them to the available set. We plot the average test F-measures over all the test sessions across 10 folds at each active learning iteration in Figures 7 and 8.

We compared the minimax example selection strategy described in section 2.2.1 with random selection. Our observations show that random strategy performs competitively to minimax on operator embedding as shown in Figure 8 and achieves earlier convergence to the eventual F-measure in the 2^{nd} iteration with 230 examples (14% training data). Minimax achieves slower convergence by iteration 3 with 430 examples and 26% training on operator embedding. Examples chosen in an iteration are used for training in the next iteration i.e., #training examples in iteration i = 30 + 200 x (i-1). Figure 7 shows that both strategies perform similarly on query embedding. A major drawback of using query embedding for active learning is the non-monotonic behavior with increasing iterations. This is due to the heavy sparsity in query embedding vectors (1 bit set out of 1190 dimensions) and fitting RNNs to more training points does not necessarily yield higher test F-measures. Minimax strategy incurs more example selection time than random selection (Figure 9) because of the expensive prediction done over the hold-out set which shrinks with increasing iterations thus also decreasing the selection times.

4 CONCLUSION

In this paper, we proposed the application of RNNs for dynamic intent prediction and two SQL specific embedding techniques for intent vector creation. Our experiments show that operator embedding is more effective than query embedding and that vanilla RNNs perform better than LSTMs or GRUs for user sessions of moderate length (#queries). We also show that an incrementally updated vanilla RNN model achieves substantially lesser response times than fully trained RNN models while making little to no sacrifice in prediction quality. Our active learning experiments show that random selection strategy achieves earlier convergence to competitive test F-measures as full training with just 14% of the training examples on operator embedding and lesser example selection time than minimax strategy.

ABSTRACT

How can one quickly answer the most and top popular objects at any time, given a large log stream in a system of billions of users? It is equivalent to find the mode and top-frequent elements in a dynamic array corresponding to the log stream. However, most existing work either restrain the dynamic array within a sliding window, or do not take advantages of only one element can be added or removed in a log stream. Therefore, we propose a profiling algorithm, named S-Profile, which is of $O(1)$ time complexity for every updating of the dynamic array, and optimal in terms of computational complexity. With the profiling results, answering the queries on the statistics of dynamic array becomes trivial and fast. With the experiments of various settings of dynamic arrays, our accurate S-Profile algorithm outperforms the existing methods, showing at least 2X speedup to the heap based approach and 13X speedup to the balanced tree based approach.

1 INTRODUCTION

Many online systems, especially with billions of users, are generating a large stream of logs [6], recording users' dynamics in the systems, e.g. users (un)follow other users, "(dis)like" objects, enter (exit) live video channels, and click objects. Then, a question is raised:

How can we efficiently know the most popular objects (including users), i.e. mode, top-K popular ones, and even the distribution of frequency in a fast and large log stream at any time?

Mathematically, the questions converge to calculating and updating the statistics of a dynamic array of finite values. Thus, the existing fast algorithms on the statistics are as follows:

Mode of an array. The mode of an array and its corresponding frequency can be calculated by sorting the array (if it's of numeric value) and scanning the sorted array in $O(n \log n)$ time, where n is the length of array [7]. Notice that through judging the frequency of mode we can solve the element distinctness problem, which was proven to have to be solved with $\Omega(n \log n)$ time complexity [12, 15]. Therefore, calculating the mode of an array has the lower bound of $\Omega(n \log n)$ as well. If the elements of array can only take finite values, the complexity of calculating the mode can be reduced. Suppose they can only take m values. One can use m buckets to store the frequency of each distinct element. Then, the mode can be calculated in $O(n + m)$ time by scanning the m buckets.

The problem of range mode query, which calculates the mode of a sub-array $A[i \dots j]$ for a given array A and a pair of indices (i, j), has also been investigated [4, 10, 13]. The array with finite values was considered. With a static data structure, the range mode query can be answered in $O(\sqrt{n/\log n})$ time [4].

Majority and frequency approximation. The majority is the element whose frequency is more than half of n. An algorithm was proposed to find majority in $O(n)$ time and $O(1)$ space [3]. Many work on the statistics like frequency count and quantiles, are under a setting of sliding window [1, 2, 5, 8, 11]. They consider the most recently observed data elements (within the window) and calculate the statistics. Space-efficient algorithms were proposed to maintain the statistics over the sliding window on a stream.

However, those existing work slow down their algorithms without considering that the increase and decrease of object frequency are always 1 at a time in log streams. Therefore, we propose an algorithm S-Profile to keep profiling the dynamic array. With such a profile, we can answer the queries of the statistics: mode, top-K and frequency distributions.

In summary, S-Profile has the following advantages:

- **Optimal efficiency:** S-Profile needs $O(1)$ time complexity and $O(m)$ space complexity to profile dynamic arrays, where m is the maximum number of objects.
- **Querying Statistics:** With the profiling, we have sorted frequency-object pairs, and can simply answer the queries on mode, top-K, majority and other statistics in $O(1)$.
- **Applicable:** Our S-Profile can be plugged into most of log streams in many systems, and profiling objects of interest.

In experiments, S-Profile compares with the existing methods in various settings of dynamic arrays, and shows its performance and robustness.

2 AN $O(1)$-COMPLEXITY ALGORITHM FOR UPDATING THE MODE AND STATISTICS

We define tuples (x_i, c_i) as a log stream, where x_i and c_i is the object id and action in the i-th tuple. Action c_i can be either "add" or "remove", which, for example, can indicate object x_i is "liked" or "disliked", or user x_i is followed or unfollowed. Conceptually, we could imagine a dynamic array A of objects associated with a log stream, by appending object x_i into A if c_i is "add", and deleting object x_i from A if c_i is "remove". Dynamic array A is not necessarily generated and stored, which is defined for convenient description of our algorithm.

Therefore, our problem can be described as follows:

Informal Problem 1 (Profiling dynamic array). ***Given:*** *a log stream of tuples (x_i, c_i) adding and removing an object each time,*

- ***To build:*** *a data structure profiling the dynamic array A of objects associated with the log stream,*
- ***Such that:*** *at any time answering the queries on mode, top-K and other statistics of objects is trivial and fast.*

Let m be the maximum number of distinct objects in a log stream or dynamic array A. Without loss of generality, we assume id $x_i \in [1, m]$, i.e. integers between 1 and m. For any m distinct objects, we can map them into the integers from 1 to m as ids.

We can use m buckets to store the frequency of each distinct object. Let F be such a frequency array with length m. $F[i] \in F$ is the frequency of object with id i. With F, most statistics of A can be calculated without visiting A itself. For example, the mode of A refers to locations in F where the element has the maximum value. Although updating F with each tuple of a log stream trivial and costs $O(1)$, finding the maximum value in F at each time is still time consuming.

Therefore, we first introduce a proposed data structure of a profile, named "block set", which can answer the statistical queries in a trivial cost. And we show later that we can maintain such a profile in $O(1)$ time complexity and $O(m)$ space complexity.

2.1 Proposed data structure for profiling

In order to find the mode of A, we just need to care about the maximum in F. If only integers are added to A, the maximum element of F can be easily updated. However, in Problem 1 removing integer is also allowed. This complicates the calculation of mode and other statistics of A. So, the sorted array T must be employed and maintained. To facilitate the queries, T can be implemented as a binary tree. The heap and balanced tree are two kinds of binary tree, and are widely used for efficiently maintaining an sorted array. Upon a modification on A, they both can be updated in $O(\log m)$ time. The root node of a heap is the array element with the extreme value. This means the heap is only suitable for producing the A's elements with either maximum frequency (the mode) or the minimum frequency. The balanced tree is good at answering the query of median of A, and can also output the mode and top-K elements, etc. It should be pointed out, these general algorithms do not take the particularity of Problem 1 into account (the modification on F is restricted to plus 1 or minus 1). By the way, no one can maintain the sorted array under an arbitrary modification with a time complexity below $O(\log m)$, because it can be regarded as a sorting problem which has been proven to have $\Omega(m \log m)$ time complexity.

We use Figure 1 as an example to illustrate the proposed data structure for maintaining T. Suppose T has frequency values in ascending order. In order to locate the index of the i-th element of T in F and vice verse, two conversion arrays are defined: $TtoF$ and $FtoT$. In other words, we have $T[i] = F[TtoF_i]$ and $F[i] = T[FtoT_i]$. Here, we use both the subscript and bracket notation to specify an element of array. As shown in Figure 1(c), we can partition T into nonoverlapped segments according to its elements. Each such segment is called *block* here and represented by an integer triple (l, r, f), where l and r are starting and ending indices respectively, and f is the element value (frequency). So, a block $b = (l, r, f)$ always satisfies:

- $1 \leq l \leq r \leq m$
- $T_i = f, \quad \forall i \in [l, r]$
- $T_l > T_{l-1}, \quad \text{if } l > 1$
- $T_r < T_{r+1}, \quad \text{if } r < m$

There are at most m blocks, which form a *block set*. It fully captures the information in the sorted array T. An array of pointers called $PtrB$ is also needed to make a link from each element in T to its relevant block. According to the definition of block, we always have:

$$T_i = PtrB[i].f, \quad \text{and} \quad PtrB[i].l \leq i \leq PtrB[i].r \,. \qquad (1)$$

Here we use ".l" to denote the member l of a block, and so on.

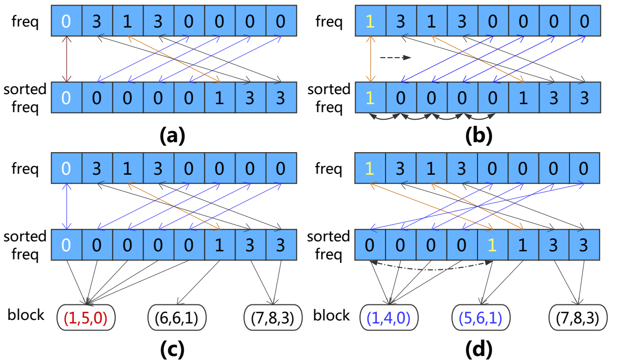

Figure 1: Illustration of the proposed *block set* for maintaining array T. (a) The initial F and T. (b) When "1"is added to A, a brute-force approach to maintain T includes four swaps of "1" rightwards and updates of $FtoT$ and $TtoF$. (c) The initial F and T, and the *block set*. F and T are up to be modified. (d) With the information of *block*, the swapping destination in T can be easily determined.

The block set B represents the sorted frequency array T, while with arrays $FtoS$, $StoF$ and $PtrB$ we no longer need to store F and T. These proposed new data structure well profile the dynamic array A. The remaining thing is to maintain them and answer the statistical queries on A in an efficient manner.

2.2 S-Profile: the $O(1)$-Complexity Updating Algorithm

We first consider the situation where an integer is added to A. As shown in Figure 1(a) and 1(b), a brute-fore approach to update T is swapping the updated frequency to its right-hand neighbor one by one, until T is in the appropriate order again. Now, with the proposed $PtrB$ and the block it points to, we can easily determine the index of T which is the destination of swapping the updated frequency. Then, we can update the relevant two blocks and pointer arrays (see Figure 1(d)).

Now, based on the situation shown as Figure 1(d), we assume a "4" is removed from A. As shown in Figure 2, we first locate the updated element in T. Then, with the information in its corresponding block we know with which it should be swapped. We further check if the updated frequency exists in T before. If it does not we need to create a new block (the case in Figure 2(b)), otherwise another block is modified.

The whole details of the algorithm for updating the data structure and returning the mode of A is described as Algorithm 1. We assume the data structures (B, $FtoS$, $StoF$ and $PtrB$) have been

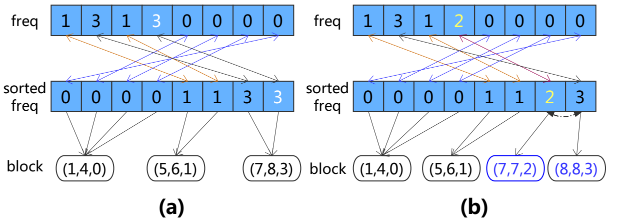

Figure 2: Illustration of the proposed data structure for a "remove" action on A. (a) The initial F and T, and the *block set*. A "4" is going to be deleted from A. (b) With the information of *block* and the pointer arrays, the *block set* can be easily updated to reflect the ordered T.

initialized, while Algorithm 1 responds to an event in the log stream and returns the updated mode and frequency.

Algorithm 1 S-Profile for updating the mode of array

Input: A tuple (x, c) in log stream, block set B, pointer arrays $FtoT$, $TtoF$ and $PtrB$, the length of sorted frequency array m
Output: The mode M, and the frequency v.

```
1:  $rank \leftarrow FtoT[x]$
2:  $b \leftarrow PtrB[rank]$
3:  $l \leftarrow b.l$ ;   $r \leftarrow b.r$;
4:  if $c$ is an "add" action then
5:      $b.r \leftarrow b.r - 1$
6:      if $b.r < b.l$ then
7:          Delete $b$
8:      end if
9:      if $r < m$ and $b.f + 1 = PtrB[r+1].f$ then
10:         $PtrB[r] \leftarrow PtrB[r+1]$
11:         $PtrB[r].l \leftarrow PtrB[r].l - 1$
12:     else
13:         Create a new block in $B$ and assign it to $PtrB[r]$
14:         $PtrB[r] \leftarrow (r,\ r,\ b.f + 1)$
15:     end if
16: else        /* It's a "remove" action */
17:     $b.l \leftarrow b.l + 1$
18:     if $b.r < b.l$ then
19:         Delete $b$
20:     end if
21:     if $l > 1$ and $b.f - 1 = PtrB[l-1].f$ then
22:         $PtrB[l] \leftarrow PtrB[l-1]$
23:         $PtrB[l].r \leftarrow PtrB[l].r + 1$
24:     else
25:         Create a new block in $B$ and assign it to $PtrB[l]$
26:         $PtrB[l] \leftarrow (l,\ l,\ b.f - 1)$
27:     end if
28: end if
29: $M \leftarrow TtoF[PtrB[m].l \ldots PtrB[m].r]$
30: $v \leftarrow PtrB[m].f$
```

As the proposed data structure maintains the sorted frequency array, it can be utilized to calculate the object with the minimum frequency (maybe a negative number) as well. We just need to replace Step 29 and 30 in Algorithm 1 with the following steps.

```
29a: $M \leftarrow TtoF[PtrB[1].l \ldots PtrB[1].r]$
30a: $v \leftarrow PtrB[1].f$
```

We can observe that the time complexity of the S-Profile algorithm is $O(1)$, as there is no iteration at all. The space complexity is $O(m)$, where m is the maximum number of objects in the log stream. Precisely, it needs $3m$ integers to store the pointer arrays and an additional storage for B. In the worst case B includes m blocks, but usually this number is much smaller than m.

Other queries on statistics of objects can also be answered. For example, the top-K order element is that whose frequency is the K-th largest. We can just use $PtrB[m - K + 1]$ to locate the block. Then, the frequency and object id can be obtained with block's member and the $TtoF$ array. Especially, the median in frequency can be located with the K/2-th element of the $PtrB$ array.

2.3 Possible Applications

For some mission-critical tasks (e.g., fraud detection) in big graphs, the efficiency to make decisions and infer interesting patterns is crucial. As a result, recent years have witnessed an increasing interest in heuristic "shaving" algorithms with low computational complexity [9, 14]. A critical step of them is to keep finding low-degree nodes at every time of shaving nodes from a graph. Thus, S-Profile can be plugged into such algorithms for further speedup, by treating a node as an object and its degree as frequency.

Furthermore, S-Profile can also deal with a sliding window on a log stream, by letting every tuple (x_i, c_i) outdated from the window be a new incoming tuple $(x_i, \bar{c}_i)$, where $\bar{c}_i$ is the opposite action of c_i.

3 EXPERIMENTAL RESULTS

We have implemented the proposed S-Profile algorithm and its counterparts in C++, and tested them with randomly generated log streams. The streams are produced with the following steps. We first randomly generate an "add" or "remove" action, with 70% and 30% probabilities respectively. Then, for each "add" action we randomly choose an object id according to a probability distribution (called *posPDF*). For each "remove" action another distribution (called *negPDF*) is used to randomly choose an object id. With this procedure, we obtained three test log streams:

- Stream1: both *posPDF* and *negPDF* are uniform random distribution on $[1, m]$.
- Stream2: both *posPDF* and *negPDF* are normal distributions with $\mu = 2m/3, m/3$ and $\sigma = m/6, m/6$, respectively.
- Stream3: *posPDF* is a normal distribution ($\mu = 4m/5$, $\sigma = m$), while *negPDF* is a lognormal distribution ($\mu = 3m/5$, $\sigma = m$).

In the following subsections, we first compare the proposed S-Profile with the heap based approach, for updating the mode and frequency. Then, the comparison with the balanced tree is presented for calculating the median. All experiments are carried out on a Linux machine with Intel Xeon E5-2630 CPUs (2.30 GHz). The CPU time (in second) of different algorithms are reported.

3.1 Comparison with the Heap

Heap is a kind of binary tree where the value in parent node must be larger or equal to the values in its children. Used to maintain the sorted frequency array, it is easy to obtain the mode (the root has the largest frequency). Notice that the balanced tree is inferior to the heap for calculating the mode.

In the experiment, a log stream is the input and the tested algorithm calculates the mode every time a tuple arrives. In Figure 3, we show the CPU times consumed by the heap based method and our S-Profile for the three log streams with varied length. The x-axis means the number of processed tuples (n). From the

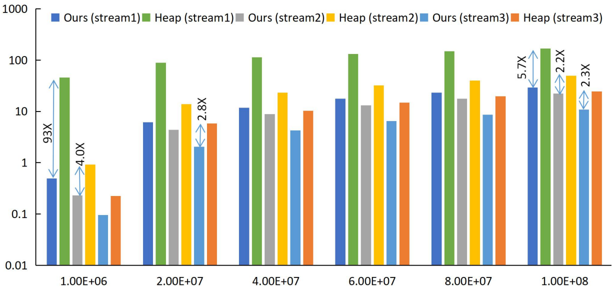

Figure 3: CPU times (in second) of the heap based method and our method for calculating the mode for n times ($m = 10^8$).

results we see that our method is at least 2.2X faster than the heap based method. Another experiment is carried out with fixed $n = 10^8$ and varied m. The results shown in Figure 4 also reveal that our S-Profile is at least 2X faster.

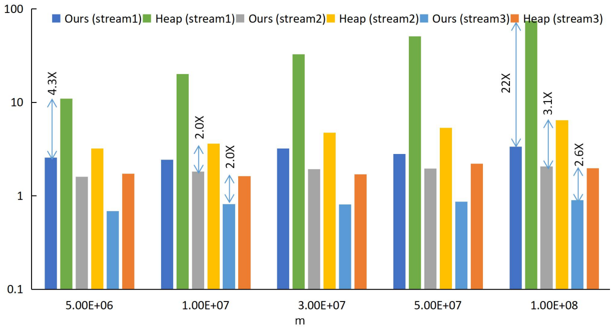

Figure 4: CPU times (in second) of the heap based method and our method for calculating the mode for $n = 10^8$ times.

For different kinds of log streams, the performance of the heap based method varies a lot. For the worst case updating the heap needs $O(\log m)$ time, despite this rarely happens in our tested streams. On the contrary, S-Profile needs $O(1)$ time for updating the data structure. This advantage is validated by the rather flat trend shown in Figure 5.

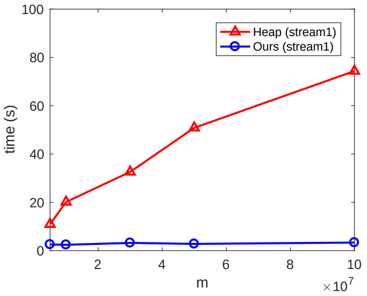

Figure 5: The trends of CPU time for varied m ($n = 10^8$).

It should be emphasized that, in addition to the speedup to the heap based method, our S-Profile possesses the advantage of wider applicability. Our method is not restricted to calculating the mode and corresponding frequency. As it well profiles the sorted frequency array, with it answering the queries on top-K and other statistics of objects is trivial and fast.

3.2 Comparison with the Balanced Tree

The proposed S-Profile can also calculate the median of the dynamic array. We compare it with the balanced tree based method implemented in the GNU C++ PBDS [16], which is more efficient than our implementation of balanced tree. The trends of CPU time are shown in Figure 6. They show that the runtime of the proposed S-Profile increases much less than that of the balanced tree based method when m increases. We can observe that the time of S-Profile is linearly depends on n, the number of modifications on array A, and hardly varies with different m. On the contrary, the balanced tree based method exhibits superlinear increase whether with n or m. Overall, the test results show that S-Profile is from 13X to 452X faster than the balanced tree based method on updating the median of a dynamic array.

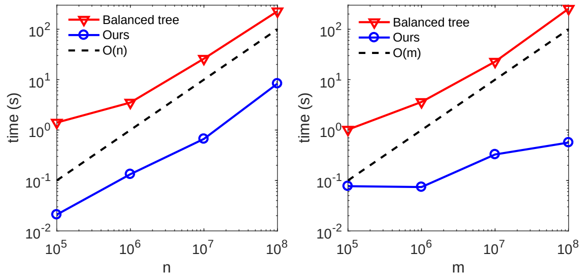

Figure 6: Comparison of the balanced tree based method and our method for calculating the median. Left: CPU time vs. n ($m = 10^6$). Right: CPU time vs. m ($n = 10^6$).

4 CONCLUSIONS

We propose an accurate algorithm, S-Profile, to fast keep profiling the dynamic array from online systems. It has the following advantages:

- **Optimal efficiency:** S-Profile needs $O(1)$ time complexity for every updating of a dynamic array, and totally linear complexity in memory.
- **Querying Statistics:** With profiling, at any time we can answer the statistical queries in a trivial and fast way.
- **Applicable:** S-Profile can be plugged into most of log streams, and heuristic graph mining algorithms.

Publishing Differentially Private Datasets via Stable Microaggregation

Masooma Iftikhar, Qing Wang, Yu Lin
Australian National University, Canberra, Australia
{masooma.iftikhar,qing.wang,yu.lin}@anu.edu.au

ABSTRACT

In recent years, differential privacy has emerged as one formal notion of privacy. Data release based on differential privacy can help researchers to perform statistical analysis on sensitive data of individuals. To publish differentially private datasets, there is a need for preserving data utility, along with data privacy. However, the utility of differentially private datasets is often limited, due to the amount of noise being added to the results of queries. In this paper, we address this issue by proposing a microaggregation-based framework that incorporates microaggregation and differential privacy into the data publishing process. We formulate a new notion of *stable microaggregation* to characterize a desired property of microaggregation and further develop a simple yet effective *stable microaggregation algorithm*. We experimentally verify the utility reduction of our proposed framework on real-world datasets. The experiments show that the proposed framework outperforms the state-of-the-art methods by providing better with-in cluster homogeneity and also reducing noise added into differentially private datasets significantly.

1 INTRODUCTION

Publishing data about individuals often poses a privacy threat because data may contain the sensitive information about individuals, e.g., medical history, and publishing them would intrude upon individual privacy. Thus, to preserve data privacy of individuals, various anonymization techniques have been proposed for data publishing, such as k-anonymity and its extensions [10]. Particularly, with the emerging of differential privacy in recent years [3, 5], a number of works have considered to release differentially private datasets [6, 11]. Such differentially private datasets can guarantee differential privacy controlled by a privacy parameter ε in a robust statistical way.

Broadly speaking, there are two common methods used for generating ε-differentially private datasets in the literature: one is based on differential privacy compliant histograms [11] and the other is based on record perturbation [9]. Histogram-based approaches have some limitations, including: being limited to histogram queries and the exponential growth of the number of histogram bins with the number of attributes [8]. On the other hand, record perturbation based approaches require a large amount of noise being added into the results of queries [9], though these approaches are not limited to histogram queries and allow dealing with any type of attributes.

Nevertheless, when generating differentially private datasets, there always is a trade-off being made between privacy and utility of published data. Ideally, we want to preserve the privacy of individuals while still maintaining the usefulness of data for performing statistical analysis. The utility of ε-differentially private datasets is however limited due to the amount of noise being added to guarantee differential privacy. To enhance the utility of ε-differentially private datasets, in [9] a microaggregation-based mechanism, i.e., *insensitive microaggregation*, has been proposed. It uses microaggregation to achieve k-anonymity in which a certain correspondence between clusters in the microaggregated datasets of two neighboring datasets is imposed. In doing so, the noise added to guarantee differential privacy can be greatly reduced. However, insensitive microaggregation still has the limitations: (1) it yields worse within-cluster homogeneity due to a total order relation required for the distance function [9], and (2) the minimum cluster size k grows with the size n of the dataset and one thus needs $k \geq \sqrt{n}$ to reduce noise.

Contributions. In this paper, we consider the problem of generating ε-differentially private datasets by incorporating microaggregation into the data publishing process. Our work makes the following contributions:

- We present a microaggregation-based framework for generating ε-differentially private datasets and formulate a novel notion of *stable microaggregation* to characterize the correspondence of clusters in microaggregated datasets.
- We propose a stable microaggregation algorithm that can ensure the correspondence of clusters in the microaggregated datasets of two neighboring datasets.
- We experimentally verify the utility reduction of our proposed framework on two real-world datasets containing numerical data. It shows that our algorithm can effectively enhance the utility of released data by providing better within-cluster homogeneity and reducing the amount of noise, in comparison with the state-of-the-art methods.

Related work. Among early works on data anonymization, k-anonymity [10] is a privacy model widely applied to guarantee data privacy of individuals. The popularity of k-anonymity has led to various attempts to address the limitations of k-anonymity [10]. On the other hand, differential privacy [3, 5] is a recent privacy notion that allows statistical analysis of sensitive data while providing strong privacy guarantees. A number of works [8, 9] have combined k-anonymity and differential privacy to enhance the utility of data release. One of these works used microaggregation to achieve k-anonymity, which can reduce the amount of noise added to differentially private datasets [2]. Microaggregation [1] is a family of anonymization algorithms that group similar (homogeneous) records into clusters, then replace each record with its cluster representative. MDAV [2] is the most widely used microaggregation algorithm. The target of a microaggregation algorithm is to yield minimum information loss by maximizing with-in cluster homogeneity. However, the existing works, including MDAV [2] and insensitive microaggregation [9], either produce a low degree of with-in cluster homogeneity or fail to reduce the amount of noise independent of the size of a dataset. Our work in this paper can alleviate both issues.

10.5441/002/edbt.2019.81

2 PROBLEM FORMULATION

Let $\mathcal{D}$ be a class of possible datasets. A dataset $X \in \mathcal{D}$ consists of a set of records, each $r_i \in X$ being associated with a set of attributes A. Each individual has only one record in a dataset X.

Definition 2.1. (*Neighboring datasets*) Two datasets $X, Y \in \mathcal{D}$ are said to be *neighboring*, denoted as $X \sim Y$, if $|X| = |Y| = n$, but X and Y differ in one record.

Given a dataset X, we want to generate X_ε (an anonymized version of X) that can provide ε-differential privacy guarantee for protecting the privacy of individuals' records in X.

Definition 2.2. (*Differentially private datasets*) A randomized mechanism $\mathcal{K} : \mathcal{D} \to \mathcal{D}$ provides ε-differentially private datasets, if for each pair of neighboring datasets $X \sim Y$, and all possible outputs $\mathcal{D}_\varepsilon \subseteq range(\mathcal{K})$, it holds

$$Pr[\mathcal{K}(X) \in \mathcal{D}_\varepsilon] \leq e^\varepsilon \times Pr[\mathcal{K}(Y) \in \mathcal{D}_\varepsilon] \qquad (1)$$

where $\varepsilon > 0$ is the differential privacy parameter. Smaller values of ε provide stronger privacy guarantees [4].

ε-differential privacy [3] was originally proposed as a privacy model to protect the responses of interactive queries to a dataset. A query is a function f that extracts data against records in the dataset. A standard way for achieving ε-differential privacy is by adding random noise to the true response of f, and the random noise is calibrated according to the *sensitivity* (Δ) of f, e.g. L_1-sensitivity [5]. For numerical data, the addition of noise can be drawn from a Laplace distribution by first computing the answer $f(X)$ and then generating the noisy answer $f(X) = f(X) + Lap(\Delta(f)/\epsilon)$ to provide ε-differential privacy. Although ε-differential privacy was not initially adapted for the purpose of generating anonymized datasets, but later in [7, 8] differentially private datasets were generated by considering data publishing as the answers to subsequent queries for each record in the dataset.

The L_1-sensitivity of f measures the maximum variation in the query f between two neighboring datasets $X \sim Y$ as follows.

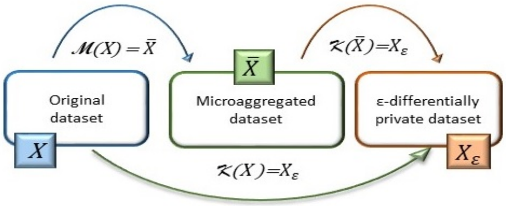
Definition 2.3. (L_1-*sensitivity*) The L_1-sensitivity of a query $f : \mathcal{D} \to \mathbb{R}^d$ is the smallest number $\Delta(f)$ such that for all neighboring datasets $X \sim Y \in \mathcal{D}$

$$\|f(X) - f(Y)\|_1 \leq \Delta(f), \qquad (2)$$

where $\|.\|_1$ denotes the L_1-norm.

Given a dataset X, a microaggregated dataset $\overline{X}$ is created by a microaggregation algorithm $\mathcal{M}$ in two stages. First, X is partitioned into a set of clusters C_X, such that each cluster in C_X has at least k records, where k is a preset constant value, and the records within each cluster are as similar as possible (homogeneous). Second, it aggregates each cluster in C_X by replacing each record with the representative record of the cluster.

In this paper, we aim to generate ε-differentially private datasets by using microaggregation for improving data utility. As illustrated in Figure 1, a microaggregated dataset $\overline{X}$ resulting from running $\mathcal{M}$ over X is added between X and X_ε to increase utility of X_ε. In doing so, the original query f is approximated by $f \circ \mathcal{M}$, since f is run on the microaggregated dataset $\overline{X}$ rather than the original dataset X. This thus introduces two kinds of errors: one is the random noise, which depends on the sensitivity $\Delta(f)$ of query f to guarantee ε-differential privacy, and the other one is due to computing f over $\overline{X}$ instead of X. As will be discussed in Section 4, the first kind of error is much larger than the second kind of error in terms of the information loss in ε-differentially private datasets. To increase the overall utility, the key challenge is how to reduce $\Delta(f \circ \mathcal{M})$ such that $\Delta(f \circ \mathcal{M}) \leq \Delta(f)$.



$\mathcal{M}(X) = \bar{X}$
$\mathcal{K}(\bar{X}) = X_\varepsilon$

3 PROPOSED FRAMEWORK

In this section we present the details of the proposed framework.

3.1 Stable Microaggregation

Given $X \sim Y$ that only differ in a single record, their microaggregated datasets $\overline{X}$ and $\overline{Y}$ however may generate considerably different clusters, leading to a much larger $\Delta(f \circ \mathcal{M})$ than $\Delta(f)$. Suppose that we modify a record x in X to x' in Y, i.e., $X \sim Y$. As depicted in Figure 2, a microaggregation algorithm $\mathcal{M}$ (e.g. MDAV [2]) with $k = 4$ can generate C_X and C_Y over X and Y, respectively. Although X and Y only differ in one record, the clusters in C_X and C_Y are completely unrelated. The maximum variation between one cluster from C_X and another unrelated cluster from C_Y is $\Delta(f)$. Since there are n/k clusters in C_X and C_Y, $\Delta(f \circ \mathcal{M}) = n/k \times \Delta(f)$, which can be significantly higher than $\Delta(f)$ when the datasets are large, i.e., n is large.

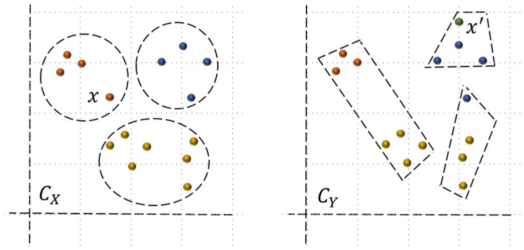

Figure 2: Clusters C_X and C_Y generated by $\mathcal{M}$ over $X \sim Y$.

To address the above issue, the notion of *insensitive* microaggregation was proposed [9]. A microaggregation algorithm $\mathcal{M}$ is said to be *insensitive* if, for every pair of neighboring datasets $X \sim Y$, there is a bijection between C_X and C_Y such that each pair of corresponding clusters differs at most in a single record. This implies that the maximum variation between each pair of corresponding clusters is reduced to $1/k \times \Delta(f)$. Since there are still n/k clusters, $\Delta(f \circ \mathcal{M})$ is $n/k \times \Delta(f)/k$. As a result, insensitive microaggregation may greatly reduce sensitivity as compared with $n/k \times \Delta(f)$ for standard microaggregation.

However, insensitive microaggregation still has some limitations. First, to achieve $\Delta(f \circ \mathcal{M}) \leq \Delta(f)$ as desired, $(n/k \times \Delta(f)/k) \leq \Delta(f)$ must hold. Therefore, one needs $k \geq \sqrt{n}$ in order to reduce added noise in comparison with directly applying $\mathcal{K}$ over X [8]. For large datasets, k thus needs to be large enough for reduced sensitivity. Second, as noted in the work [8] and will also be discussed in Section 4, the clusters generated by insensitive microaggregation are often less homogeneous than the clusters generated by standard microaggregation, such as MDAV [2]. This is because, to ensure the insensitive property, the distance function used by insensitive microaggregation algorithms must be consistent with the total order relation $\leq_X$ [9]. To alleviate these limitations, we define the notion of *stable* microaggregation.

Definition 3.1. (*Stable microaggregation*) Let $\mathcal{M}$ be a microaggregation algorithm, $C_X = \{c_1, ..., c_n\}$ be the set of clusters that results from running $\mathcal{M}$ on X, and $C_Y = \{c'_1, ..., c'_n\}$ be the set of clusters that results from running $\mathcal{M}$ on Y. $\mathcal{M}$ is *stable* if, for every pair of neighboring datasets $X \sim Y$, there is a bijection between C_X and C_Y such that at most two pairs of corresponding clusters in C_X and C_Y differ in a single record.

Since stable microaggregation affects at most two pairs of corresponding clusters in C_X and C_Y, $\Delta(f \circ \mathcal{M})$ is further reduced to $(2 \times \Delta(f)/k)$ as compared to $(n/k \times \Delta(f)/k)$ for insensitive microaggregation. Thus, when $k \geq 2$, the addition of noise can always be reduced in comparison with directly applying $\mathcal{K}$ over X, regardless of the size of a dataset.

Algorithm 1: *Stable Microaggregation Algorithm*

```
Input: $X \sim Y$ where $r := X - Y$ and $r' := Y - X$

Output: $\overline{X}, \overline{Y}$
1  $C_X \leftarrow \{c_1, ..., c_n\}$ generated by $\mathcal{M}_p$ over $X$
2  $C_Y \leftarrow replace(C_X, r, r')$
3  $D, L := \phi$
4  foreach $c_i \in C_X$ do
5      $D := D \cup \{(dist(r', r_{c_i}), c_i)\}$
6  $d_{min}, c_{min} \leftarrow \mathcal{F}_{min}(D)$
7  if $r' \in c_{min}$ then
8      $\overline{Y} \leftarrow \mathcal{M}_a(C_Y)$
9  else
10     $c_i := c(r')$
11     $D := D - \{(\mathcal{G}_{dist}(D, c_i), c_i)\}$
12     foreach $c_j \in C_X \setminus \{c_i\}$ do
13         $d_j \leftarrow \mathcal{G}_{dist}(D, c_j)$
14         $D := D - \{(d_j, c_j)\} \cup \{(dist(r_{c_i}, r_{c_j}) + d_j, c_j)\}$
15     $d_{min}, c_{min} \leftarrow \mathcal{F}_{min}(D)$
16     foreach $r_i \in c_{min}$ do
17         $swap(C_Y, r', r_i)$
18         $\overline{Y}_i \leftarrow \mathcal{M}_a(C_Y)$
19         $L := L \cup \{(\mathcal{I}_{loss}(Y_i, \overline{Y}_i), \overline{Y}_i)\}$
20     $\overline{Y} \leftarrow \mathcal{F}_{min}(L)$
21 $\overline{X} \leftarrow \mathcal{M}_a(C_X)$
22 Return $\overline{X}, \overline{Y}$
```

3.2 Algorithm Description

Our proposed *stable microaggregation algorithm* is described in Algorithm 1. Given $X \sim Y$, we start with partitioning the dataset X into C_X by $\mathcal{M}_p$, i.e., the partition function of a microaggregation algorithm $\mathcal{M}$. Then we replace the record $r \in C_X$ with r' and initialize D and L (Lines 1-3). For each cluster $c_i \in C_X$, by means of function *dist*(), we compute distance between r' and r_{c_i}, where r_{c_i} is the representative record of c_i. Then, we compute d_{min}, i.e., the minimum distance in D, and c_{min}, i.e., the cluster in C_X with d_{min}, by means of $\mathcal{F}_{min}$ function (Lines 4-6). If r' is in the cluster c_{min} of C_Y, then we aggregate C_Y by $\mathcal{M}_a$ that is the aggregation function of the microaggregation algorithm $\mathcal{M}$ (Lines 7-8). In this case, only one pair of corresponding clusters in C_X and C_Y is affected. Otherwise, for each cluster $c_j \in C_X \setminus \{c_i\}$ where $r' \in c_i$, we compute the distance between the representative records of clusters c_i and c_j, i.e., r_{c_i} and r_{c_j}. We proceed with updating D by summing up both distances of the corresponding clusters, excluding the distance of c_i obtained by function $\mathcal{G}_{dist}$ (Lines 10-14). In order to get the cluster c_j that is of the minimum distance from c_i, we find d_{min}, i.e., the minimum distance, and c_{min}, i.e., the cluster $c_j \in C_X$ with d_{min} from D, by means of $\mathcal{F}_{min}$ function. After that, we swap r' in c_i of C_Y with each record r_i in c_{min} of C_Y, and compute C_Y with the minimum information loss by function $\mathcal{I}_{loss}$ (Lines 15-20). In this case, at most two pairs of clusters differ at most in a single record. The algorithm terminates by returning the microaggregated datasets $\overline{X}$ and $\overline{Y}$ that have the minimum information loss.

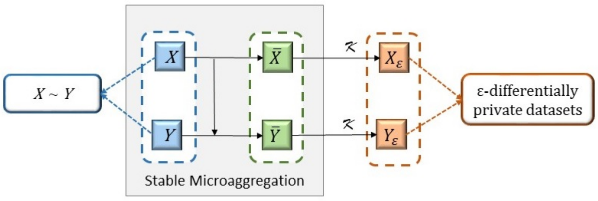

Figure 3: Proposed framework to generate ε-differentially private datasets via stable microaggregation.

A high-level description of our proposed framework is presented in Figure 3, in which stable microaggregation is applied to generate $\overline{X}$ and $\overline{Y}$ by running *Algorithm 1* over $X \sim Y$. Then ε-differentially private datasets X_ε and Y_ε are generated by applying $\mathcal{K}$ over $\overline{X}$ and $\overline{Y}$, respectively.

4 EXPERIMENTS

We evaluated the proposed framework to study how stable microaggregation enhances the utility of differentially private datasets.

Datasets. We used two datasets in the experiments: (1) CENSUS dataset[1] contains 1,080 records [2, 8, 9]. As in [9] we took 4 numerical attributes FEDTAX (Federal income tax liability), FICA (Social security retirement payroll deduction), INTVAL (Amount of interest income) and POTHVAL (Total other persons income). (2) EIA dataset[1] contains 4,092 records [1]. We took 4 numerical attributes attributes RESREVENUE (Revenue from sales to residential consumers), RESSALES (Sales to residential consumers), TOTREVENUE (Revenue from sales to all consumers), and TOTSALES (sales to all consumers).

Following [9], we consider the sensitivity of an attribute to be the difference between the lower bound (i.e. 0) and upper bound (1.5 × the maximum value) of the attribute. For both CENSUS and EIA datasets, the value of k is set to between 2 and 100.

Evaluation measure. We used the measure $IL1s$ [12] to compute the *information loss* between the original and differentially private datasets. Formally, for each record r_i,

$$IL1s = \frac{1}{|A| \cdot n} \sum_{i=1}^{n} \sum_{j=0}^{|A|} \frac{|x_{ij} - x'_{ij}|}{\sqrt{2} S_j} \tag{3}$$

where $|A|$ is the number of attributes, n is the number of records in the dataset, x_{ij} is the value of attribute $a_j \in A$ for record r_i in the original dataset, x'_{ij} is the value of attribute $a_j \in A$ for record

[1] http://neon.vb.cbs.nl/casc/CASCtestsets.htm

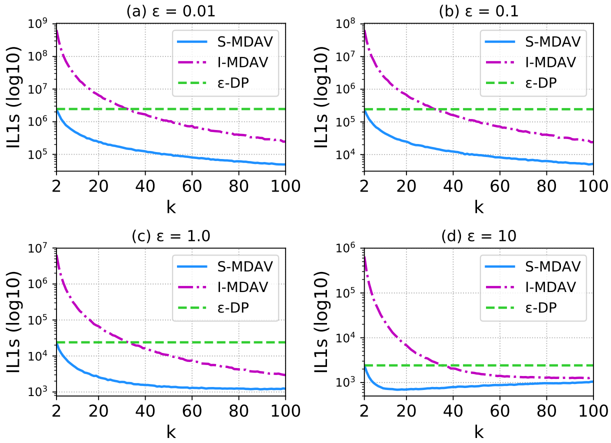

Figure 5: Evolution of $IL1s$ using S-MDAV, I-MDAV and ε-DP for different values of k and ε in CENSUS.

r_i in the corresponding differentially private dataset, and S_j is the standard deviation of attribute $a_j \in A$ in the original dataset.

Baseline Methods. We considered the following baseline methods: (1) MDAV, which is a standard microaggregation algorithm [2], (2) I-MDAV, which is an insensitive microaggregation algorithm proposed in [9], and (3) ε-DP, which is a standard ε-differential privacy algorithm in which noise is added using the Laplace mechanism [5]. We use S-MDAV to refer to our proposed stable microaggregation algorithm, which extends MDAV in partitioning and aggregation.

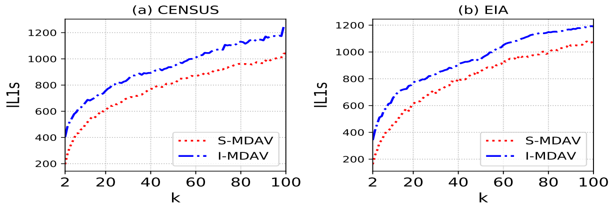

Figure 4: Evolution of $IL1s$ using MDAV and I-MDAV for different values of k: (a) CENSUS and (b) EIA.

Experimental results. We first conducted experiments to compare the information loss of microaggregated datasets that are generated by MDAV and I-MDAV under varying k between 2 to 100. The results are shown in Figure 4. We observe that, for both CENSUS and EIA datasets, the information loss of microaggregated datasets is less with MDAV as compared to I-MDAV. This is because the clusters generated by MDAV are more homogeneous than the clusters generated by I-MDAV. As we used MDAV in our algorithm S-MDAV to generate the clusters in C_X as well as most of the clusters in C_Y, S-MDAV decreases the sensitivity of $f \circ \mathcal{M}$ and thus reduces the errors caused by microaggregation.

Then, to verify the overall utility of ε-differentially private datasets, we conducted experiments to compare the information loss between the original and ε-differentially private datasets generated by using our algorithm S-MDAV and the baseline methods I-MDAV and ε-DP. Figures 5 and 6 present our experimental results. For ε-DP, we used the following privacy parameters $\varepsilon = [0.01, 0.1, 1.0, 10.0]$, which cover the range of differential privacy levels widely used in the literature [4, 7, 8]. For each parameter setting of ε, we ran 3 times and take the average result. The information loss for ε-DP is displayed as horizontal lines, as ε-DP does not depend on k.

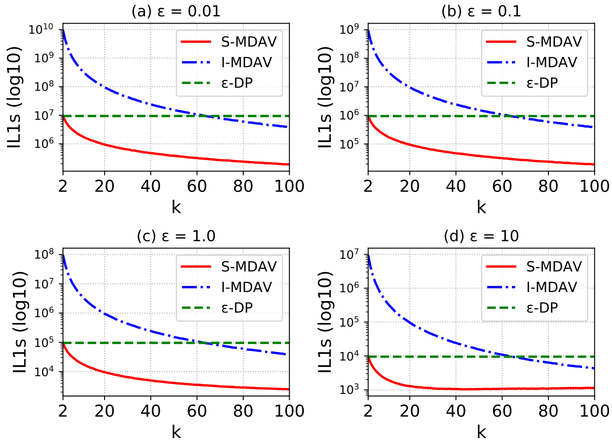

Figure 6: Evolution of $IL1s$ using S-MDAV, I-MDAV and ε-DP for different values of k and ε in EIA.

Regarding the evolution of $IL1s$ values shown in Figures 5 and 6, we can see that, for every value of ε, I-MDAV is only able to achieve $\Delta(f \circ \mathcal{M}) \leq \Delta(f)$ if $k \geq \sqrt{n}$, i.e., ($k = \sqrt{1,080} \approx 33$ for CENSUS and $k = \sqrt{4,092} \approx 64$ for EIA). This is consistent with the previous discussion in Section 3. Nonetheless, this also means that for large datasets I-MDAV requires k to be enough large in order to effectively reduce $\Delta(f \circ \mathcal{M})$, i.e., the size of k grows with the size of a dataset n. In contrast, for S-MDAV, as stated in Section 3, one needs $k \geq 2$ to reduce $\Delta(f \circ \mathcal{M})$ as compared to ε-DP. As the experiments show that our proposed algorithm S-MDAV leads to less information loss for every value of ε as compared to I-MDAV and ε-DP in both CENSUS and EIA datasets. This is because the sensitivity $\Delta(f \circ \mathcal{M})$ is significantly reduced when S-MDAV is used for microaggregation.

We have also noticed that by approximating a query f to $f \circ \mathcal{M}$ via microaggregation, the errors caused by random noise that depends on the sensitivity of $f \circ \mathcal{M}$ dominate the impact on the utility of differentially private datasets generated via microaggregation, compared to the errors existing between the original and microaggregated datasets.

ABSTRACT

Privacy is a major concern in cloud computing since clouds are considered as untrusted environments. In this study, we address the problem of privacy-preserving range query processing on clouds. Several solutions have been proposed in this line of work, however, they become inefficient or impractical for many monitoring applications, including real-time monitoring and predicting the spatial spread of seasonal epidemics (e.g., H1N1 influenza). In this case, a system often confronts a high rate of incoming data. Prior schemes may thus suffer from potential performance issues, e.g., overload or bottleneck. In this paper, we introduce an extension of PINED-RQ to address these limitations. We also demonstrate experimentally that our solution outperforms PINED-RQ.

1 INTRODUCTION

Reducing the impact of seasonal epidemics (e.g., H1N1 influenza) is demanding for public health officials. Early detection of spatial spread of the epidemics could help alleviate severe consequences. It is thus important to track and predict the spread of such diseases in the population. To do that, an individual can interact with a website or mobile application to report personal data (e.g., age, phone, sex, symptoms, travel plan, social network user name, ...), to be utilized for real-time predicting analyses. Systems usually run in very short periods, a few days or weeks after an epidemic emerges. Due to the need of significant computing capacity and the high speed of incoming data, it is desirable to use cloud services for managing and exploiting submitted data. However, cloud computing suffers from privacy issues, e.g., sensitive information can be exploited by cloud's administrators.

Encrypting outsourced data is a common solution to handle privacy issues in clouds. In this study, we focus on range queries over encrypted data since it is a fundamental operation. Over the last years, different approaches have attempted to strike a trade-off between security and practical efficiency [2, 10, 11]. Index-based schemes [5, 13, 15] have also been proposed to increase query performance while ensuring strong security. Nevertheless, prior schemes cannot cope with the high rate of incoming data that occurs in a wide range of monitoring applications, especially in the proposed context.

To solve the drawback of existing works, we propose a solution based on PINED-RQ [15] that enables the building of a secure index over sensitive data at a trusted component (hereinafter referred to as a collector). The collector then publishes the secure index and the encrypted data to the cloud for serving range queries. Our choice is motivated by the fact that PINED-RQ offers strong privacy protection while it has significantly faster range query processing and requires less storage space, compared to its counterparts [5, 13]. Nonetheless, PINED-RQ has to publish data in batches and partially processes data at the collector. Consequently, a bottleneck may occur as incoming data and query requests arrive at a high rate. Moreover, since PINED-RQ partially evaluates queries at the collector, which often has limited resources, they may also confront scalability problems. Publishing small batches may help PINED-RQ ease those potential problems, however, because it is built upon differential privacy [6, 8], small batches would cause large aggregation noise, destroying index's utilities.

Therefore, in order to adapt PINED-RQ to the targeted context, we aim to shift heavy workload from the collector to the cloud, that is able to provide on-demand capacity. In particular, instead of publishing data in batches, when a new tuple arrives, the collector immediately sends it to the cloud. The challenge to our approach is how to build PINED-RQ's index for the new tuples that are previously moved to the untrusted cloud.

In this paper, we propose PINED-RQ++, an extension of PINED-RQ, to mainly prevent potential bottlenecks at the collector while ensuring a secure index for new data. The key idea behind our prototype is to reverse the process of constructing PINED-RQ's index. This allows the sending of new data to the cloud as soon as possible without sacrificing privacy. The experimental results give promising performance, e.g., the publishing time of the NASA dataset (~0.5M tuples) [1] is reduced up to ~35x while maximum data rate at the collector experiences a reduction of up to ~2.7x. In particular, our solution eliminates query processing at the collector, making the system more scalable. The contributions of this paper are as follows.

(1) We introduce a notion of index template within PINED-RQ to support frequently published data.
(2) We propose a mechanism, PINED-RQ++, for updating the index template while still retaining privacy protection for frequently published data comparable to PINED-RQ.
(3) We also develop a parallel version of PINED-RQ++ to improve the throughput of the system.
(4) We implement (non-)parallel PINED-RQ++ to show the superiority of our solutions compared with PINED-RQ.

The paper is structured as follows. In Section 2, we briefly review background. We then introduce our solution in Section 3. In Section 4, we present our experimental results before giving conclusion and future work in Section 5.

2 BACKGROUND

2.1 Related Work

Various schemes have been developed to preserve privacy for processing range queries in clouds over the last years. Hidden vector encryption approaches [4, 16] use asymmetric cryptography to conceal data's attributes in an encrypted vector. These

10.5441/002/edbt.2019.82

methods incur prohibitive computation costs. Many bucketization schemes [9–11] have been proposed for range query processing in clouds. These solutions partition an attribute domain into a finite number of buckets. The range query retrieves all data falling within the range. However, bucketing approaches disclose data distribution and suffer from large aggregation false positives. Agrawal *et al.* [2] and Boldyreva *et al.* [3] present order-preserving encryption schemes that preserve the relative order of plain data under encryption. A downside of these schemes is that they leak the total order of plain data to the cloud. This is vulnerable to statistical attacks. Meanwhile, Li *et al.* [13] and Demertzis *et al.* [5] propose index-based strategies for answering range queries over outsourced data. Unfortunately, both suffer from prohibitive storage cost. On the other hand, Sahin *et al.* [15] present PINED-RQ for serving efficient range query processing in clouds via secure indexes. Nonetheless, the high rate of new data is not discussed in this work. Based on PINED-RQ, we develop our solution to tackle the limitations of the current works.

2.2 Differential Privacy

Definition 1 (ϵ-differential privacy [6, 8]): A randomised mechanism M satisfies ϵ-differential privacy, if for any set $O \in Range(M)$, and any datasets D and D' that differ in at most one tuple,

$$Pr[M(D) = O] \leq e^{\epsilon}.Pr[M(D') = O]$$

where ϵ represents the privacy level the mechanism offers.

Laplace Mechanism [7]: Let D and D' be two datasets such that D' is obtained from D by adding or removing one tuple. Let $Lap(\beta)$ be a random variable that has a Laplace distribution with the probability density function $pdf(x, \beta) = \frac{1}{2\beta}e^{-|x|/\beta}$. Let f be a real-valued function, the Laplace mechanism adds $Lap(max \parallel f(D) - f(D') \parallel_1 / \epsilon)$ to the output of f, where $\epsilon > 0$.

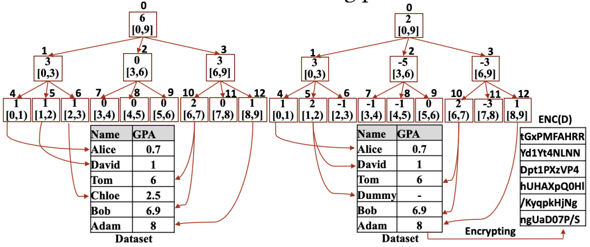
Theorem 1 (Sequential Composition [14]): Let $M_1, M_2, ..., M_r$ denote a set of mechanisms and each M_i gives ϵ_i-differential privacy. Let M be another mechanism executing $M_1(D), M_2(D), ..., M_r(D)$. Then, M satisfies $(\sum_{i=1}^{r} \epsilon_i)$-differential privacy.

2.3 PINED-RQ

We briefly describe PINED-RQ [15], which is built upon differential privacy [6]. We only focus on the insertion operation in this study. There are two main steps for building a PINED-RQ index.

(a) Building an index: Given a dataset at the collector, a PINED-RQ's index is constructed based on a B+Tree. In PINED-RQ, the set of all nodes is defined as a histogram covering the domain of an indexed attribute. For example, the students' GPA is used to build histograms (see Figure 1a). Each leaf node has a count representing the number of tuples falling within its interval. It also keeps pointers to those tuples. Likewise, the root and any internal node have a range and a count, combining the intervals and the counts of their children, respectively.

(b) Perturbing an index: All counts in the index are independently perturbed by Laplace noise [7]. The noise may be positive or negative, thus, after this step, the count of a node may increase or decrease, respectively. As shown in Figure 1b, the count of node 6 changes from 1 to -1 while the count of node 5 changes from 1 to 2. Such changes consequently lead to inconsistencies between a leaf node's noisy count and the number of pointers it holds. To address that issue, PINED-RQ adds dummy tuples (fake tuples) to the dataset as a leaf node receives positive noise. Otherwise, if a leaf node receives negative noise, real tuples are moved from the dataset to the corresponding overflow array. An overflow array [15] of a leaf node is a fixed-size array, which is randomly filled with dummy tuples at the publishing time to conceal removed tuples from the adversary. As illustrated in Figure 1b, the tuple (Chloe) belonging to node 6 is deleted from dataset while one dummy tuple is added and linked to node 5. Finally, the perturbed index is sent to the cloud along with the encrypted dataset. Notably, PINED-RQ satisfies $(\epsilon, \delta)_n$-Probabilistic-SIM-CDP privacy model [15], a variant of differential privacy [8]. Intuitively, this variant results from the introduction of the encryption and the overflow arrays to the index building process.



(a) Clear index **(b) Secure index**

Figure 1: Example of PINED-RQ index

Clearly, an update directly to such published indexes would violate differential privacy [6, 8], thus, PINED-RQ cannot support live updates. Furthermore, PINED-RQ is also reluctant to publish very small datasets since the aggregation noise would destroy index's utilities. These properties make PINED-RQ impractical for high speed monitoring applications. In contrast, our proposal aims to send new data immediately to the cloud. Thus, one technical challenge is how to manage such dummy and removed tuples, which help protect the privacy of the index, as new data are stored at the cloud instead of at the collector.

3 PINED-RQ++

We focus on the architecture as depicted in Figure 2. Data generators produce raw data and send them to a collector. The incoming data are then pre-processed prior to being sent to a cloud. A consumer poses range queries to the cloud. In PINED-RQ++, we assume that the cloud is *honest-but-curious* while the other components are trusted. Thus, the adversary can use all information exchanged between the cloud and the other trusted components to deduce anything in a computationally-feasible way.

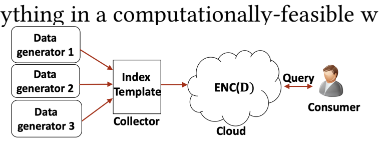


Figure 2: Proposed architecture

At the beginning, an index template is built at the collector. Whenever a new tuple arrives, the index template is updated with that tuple. Next, the tuple is encrypted and forwarded to the cloud. When the index template is published at a later time, the cloud associates it with unindexed data to produce a secure index as described in Section 2.3. The collector then initiates a new index template for future incoming data.

A query is only processed at the cloud which holds both indexed and unindexed data at time. As a result, as a consumer issues a query, it is first evaluated on indexed data (as in PINED-RQ's query processing [15]), the result of this evaluation and all the unindexed data are returned to the consumer. Finally, the consumer decrypts and filters the returned data for the final results.

3.1 Index Template

The process of building an index template is typically the same as in PINED-RQ (see Section 2.3). However, since initially there are no data, its count variables only contain Laplace noise [7] and its leaves have no pointers. Such count variables and pointers are updated during a publishing time interval, which is defined as the period from when an index template is initiated to when it is published. This poses several challenges to our approach, for instance, how to publish dummy tuples generated during the index template building process or how to ensure that pointers between leaves and the new data do not leak privacy. Section 3.2, and 3.3 discuss these challenges as well as possible solutions.

3.2 Matching Table

Recall that when an index template is published, the cloud associates it with unindexed data to form a PINED-RQ's index for those data. To prepare for this association, the collector needs to keep the pointers between unindexed data and leaves. To do that, a simple way is to mark the ciphertext of a new tuple by the id of the leaf node to which the tuple belongs, and send the marked ciphertext to the cloud. Later, the cloud can rebuild pointers from marked ciphertexts when the index template is published. However, these marked ciphertexts reveal the real pointers between unindexed data and leaves during a time interval. PINED-RQ++ consequently discloses more extra information, e.g., the actual distribution of the incoming time of real data, when compared to PINED-RQ.

To prevent the leakage of such information, we use unique random numbers which are viewed as temporary ids of tuples and a matching table (see Figure 3). The first column in this matching table stores leaves' id while each row of the second column holds the temporary id of tuples belonging to the corresponding leaf node. For instance, tuples 1 and 7 belong to node 6 while tuple 5 belongs to node 9. In particular, when a tuple arrives, the collector encrypts it, generates a unique random number, and sends the *<random number, ciphertext>* pair to the cloud. This number is stored in the corresponding row in the matching table at the collector. The randomness guarantees that no useful information about the index template is leaked to the adversary. When an index template and its matching table are published, the cloud simply loops over the matching table and replaces random numbers with the leaves' pointers.

3.3 Noise Management

One challenge to our approach is that the collector initiates and perturbs the index template without any existing data. This means that no tuples are available to be deleted in case of negative noise. Also, when leaves receive positive noise, the collector can initially generate dummy tuples. However, when those dummy tuples are published to ensure privacy protection must be considered. To this end, we present two approaches as follows.

Regarding positive noise, the collector can immediately generate and send dummy tuples to the cloud at any random time point within a time interval. However, the arrival of all dummy tuples at the same time could be unsafe since the distribution of arrivals may be exploited by an adversary. Instead, we randomly release dummy tuples over the time interval. For instance, given 10 dummy tuples and a time interval of 100ms, then 10 discrete points can be randomly chosen between 1 and 100. At each chosen time point, a dummy tuple will be published along with a unique random number. It is, however, true that the privacy would be leaked as a dummy tuple might arrive at a chosen time at which real tuples are improbable. To avoid that case, the collector sends dummy data according to the actual distribution of the sending time of the real tuples. With this approach, when a *<random number, ciphertext>* pair comes to the cloud, the adversary cannot distinguish which pair is dummy or real data.

For negative noise, if a leaf node initially receives negative noise c, the collector moves the first c tuples (when they arrive) of that leaf node to the corresponding overflow array. At publication time, the collector randomly fills all overflow arrays with dummy tuples and sends these overflow arrays to the cloud. Notably, the movement of tuples only occurs at the collector and the adversary does not know which nodes receive negative noise. Thus, the privacy of such movements is also preserved.

3.4 Index Template Update Management

The main goal is to guarantee that the counts of PINED-RQ++'s index template are the same as those of PINED-RQ's index when the index template is published. In PINED-RQ, a leaf node's count represents the number of tuples falling within its interval. The count of internal nodes and the root is a summation of their children's counts. All counts are then perturbed by noise. In contrast, an index template only contains noise at first and it will increase its counts as soon as a tuple arrives at the collector.

Basically, when a tuple arrives at the collector, the leaf node to which the tuple belongs is determined. Then, the count of that leaf node and all its ancestors will be increased by 1. As shown in Figure 4, as the new tuple <Madison, 3> has GPA lying within the interval of node 7, the count of node 7 and all its ancestors (node 2 and node 0) are increased to 1, 2 and 3, respectively.

Figure 4: Index template and matching table are updated after the arrival of a new tuple

3.5 Parallel PINED-RQ++

Since the collector, that is assumed to be a small private node with a few cores, updates the index template, its throughput would be impacted as the rate of incoming tuples increases. We therefore parallelize the construction of the index template to improve the collector's throughput. Instead of keeping only one index template for updating, we create many clones of the original, each of which is independently updated. As a result, incoming tuples are equally distributed to clones for local updating. At publish time, all clones are merged together and sent to the cloud.

3.6 Privacy Analysis

As compared to PINED-RQ, both PINED-RQ++ and its parallel version only leak extra information of *<random number, ciphertext>* pairs and the time, when such pairs arrive at the cloud, to the adversary. Random numbers will not disclose any information about the data. Besides, as discussed in Section 3.3, when a pair arrives at the cloud, an adversary cannot distinguish between a dummy and a real tuple. Thus, PINED-RQ++'s privacy protection is similar to that of PINED-RQ.

4 EVALUATION RESULTS

4.1 Benchmark Environment

We ran our experiments on a cluster, whose configuration is illustrated in Table 1.

Table 1: Experimental environment

Component	CPU (2.4 GHz)	Memory (GB)	Disk (GB)
Collector	12	16	20
Cloud	16	16	40
Data generator	4	8	80
Consumer	4	16	10

We evaluate our proposal on four metrics namely network traffic, the time needed to publish an index (template), time response latency, and throughput. We use two real datasets NASA log [1] (1569898 tuples, five attributes) and Gowalla [12] (6442892 tuples, three attributes) for our experiments. We use the reply byte and check-in time as indexed attributes, respectively. Based on the values in the datasets, the reply byte's domain is divided into 350 bins while that of check-in time into 1502 bins. The fanout is set to 16. We use a time interval of 1 minute.

4.2 Results

(a) Network traffic: The network traffic metric gives an idea of the stability of the overall system, which is crucial for analytical processing. In this scenario, the data generator sends 3K tuples/second. Network traffic in terms of data rate is monitored at the collector over ten minutes. Figure 5 shows that the network traffic in PINED-RQ++ is much more stable than that in PINED-RQ. The maximum data rate is reduced by up to ~2.7x (NASA) and ~2.5x (Gowalla) in PINED-RQ++.

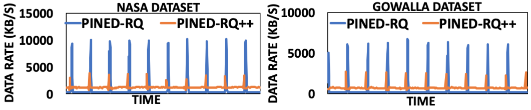

Figure 5: Network traffic over a ten minutes period

(b) Publishing time: We compare the time required to publish an index (template) according to dataset size. This metric is essential for monitoring applications since a long delay may cause bottlenecks at the collector. Different sizes of datasets are obtained by adjusting the incoming data speed and time interval parameter. As shown in Figure 6, when the dataset size increases, the time gradually rises in PINED-RQ while the publishing time in PINED-RQ++ remains almost unchanged. In particular, the publishing time is reduced by up to ~35x for NASA (514972 tuples) and ~16x reduction for Gowalla (1116907 tuples). Notably, when the dataset size rises, the gap between the two prototypes goes up.

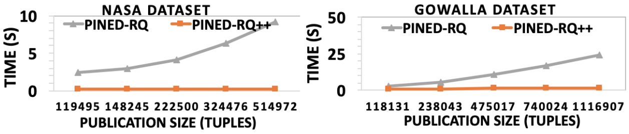

Figure 6: Average publishing time of 10 datasets

(c) Response time latency: We turn our attention to query latency. The data generator produces 2K tuples/second. The consumer sends one query per second. The query range is randomly chosen between 25% and 100%. In Figure 7, the results indicate that PINED-RQ has lower latency for small ranges compared to PINED-RQ++. However, our approach performs slightly better with large ranges (100%) because PINED-RQ's collector experiences higher workload for processing consumers' queries.

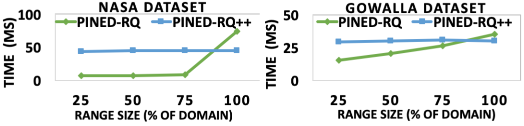

Figure 7: Average response time latency of 1000 queries

(d) Throughput: We compare the parallel PINED-RQ++'s throughput with the non-parallel version. The incoming data rates are chosen to be higher than the maximum throughput of the non-parallel version, 6.5K and 18K tuples/second for NASA and Gowalla, respectively. The different data rates are chosen since the tuple size of NASA is larger than that of Gowalla. The parallel version always has better throughput than the non-parallel version. The results in Figure 8 show that when the number of clones increases, the throughput is improved. The two-clone setting gives the best throughput, increasing by about 18% (to ~3K tuples/second) for NASA and about 47% (to ~8.3K tuples/second) for Gowalla when compared to the non-parallel version. Using a larger number of clones is not meaningful due to the merging process's costs.

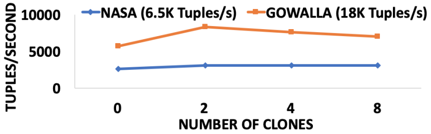

Figure 8: Parallel PINED-RQ++

5 CONCLUSION

We developed PINED-RQ++ to address the challenges of high rates of incoming data for processing range queries in clouds and the scalability problems of the prior schemes. The experimental results show that our solution provides better performance than PINED-RQ while privacy is also protected. This proves that PINED-RQ++ is appropriate for real-world monitoring applications. Besides, we introduce the parallel version, that helps enhance throughput.

Future work includes improving query performance, caching techniques and a dynamic adaptation to the query workload.

ABSTRACT

When searching for complex data entities, such as products in an e-shop, relational attributes are used as filters within structured queries. However, in many domains the visual appearance of an item is important for a user, while coverage of visual appearance by relational attributes is left to database designer at design time and is by nature an incomplete and imperfect representation of the entity. Recent advances in computer vision, dominated by deep convolutional neural networks (DCNNs), are a promising tool to cover the gaps. It has been shown that activations of neurons of DCNNs correspond to understandable visual-semantic features of an input image. We envision that activations of neurons are of great use for search queries in domains with strong visual information, even when obtained from DCNNs models pre-trained on general imagery. Locally scoped visual features obtained using them can be combined to form search masks which would correlate to what humans understand as an attribute, when applied on the entire dataset. Ultimately, combination of visual features can be identified automatically and formed into immediate suggestion of a new relational attribute, leaving one last task for humans to turn this into augmentation of the database schema – putting a label on it.

1 INTRODUCTION

Many approaches to information retrieval tasks, e.g., querying or exploration, assume structured data entities. These are modelled using composition of simple attributes and relations to other structured entities and as such, they represent a simplified model of the real world entity. Object's attributes either comply to a fixed schema in relational database model, or there is an implicit schema defined by existence of attributes in non-relational models such as document databases, key-value stores or linked data. Even though some data representations (e.g., JSON, XML) might be referred as schema-less and compliance is not always enforced, applications are working against an expected structure of the data and their attributes. In either case, these attributes are defined in a supervised manner by domain experts.

As an example application, let us consider an e-shop with a search interface. Within its search interface, users can define structured queries, which operate on a pre-defined set of attributes, utilizing range filters, exact matching or similar filtering mechanisms. An example query might be "*category = 'shoes' AND price between 100 and 200 AND color = 'black' AND description matches 'summer'*". Usability of the querying mechanism is limited both by the expressiveness of the database schema as well as capability of the user. In many domains (e.g., art, cars, dating, decorations, fashion or furniture), schema expressiveness is rather inferior due to the low information gain of available structured data. Therefore, the final filtering step of a retrieval task has to be executed by a human via examination of non-structured data (images, audio, video, etc). Scientific communities have been trying to reveal the internal structures of multimedia content in the last decades with gradually improving results. However, disclosing the multimedia object's representation in a way comprehensible for end-users remains extremely challenging. Partial solutions of this challenge are query-by-example search or multimedia exploration paradigms, accompanying the classical structured search as a refinement step.

Recent advances in neural network architectures, such as deep convolutional neural network AlexNet [8] represent a promising direction in revealing the internal structure of multimedia. Due to their layered nature, learned concepts are more high-level, and can bridge the semantic gap in computer vision. Although the task of many pioneer architectures was to classify data into a fixed set of pre-defined categories, it has been shown that the trained models can generalize to unknown domains, if the activation of neurons is used as a high-dimensional descriptor of objects [3]. Existing network models can also be fine-tuned to operate on a finer subset of data, increasing the precision for a particular dataset [4]. Finally, a layered networks' architecture allows to generate descriptors on different levels of a semantic scale [13, 19], ranging from low-level visual features (e.g., edges) up to high-level concepts, such as a cat. It is also possible to focus on individual regions of an image, denoted as patches [5, 18].

In our vision, we propose to extract information encoded in these descriptors via identification of commonly occurring combination of features. In order to analyze the behaviour of descriptors in the domain of product imagery, we implemented a multi-example similarity search mechanism [15]. This was also used to better understand applicability of different layers of the network by evaluating precision of their descriptors against manually selected proposals of new attributes acting as a test dataset. In this first step, the similarity was evaluated only globally, by extracting and comparing descriptors representing the whole object. As a second step, evaluation of individual image parts, patches, was done [14]. Human users were tasked to manually highlight interesting part of the image when selecting a set of images as an input for the search. Selected parts of an image were powering the search mechanism, which operated on an aggregation of global representations of images as well as on individual descriptors of each image patch, matching patches in the input query and in the overall database. This was partly done as an analytical step to better understand the behaviour and patterns within the data and how they correlate to what humans understand as an attribute.

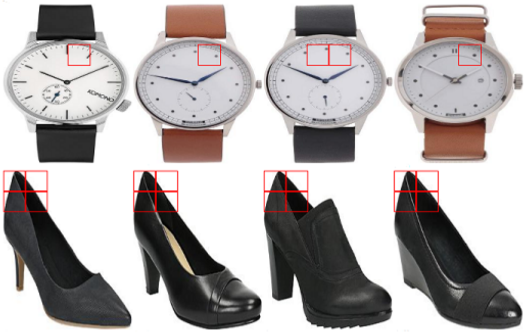

Figure 1: Examples of two proposed attributes. First row are "hand watches without labels". Second row are "lady shoes with sharp corner in the ankle area".

In the final stage of our vision, patterns of descriptors occurring frequently in the dataset can be automatically suggested as candidates for new attributes, immediately augmenting the original database schema (see Figure 1). Once the schema is augmented, all of the existing applications using it as a building block, e.g., recommender systems, data analytics, search functions and many others, can utilize this augmentation and therefore cummulatively increase the added value of the newly discovered "virtual" attribute. This implies benefits from an overall data-engineering perspective, and not just an application-specific improvement of a search function.

2 RELATED WORK

To the best of our knowledge, there have been no attempts to augment database schema using multimedia features. However, there are many similar disciplines that were used as inspiration and many technologies that could be used as building blocks to help implementing the vision. We want to highlight that rather than solving a single application-specific task (e.g., using images for product recommendation) we define the problem from database-engineering perspective, so that each service utilizing a database schema could benefit from its refinement.

Deep learning approaches have been evolving in the last years. Recent advances include inception modules (Googlenet), residual networks (ResNet, ResNeXt, DenseNet), and meta-learning approaches for searching an optimal architecture automatically (NAS), with better architectures being proposed every year. The target of our vision is to work with any network pre-trained on general imagery, making the choice of network architecture orthogonal to the main problem.

One of anticipated outcomes of our vision is an improvement of product recommendation techniques. Several papers focusing on fashion recommendation were published recently [6, 7, 9, 12, 17]. In fashion domain, visual-similarity based recommending approaches managed to considerably improve conversions of visitors to buyers [12]. In [6, 7, 12], authors focused on similarity and identity matching of "wild" images (i.e., pictures taken on streets or non-canonical representations of objects), while our scenario allows us to restrict on canonical representations of objects shot from similar angles with uniform background, etc.

Somewhat similar to our work is the approach by Yu et al. [17] on utilization of aesthetic-based features of objects together with common CNN features. However, using sole aesthetic features did not improve over CNN features and therefore we kept focusing on local visual similarity of objects instead of their aesthetics. The main difference between our vision and mentioned related work is the aim on materializing relevant similarity pattern instead of just utilizing them as a part of similarity calculations.

The topic of schema augmentation is not new, however, it has not been targeted via latent visual information so far. Selke et al. [11] focused on crown-enabled databases, which could enrich database schema at the query-time by utilization of manual labor to power search execution. Yakout et al. [16] automatically augmented entities via scraping of online available HTML tables and matching their information.

3 ROAD MAP

In this section, we overview the main points of our vision, describe the context, where it brings the most benefit, and define individual milestones and already completed goals, which altogether form a road map towards turning the vision into reality.

3.1 Vision

The body of our vision is to provide global as well as a user-based schema extensions by virtual attributes not present in the original database schema. Virtual attributes are to be derived from a visual information in domains, where it can provide a significant information gain, e.g., fashion, art, decorations, furniture, etc. We do not meant to replace classical search or recommendation methods, but rather boost them by providing additional relevant features. In addition to the applications in automated content processing methods, virtual attributes (if properly labeled) can be revealed to the end-users or utilized in data analytics.

Implicit feedback collected in an application-specific scope, such as browsing history in an e-shop, can be used as crowd-based evidence for the suggested attributes. If an attribute correlates with contents of search history, it is likely to have a meaning to humans. The evidence could naturally grow from single random visitors, over long-term users, up to large groups of similar users and thus increasing the level of confidence for the suggestion.

A particular objective aims at straightforward applicability for general usage; not relying on extensive training phase and pre-existing definitions of attributes/classes. The main challenge relies in an operation on previously unseen and undefined attributes, and an evolution of the model at runtime. Generally, training images and classes are essential for today's state-of-the-art computer vision models such as neural networks. However, the real world has unlimited number of classes assignable to objects, and it is impossible to prepare such data upfront. At the same time, requiring a special design and training phase would implicitly mean a need for a trained machine learning specialist, which limits the benefits to a small portion of data owners. We believe that it is possible to finalize the envisioned method in a set of unsupervised-pipeline steps, leading to a deployment-enabled black-box component which can be integrated into a broad range of today's applications.

3.2 Context

The envisioned approach of automatically detecting attributes is not guaranteed to be beneficial within all domains, not even when restricting the idea to products with visual information. The main preconditions are that visual information is an important factor influencing users' decisions and that information gain of existing relational attributes is low compared to information retrieved from multimedia data. This condition disqualifies product domains such as computer components, where the visual information is available, but existing relational attributes cover most of the users' information needs.

The applicability of our approach rises in scenarios, where objects may contain multiple important visual attributes and therefore it is not possible to simply label objects w.r.t. some class hierarchy. It is the dynamic point of view making it a challenge, since different users looking at the exact same image might have different understanding what is the attribute of interest for them. For example, several virtual attributes, e.g., leather-build, high heel, floral texture and black zipper may be detected for a single shoe, however for various users, only some of the attributes may be relevant in their decisions.

3.3 Milestones

In the following we summarize the milestones of the road map, also sketched in Figure 2.

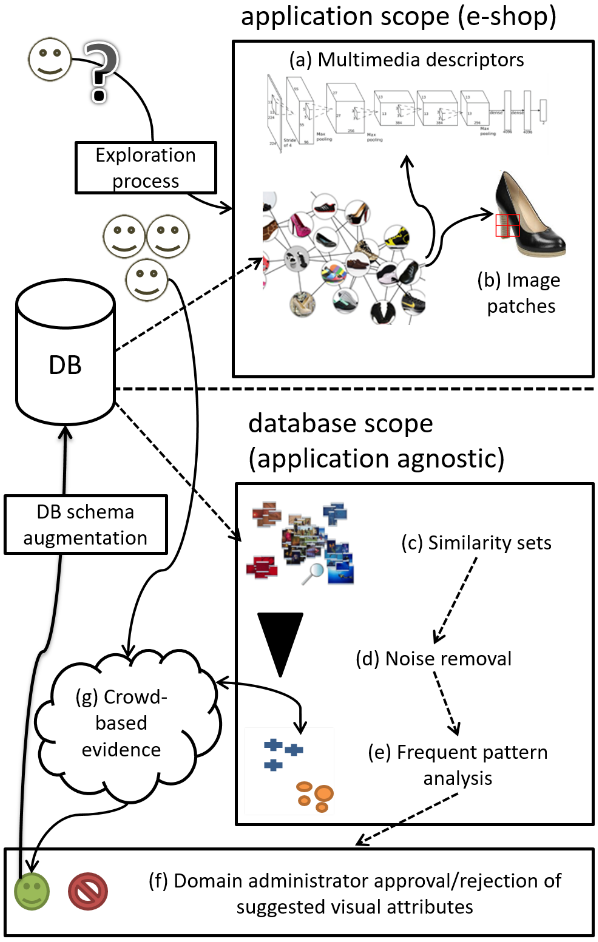
Descriptor extraction (a). As a first step of our vision, proper image descriptors need to be selected. However, due to the broad range and complexity of today's techniques, it is almost impossible to evaluate all possible variants and combinations. Even with simple DCNN like AlexNet, there are several layers to choose from and different aggregation methods to turn convolutional layers into a single vector. We have evaluated performance of different layers in [15] with the conclusion that there is no single dominating layer for all search tasks. Therefore, this aspect still deserves more research attention. Nonetheless, as all further tasks are independent on the choice of image descriptors, it is plausible to start with some simple selections, e.g., based on AlexNet and research this area in parallel with further tasks.

Image patches (b) are regions of an image that enable to focus on a particular part of it and, as a consequence, evaluate its similarity locally. Within standardized product datasets, it can be sufficient to cut images using regular grids, since all images have same orientation, centering and background. If we move towards "images in the wild" scenario, some trainable image segmentation approach might be necessary. In either case, the final image representation is a list of patches' descriptors. Another challenge in this task is to define methods to aggregate similarity w.r.t. different patches. We already reported results of some basic aggregation methods in [14].

Similarity sets (c), defined by image patches that are similar to each other in a given feature-space, could be the first step towards a virtual attribute. There are multiple ways to model similarity between image patches, e.g., by evaluating only the distance between their respective descriptors or by weighting it together with global similarity of the entire entity.

Noise removal (d) in the area of similarity sets is a challenging problem given the unsupervised nature of the desired pipeline, i.e., the only available information are images, their descriptors, and similarity values. The distribution of distance values can be a useful heuristic to filter out sets which are unlikely to form a good attribute, such as near-duplicates (distance close to zero), trivial patches (small distance to single-color patches) or sets being too large (attributes would no longer be discriminatory). Another possibility is to eliminate noise by cross-checking data coverage by existing relational attributes, e.g., to remove suggestion for an attribute that is already known in the data and correlates highly with the new suggestion.

Frequent patterns (e) within the filtered similarity sets should be prioritized in order to provide a ranked list of suggested attributes to the domain administrators. Existing approaches to the frequent patterns mining, such as the Market Basket Analysis [1], could be utilized. The algorithm should be optimized to reduce the number of suggested patterns/rules, while preserving a good coverage of entities in the database and a reasonable confidence level that can be used for sorting purposes.



application scope (e-shop)
(a) Multimedia descriptors
Exploration process
(b) Image patches
DB
database scope (application agnostic)
DB schema augmentation
(c) Similarity sets
(d) Noise removal
(g) Crowd-based evidence
(e) Frequent pattern analysis
(f) Domain administrator approval/rejection of suggested visual attributes

Figure 2: Road map/architecture of the vision.

Domain administrator (f) could be presented with n-tuples of items that match a suggested attribute. Furthermore, if the feedback from users is available (e.g., their browsing history or shopping baskets), frequently co-occurring items possessing a suggested attribute may be prioritized. The interface could also highlight the features on which the similarity of the set is based, e.g., by highlighting relevant image patches. If the suggestion gets approved and labeled, the similarity set could be turned into a search mask, evaluated w.r.t. the full database of descriptors to turn it into a new attribute. Since the database of descriptors contains also individual patches, certain attributes could be detected multiple times within a single object (a 1:N relation).

Collaborative techniques (g) based on implicit user feedback could not only refine suggestions to the domain administrators, but could also establish sets of latently approved virtual attributes specific for a cluster of users, or a single long-term user. In such a way, we may postpone the work of domain administrators and label the attributes only upon a request from a component that disclose attributes to the users (e.g., data analytics or attribute search). Challenges of this task are balancing the granularity of collected feedback (e.g., a single user, top-k similarity, user clustering), maintaining different augmented schemes for multiple user scopes and proposing methods capable to aggregate more granular augmented schemes (e.g., on a level of single users) and bring them to the higher level, eventually reaching the main database schema.

3.4 Challenges

In this section, we summarize the major challenges of the proposed vision and offer ideas on how to address them. The challenges are evaluation, noise reduction, scalability, personalization, continuous schema evolution and applicability on other forms of content.

By far the most significant challenge for database augmentation is the lack of an established evaluation framework and standardized datasets. The nature of human-system interaction will require time-consuming user studies in order to collect sufficient training data and feedback. The evaluation metrics could measure the overall user satisfaction, impact on speed in information retrieval tasks, as well as indirect impact obtained due to improved recommendation and search, e.g., the conversions ratio. Also, the practically unbound volume of possible attribute suggestions and the lack of training data for ranking the candidates makes human-in-the-loop a critical part of the evaluation.

The second challenge is the reduction of noise. The amount of attributes within a dataset is subject to a combinatorical explosion of common patterns across the dataset. The system can verify their meaningfulness using automated techniques operating on similarity data and visual descriptors, but it might be very difficult to systematically estimate if a pattern is indeed a new attribute, or if it was a random set of data points.

In order to deal with a large volume of possible patterns, the system must be efficient and scalable in all parts of data processing pipeline. In the existing work, the MapReduce paradigm was used in the implementation, allowing the computation to run on a large cluster of machines. The computationally intensive step of similarity self-join identifying common patterns across the dataset, was executed using the Hadoop MapReduce algorithms of Čech et al. [2].

The fourth challenge is personalization. Whenever the system starts inferring new attributes based on the implicit feedback input, the correct scope must be identified. The trivial cases are single-user scoped and globally scoped attributes. However, collaborative approaches may consider various, possibly overlapping clusters of similar users. This would require more extensive verification of an attribute across different user clusters, in order to estimate its benefit for the respective user groups.

The fifth challenge is the continuous schema evolution, fostered by a stream of new attributes, and its propagation into classical database tasks, e.g., similarity search. Therefore, the inclusion of new attributes must be done in a transparent way, so the successive techniques can automatically incorporate it without explicit intervention. Transitively, this has also impact on all other components operating on a set of relational attributes, such as data exploration or recommendation engine.

The last challenge is to generalize the proposed model into other forms of multimedia, such as sound or video. This might be appealing in domains, where short video material represents an inherent part of information retrieval tasks. One example might be a database of movies with their trailers. Recently, there have been significant improvements in video browsing techniques, such as the work of Lokoč et al [10]. The proposed schema augmentation approach could be beneficial in such scenarios as well.

4 CONCLUSION

This vision paper outlines a novel research problem, which aims at augmenting database schemes by attributes extracted from visual information. Initial attempts have outlined a possible direction for future research and identified several sub-problems and challenges to solve.

Short Paper

Workload-Driven and Robust Selection of Compression Schemes for Column Stores

ABSTRACT

Modern main memory-optimized column stores employ a variety of compression techniques. Deciding for one compression technique over others for a given memory budget can be challenging since each technique has different trade-offs whose impact on large workloads is not obvious. We present an automated selection framework for compression configurations. Most database systems provide means to automatically choose a compression configuration but lack two crucial properties: The compression selection cannot be constrained (e.g., by a given storage budget) and robustness of the compression configuration is not considered. Our approach uses workload information to determine robust configurations under the given constraints. The runtime performance of the various compression techniques is estimated using adapted regression models.

1 COLUMN COMPRESSION IN HYRISE

Two of the main driving forces of current database development – both industrial and research – are autonomous database systems and cloud-based installations. Both topics are strongly connected as database vendors are increasingly interested in optimizing their operational costs for large self-hosted database installations.

One way to lower the costs – especially for main memory-optimized database systems – is to reduce the memory consumption of large databases. Such a reduction allows storing databases on smaller and thus less expensive server machines or adding more instances to a shared server. But the sheer size of large cloud installations hampers manual optimization of compression configurations by database administrators. This development has recently sparked the research on autonomous database systems.

The work presented in this paper is an intermediate step to approach the issue of optimizing memory consumption while still retaining the performance advantages of main memory-optimized databases. When cost considerations are gaining importance, the optimization objective for compression configurations is less runtime performance rather than to retain the current runtime performance while minimizing the storage requirements. With the goal of automatically finding a compression configuration for a given memory budget, this project intends to provide the building blocks for autonomous systems.

The area of data compression has been thoroughly studied for decades in database research. Virtually all modern database systems implement various techniques to compress data and most commercial systems further provide means to adjust the compression level (e.g., Oracle's declarative policies for the *automatic data compression* (ADO), cf. [12], or SQLServer's *database engine tuning advisor* (DTA), cf. [11]). However, we see two distinct issues that remain open from a research perspective: **(i)** workload- and constraint-based compression configurations and **(ii)** determination of configurations whose runtime performance is robust to changing workloads.

We present and discuss the three main components in our research database Hyrise [10] with which we approach workload-driven and robust compression configurations:

- We introduce Hyrise's compression framework which implements an efficient and maintainable interface for various column compression techniques (Section 2).
- We present our runtime estimation, which predicts the performance of compression techniques (Section 3).
- We discuss the applicability of existing approaches for the optimization of physical database designs and how they perform for the task of compression selection (Section 4).

2 COLUMN COMPRESSION FRAMEWORK

Virtually every database management system for hybrid transactional and analytical processing (HTAP) employs a variety of compression schemes. Besides the advantage of reducing the main memory footprint, light-weight compression can even improve runtime performance, e.g., by reducing the memory traffic (cf. [2, 4]) or broadening applicability of vectorization (cf. [17]).

But supporting a variety of compression schemes is challenging as it needs to balance maintainability and efficiency. Most existing approaches optimize either (i) for performance while hampering maintainability and increasing complexity or (ii) provide unified interfaces for improved maintainability which potentially introduces runtimes issues.

2.1 Hyrise's Storage Concept

Hyrise is a main memory-optimized database with a column-major storage format [10]. Each table in Hyrise is horizontally partitioned into n chunks with a predefined maximum size. Each attribute of a table is hence distributed over all chunks whereby a column in a chunk is referred to as a segment. Modifications (i.e., insertions or MVCC-enabled updates) are appended to the most recent mutable chunk. When this chunk reaches its size limit, the chunk is considered immutable and a new mutable chunk is created. Immutable chunks might be compressed asynchronously. Hyrise encodes and compresses segments independently.

2.2 Balancing Performance and Maintainability

There are multiple approaches to integrate column compression schemes into the database system. One is to decompress vectors before an operator accesses the data, eliminating the need to handle different compression schemes in every operator. While this approach might be sufficient for analytical purposes which

Series ISSN: 2367-2005

10.5441/002/edbt.2019.84

are dominated by sequential operations, it is not feasible for HTAP processing where single row accesses are frequent.

Another approach is to adapt operators so that they can directly execute on compressed data using late materialization. This approach lowers the memory bandwidth required and further allows to exploit encoding-specific optimizations (e.g., early exiting a predicate when the searched value does not exist in the dictionary). While this approach promises the best performance, it also increases maintenance efforts significantly.

The middle ground between the upfront decompression of segments and encoding-specialized operators are abstraction layers that provide a unified interface to access data (cf. [2, 14]). However, this approach usually introduces dynamic polymorphism and thus virtual method calls per tuple, which are prohibitively expensive in analytical scenarios [5]. Dynamic polymorphism adds instructions, impedes cache utilization, and further hinders compilers to automatically apply vectorization primitives.

2.3 Integrating Compression Schemes

To overcome the issues mentioned in the previous section, Hyrise implements an efficient abstraction layer that provides a unified interface while still allowing encoding-specific optimization when desirable. The implementation uses *zero-cost abstractions* based on C++ metaprogramming and templating.

The column compression framework handles both encoding as well as decoding of compressed segments. The framework separates the various concerns by splitting data storage, encoding, and decoding into separate components. To decode columns, Hyrise uses C++'s iterator concept which – amongst other advantages – allows to apply algorithms of the standard library as if data would simply reside unencoded in an `std::vector`. Moreover, iterators can have state which enables block-based compression schemes to cache the most recently decoded block for potential upcoming accesses to the same block.

In Hyrise, column segments are usually accessed in two ways: fully sequentially or semi-randomly via a position list. As a consequence, each compression scheme provides these two access paths via a *sequential iterator* and a *point-access iterator* which accepts a position list. The impact of providing a positional access path over upfront decompression is shown in Figure 1.

Following the separation presented in [8], Hyrise distinguishes between logical-level and physical-level compression techniques and allows to cascade them. The logical-level techniques currently implemented are dictionary, frame of reference, and run length encoding. The physical-level techniques include fixed-size byte-aligned (FSBA) compression and SIMD-BP128 compression (cf. [8] for more details on the mentioned techniques).

Implementation Aspects: Hyrise is written using C++17 and uses of Boost Hana[1] for metaprogramming. To provide static interfaces within the encoding framework, we use the *curiously recurring template pattern* (CRTP). The runtime effects of static over dynamic polymorphism are shown in Figure 1. The combination of Boost Hana, CRTP, and C++14's generic lambda expressions allows us to avoid typical type resolving patterns such as the visitor pattern or hardly maintainable switch/case statements.

Hyrise's Execution Model: The mentioned iterators cover both major reading access patterns: full sequential and point accesses. The basic execution model in Hyrise (with few exceptions for the query compilation engine) follows the principles used in most modern columnar databases (cf. [1]). Predicates are descendingly ordered by their estimated costs and executed successively where each operator passes a list of qualifying positions to the next operator (i.e., position lists instead of materialized vectors). When parallel reads are preferable (e.g., as SIMD can be used), filters are executed in parallel and the results are intersected afterwards. Hence, the sequential iterator is typically used for the first filter predicate, while the following operators (e.g., following filters, joins, and aggregates) use the point-access iterator.

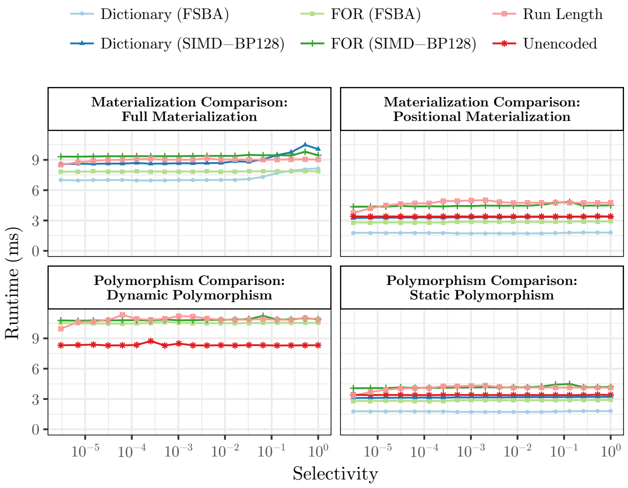

Figure 1: Positional aggregation (i.e., aggregating 25% of the tuples via a given position list) on a vector of 1M integers. Top: impact of decompressing the full column upfront vs. positional accesses. Bottom: impact of dynamic polymorphism vs. static polymorphism for row accesses.

3 ESTIMATING PERFORMANCE

In order to decide for one compression technique over another, the runtime performance as well as the resulting storage requirements need to be estimated. Estimating runtime of a particular action is implemented in any database that optimizes incoming queries and needs to decide on the order of actions to some extent. However, we think that existing approaches are by far too inaccurate for our goals. The reason is that most databases do not optimize for the accuracy of each runtime prediction they make, but rather optimize to correctly estimate *the order of alternative decisions* to take. As soon as the order is sufficiently accurate, better models with smaller errors do not provide any further advantages. We argue, however, that for any reasonable decision on the physical database design, both the potential advantages (here, reduction of allocated memory) as well as the drawbacks (here, potentially increased runtimes) need to be known upfront.

While storage requirements are rather straightforward to estimate for most compression techniques (assuming knowledge about, e.g., the row count and the number of distinct elements), we found manually crafted cost models for runtime predictions to be problematic. Due to the various CPU and compiler optimization techniques on modern platforms (e.g., out of order execution, branch prediction, code reordering) manually crafted runtime models often turn out to be too inaccurate and cumbersome.

To accurately estimate runtimes nonetheless, we create an array of regression models for each compression technique (e.g., for different data types). We measured the runtimes of sequential as well as random accesses to compressed data structures. Note

[1] Boost Hana: https://boostorg.github.io/hana/

that we do not estimate the compression runtime or write performance of encoded schemes for two reasons. First, Hyrise ensures that mutable chunks are never compressed but only immutable chunks are. Hence, no writes to immutable chunks occur apart from MVCC modifications. Second, the decoding of segment columns for reading happens significantly more often than encoding. Thus, we consider the compression costs to be amortized soon after anyways and ignore them.

We evaluated three established regression methods: gradient-boosted regression trees (in our case, XGBoost [7]) and two linear regressions with different minimization objectives. One linear regression variant uses ordinary least squares (OLS) and the other has been adapted to use a relative (normalized) error metric. The reason to use a model minimizing relative errors is that non-normalizing models are less suitable in our case as they tend to optimize the prediction of long runtimes.

Typically, the runtimes of database operators are, however, heteroscedastic, meaning that the variance differs significantly for varying input parameters (e.g., the selectivity or the table size). As a result, when estimating runtimes of operations with very short expected runtimes (e.g., a scan operation on a small dimension table with a low selectivity), extrapolating models often estimate negative runtimes. In our case, a relative error metric is a better fit as estimation errors are equally important on short and long running operations.

Table 1 shows the error rates on the example of the dictionary-encoded model for integer values. We evaluated three data sets (each set has previously been split for training and testing), one including all measurements, one including measurements below the median runtime, and one including measurements equal to or above the median runtime. For typical regression metrics, such as the *mean squared error* (MSE), XGBoost shows the best results for all data sets. However, looking at the relative error metrics *mean average percentage error* (MAPE) and *Ln Q* [15] shows that the adapted linear regression has a lower error on two of the three data sets. In Hyrise, we consider relative error metrics to be superior as the resulting model's applicability increases. On top of determining accurate rankings during access path selection, it can also be used to estimate the runtime of complex queries (e.g., queries containing nested queries which are short running but executed many times).

Quartiles	Metric	Linear Regression		XGBoost
		(OLS)	(adapted)	
$(Q1-Q4)$	MSE	498	499	323
	MAPE	1.18	1.03	2.07
	Ln Q	0.000 250	0.000 172	0.001 72
$(Q1, Q2)$	MSE	3.34	3.34	2.80
	MAPE	1.39	1.10	3.29
	Ln Q	0.000 352	0.000 196	0.003 35
$(Q3, Q4)$	MSE	993	995	643
	MAPE	0.971	0.969	0.855
	Ln Q	0.000 148	0.000 148	0.000 099 0

Table 1: Comparison of three regression models and varying error metrics (model for dictionary-encoded columns storing integers; green showing the best model).

As a consequence, we decided for the adapted linear regression model as it yields lower estimation errors and has two further advantages over more sophisticated approaches such as gradient-boosted trees or net-based approaches. First, most tree-based approaches do not support inter- and extrapolating predictions of out of sample values, which regularly happens in our scenario. Second, both learning as well as predicting of linear models is efficient, fast, and can be implemented without additional dependencies in a comparably short time frame.

While the current approach to estimate runtimes is suitable for the scenario described here, i.e., finding the best configuration for a given memory budget, it is not sufficiently covering other important scenarios. Besides storage constraints, one common constraint is limiting the expected end-to-end runtime for a given workload to be at most *n*% larger than the runtime with the current configuration. Think of cloud scenarios where a database system can be redeployed on another (potentially virtualized) server at any time. A given workload in this example can consist of a set of queries with tight runtime constraints (e.g., caused by existing service level agreements).

4 COMPRESSION SELECTION

Selecting a suitable compression configuration requires knowledge about the particular data characteristics as well as the workload. Most current databases use simple heuristics to choose a compression scheme for a given column. However, those approaches neglect three major issues that we deem crucial: Compression configurations ought to be (i) adaptable with respect to a given memory budget, (ii) consider its impact on the decisions the query optimizer is going to make given the configuration, and (iii) consider opportunity costs usually exploitable in real-world systems and workloads.

While cost considerations always played an important role in database systems, the current trend towards self-adapting cloud systems emphasizes the need to reduce the memory consumption (amongst others) as much as possible while ensuring acceptable performance. In fact, a large database vendor told us that for many cloud installations, TCO (total cost of ownership) reductions are a far more pressing issue than performance.

As such, the database must understand the performance impact of varying memory budgets. It needs to understand the interplay between space consumption and performance, e.g., to apply maximum compression to a table that is virtually never accessed. At the same time, such a memory budget-driven system should degrade gracefully for decreasing budgets.

Our selection framework accepts a given memory budget that should not be exceeded. The system uses heavier compression schemes for data that is rarely accessed or whose access patterns do not suffer from heavy compression, while frequently accessed tables might use light-weight compression schemes or no compression at all. With the workload at hand, it might make sense to lose certain performance by applying heavier compression for a less often accessed table and invest that gained space to frequently accessed tables (cf. opportunity costs).

4.1 Greedy Selection Heuristics

The goal of compression selection is to determine a compression configuration for a given data set and workload. The selected configurations should gracefully degrade for decreasing memory budgets. The memory consumption of the resulting compression configuration ought to be within the given memory budget. We evaluated two heuristics and static configurations for a synthetically generated CH-benCHmark-like workload.

To gather workload information, Hyrise parses the database's query plan cache. This information is fed to the selection heuristics and includes for each physical column, e.g., which operations are executed with which access path taken (e.g., full linear accesses or random probing accesses).

We implemented two greedy heuristics which have been proposed for a related field of physical design optimization: index selection. As the first heuristic, we implemented a density-based heuristic that chooses the first compression technique from all applicable techniques ordered ascendingly by their size-to-performance improvement ratio, comparable to [16]. As the second heuristic, we implemented a performance-greedy heuristic that selects compression schemes ordered ascendingly by their expected performance improvement, comparable to [11].

The results are shown in Figure 2. We make two observations. First, the "All FOR (FSBA)" configuration has shown to be a good trade-off between performance and memory consumption. No heuristic was able to find a comparable configuration as FOR encoding is often neglected by both greedy heuristics. Second, simple greedy heuristics are not sufficient as they (i) fall short in covering the whole range of permitted memory budgets and (ii) can even be outperformed by simple static heuristics.

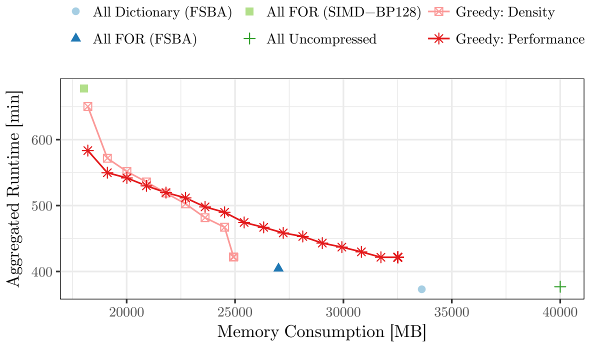

Figure 2: Comparison of static compression configurations and budget-driven heuristics.

The reason is that simple heuristics do not incorporate interactions affecting the optimization of query plans (cf. *index interaction*). One simple example is the effect of ordering conjunctive filter chains when the predicate with the lowest selectivity (hence, preferably being executed first) happens to be heavily compressed and hence slow to access. Optimizers using non-logical cost models – as done in Hyrise – might yield completely different query plans. To cover such cases, we think more elaborate selection approaches (e.g., recursive approaches as [3] and [6], or ILP-based approaches as [9]) are a necessary next step.

4.2 Robustness

The robustness of compression configurations is another crucial aspect. The more a segment is compressed as the expected workload is infrequently or not accessing it at all, the more expensive this decision might turn out when workloads shift.

To provide robust configurations, we use a simple framework to generate additional workloads which are evaluated together with the actually provided workload. Instead of selecting the compression configuration with the lowest runtime for the given workload, we choose the configuration minimizing the aggregated runtime of all workloads.

The creation of alternative workloads is done by shuffling and adding queries. First, for every query being part of the provided workload, we randomly select a new execution count based on the normal distribution around the actual execution count. Second, to counter the problem of heavy-weight compression for infrequently accessed segments, we manually add a query for each table to the workload that projects all columns. Both the number of generated workloads as well as the number of executions for the manually added query are configurable.

5 RELATED WORK

The object of integrating and selecting compression schemes has been researched in several previous works. Abadi et al. presented their C-Store extension to support various compression schemes [2] allowing operations directly on compressed data. A unified interface allows exploiting several compression scheme-unique optimizations while some operations have to fall back to a virtual method call-based interface. Further, the authors proposed a decision tree for the selection of compression schemes which uses both workload and data properties, but which does not adapt to changing environments nor considers memory budgets.

Lemke et al. presented a performance-optimized approach for TREX, the predecessor to SAP HANA [14]. At the cost of code complexity and maintenance efforts, compression schemes are explicitly handled within most database operators allowing to fully exploit vectorization and other optimizations.

Lang et al. presented data blocks for HyPer [13]. The authors focus the interplay of vectorizing operation on compressed vectors and their query compilation engine. HyPer selects compression schemes based on data characteristics.

6 CONCLUSION

We presented the current state of column compression in Hyrise. We think that compression selection will be an increasingly crucial topic. Mostly caused by (i) an increasing autonomy of database systems adapting themselves to changing environments and (ii) the move from on-premise to cloud-based installations which emphasizes the need for reduced main memory footprints.

ABSTRACT

Record linkage aims at identifying duplicate records across datasets. Most existing record linkage techniques have been designed for monolingual datasets. In this paper, we propose a novel approach, CLRL, that links the records in a cross-language setting, where each input dataset is in a different language. CLRL combines monolingual similarity measures with multilingual cross-language word embedding similarities to identify the correspondence of records across datasets. As our experiments show, CLRL outperforms baseline approaches in cross-language data integration settings.

1 INTRODUCTION

Record linkage is one of the most relevant tasks in a data integration process. The goal of record linkage is to identify records from two different datasets that represent the same real-world entity. One of the major challenges in record linkage is to identify similarity heuristics that are effective at approximating the equality of two heterogeneously represented entities [8]. Numerous similarity measures have been proposed so far to capture various similarity levels such as character-based and phonetic-based similarities [3]. These measures are effective in the monolingual setting, where similar words have a high lexical similarity. However, they are often ineffective in a cross-language settings, where each dataset adheres to a different language.

A naive solution to overcome this problem is to first translate one dataset into the other corresponding language and then apply an off-the-shelf record linkage approach. However, this approach suffers from two major problems.

(1) *Ambiguity in translation.* Short texts in structured datasets do not usually provide enough context for machine translation models to translate accurately.
(2) *Out-of-vocabulary terms.* The machine translation model cannot translate out-of-vocabulary terms, such as the concatenation "firstsight", which is not among the standard language vocabulary.

Motivation example. Table 1 illustrates two movie datasets in English (dataset *A*) and German (dataset *B*). Among all the 4 possible pairs of records in $A \times B$, only the second record of the English dataset should be linked to the first record of the German dataset. Traditional record linkage approaches would fail to identify their correspondence as there is no lexical similarity between the title "Forbidden Planet" and the title "Alarm im Weltall". Translating one of the datasets and then applying a traditional record linkage approach also fails because the translation of "Alarm im Weltall" is "Alarm in the Universe"; it is still not lexically similar to "Forbidden Planet".

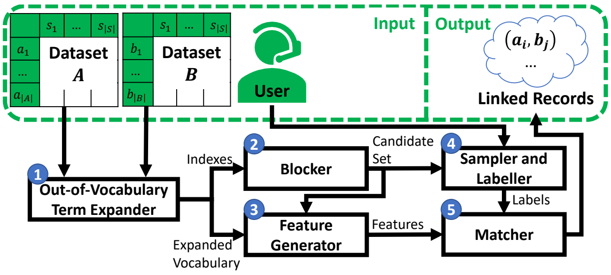

Figure 1: The workflow of CLRL.

Table 1: Two movie datasets in English and German.

ID	Name	Year	ID	Name	Jahr
1	Heat	1995	1	Alarm im Weltall	1956
2	Forbidden Planet	1956	2	Der Pate	1972

However, our approach is able to identify the correspondence by using the latent similarity of these two multilingual short movie titles based on cross-language word embedding models [14]. In particular, our maximum vector similarity feature (see Section 3.2) captures the similarity of the words "Planet" and "Weltall" (means "universe" in German) as these semantically similar words have similar word embedding vectors. □

Contributions. In this paper, we propose a novel approach to link the records across multilingual datasets. To this end, we make the following contributions:

- We design a term expansion scheme (Section 3.1) to expand each out-of-vocabulary term into a set of in-vocabulary terms. In fact, CLRL leverages a three-step policy to expand different types of out-of-vocabulary terms differently.
- We propose an effective set of similarity features (Section 3.2) for cross-language record linkage problem. In addition to state-of-the-art monolingual similarity measures, we include four multilingual similarity measures, adopted from cross-language word embedding models.
- We empirically evaluate our approach on six real-world datasets (Section 4). In particular, we show that CLRL outperforms three existing record linkage approaches in cross-language setting.

2 CLRL OVERVIEW

Figure 1 illustrates the record linkage procedure with CLRL. The multilingual datasets and the user feedback are the input and the set of linked records is the output of the approach.

CLRL adheres to the well-known pipeline of existing record linkage approaches, i.e., preprocessing, blocking, and matching. In addition to standard preprocessing operations, such as value normalization and identifying corresponded attributes, our approach can apply a novel preprocessing step to expand out-of-vocabulary terms into in-vocabulary terms (Step 1). We will detail this step in Section 3.1. In the blocking step, a state-of-the-art blocker is used to generate a set of candidate links between record

Series ISSN: 2367-2005

10.5441/002/edbt.2019.85

pairs of the input datasets (Step 2). Then, CLRL generates features for each candidate pair (Step 3). We will detail this step in Section 3.2. Depending on the sampling strategy and user-interaction model, a sample set of candidates are chosen to be labeled by the user as matches or non-matches (Step 4). Finally, a state-of-the-art classifier takes the features and labeled record pairs to classify all record pairs in the candidate set (Step 5).

3 FEATURE ENGINEERING

We first explain how out-of-vocabulary terms are expanded into in-vocabulary terms. Then, we describe our extensive feature set.

3.1 Out-of-Vocabulary Term Expansion

Out-of-vocabulary terms are those terms that could not be found in formal vocabularies and therefore are not translatable. The goal of out-of-vocabulary term expansion is to transform these non-translatable terms into in-vocabulary terms. This way, we can later leverage cross-language word embedding models to capture the similarity of these terms as well. CLRL applies the following steps to the out-of-vocabulary terms.

Morphological checking. CLRL first tries to find morphological variants of the out-of-vocabulary term. In morphological check, the out-of-vocabulary term is transformed into its morphemes (i.e., primitive units), if applicable. For example, the out-of-vocabulary term "firstsight" is transformed into in-vocabulary terms "first" and "sight". We leverage Polyglot Python module [16], which supports 100 languages, to conduct morphological transformations. Note that our morphological checking already covers lighter lemmatization and stemming transformations as well.

Spell checking. Spelling errors could be the emerging cause of many out-of-vocabulary terms. Therefore, in case of failure in morphological transformation, CLRL tries to fix spelling errors. To this end, the approach collects all the in-vocabulary terms whose Damerau-Levenshtein edit distance to the out-of-vocabulary term is less than equal to $\theta_{dist} = 1$. To minimize the risk of replacing an out-of-vocabulary term with the wrong in-vocabulary term, we restrict the threshold to the minimum possible distance, i.e., $\theta_{dist} = 1$, and replace the term only when exactly one in-vocabulary candidate has been found.

Ostrich policy. CLRL ignores transforming all the other out-of-vocabulary terms that could not be transformed by the previous treatments. These out-of-vocabulary terms are mainly numbers (e.g., "2001" in "2001: A Space Odyssey") or named entities (e.g., "Lebowski" in "The Big Lebowski") that do not need any transformation.

3.2 Feature Vector

Each pair of records in the candidate set is mapped to a feature vector that contains all the similarity scores of the two records. Let $A = \{a_1, a_2, \dots, a_{|A|}\}$ and $B = \{b_1, b_2, \dots, b_{|B|}\}$ be two relational datasets with different languages, where each $a \in A$ or $b \in B$ is a record. Let $S = \{s_1, s_2, \dots, s_{|S|}\}$ be the set of mapped attributes in these datasets. Therefore, the data cell $a[s]$ refers to the record $a \in A$ and the attribute $s \in S$. Let f be a similarity function that takes two data cells $a[s]$ and $b[s]$ and returns a similarity score $f(a[s], b[s]) \in [0, 1]$. Therefore, the feature vector of a candidate record pair (a, b) is

$$V(a, b) = [f(a[s], b[s]) \mid \forall f \in F \wedge \forall s \in S], \tag{1}$$

where F is the set of all the similarity functions. Due to the cross-language setting, the similarity functions should be able to capture, not only the monolingual similarity, but also the multilingual similarity of terms in different languages. That is why, we leverage monolingual and multilingual similarity functions.

3.2.1 Monolingual Similarity Functions. Monolingual similarity functions are typical lexical similarity measures. The goal of incorporating these measures is to capture lexical similarity of named entities, such as "Brad Pitt", which are written similarly in languages with the same scripting system. In particular, we calculate Jaccard, Levenshtein, Jaro, Jaro-Winkler, Needleman-Wunsch, Smith-Waterman, and Monge-Elkan similarity measures [5].

3.2.2 Multilingual Similarity Functions. Multilingual similarity functions capture the similarity of data values across different languages. We leverage cross-language word embedding models [14] to capture the similarity of short multilingual data values of datasets. Word embedding models, such as word2vec [12], learn to map each term into a dense vector in a way that terms with similar context (i.e., surrounding words) have similar vector representations as well. Cross-language word embedding models, such as fastText [7], are a special kind of word embedding models. These models share the same cross-language space for two different languages so that similar words from different languages can have similar vector representations. Thus, a cross-language word embedding model m can take a word w and returns its correspondent vector $m(w)$ in a cross-language shared space. In this shared space, not only monolingual similar words such as "Dog" and "Puppy" would have close vector representations, but also cross-language similar words such as "Dog" and "Hund" (means "dog" in German) would have close vector representations, i.e., $m(\text{"Dog"}) \approx m(\text{"Hund"})$.

Now, let m be the cross-language word embedding model and let $P = \{p_1, p_2, \dots, p_{|P|}\}$ and $Q = \{q_1, q_2, \dots, q_{|Q|}\}$ be the sets of words in data cells $a[s]$ and $b[s]$, respectively. We define the following four similarity functions.

Mean vector similarity (MeVS). The Mean of word vectors in a data cell is a representative vector for the whole data cell. Considering each data cell as a set of word vectors, we calculate the cosine similarity of mean vectors of data cells. Formally,

$$MeVS(P, Q) = \text{cosine}\Big(\frac{1}{|P|}\sum_{p \in P} m(p), \frac{1}{|Q|}\sum_{q \in Q} m(q)\Big). \tag{2}$$

Maximum vector similarity (MaVS). When the data cell contains noisy (i.e., irrelevant) words, it is desirable to represent the data cell by the vector of its most important word. For example, "Forbidden Planet" and "Alarm im Weltall" are the same movie titles in English and German. Since "Weltall" means "universe" in German, $m(\text{"Weltall"})$ is a more accurate representation for the German movie title rather than mean of all the word vectors inside the complete German movie title. This similarity function outputs the maximum cosine similarity between all the pairs of words $P \times Q$. Formally,

$$MaVS(P, Q) = \max_{(p,q) \in P \times Q} \text{cosine}\Big(m(p), m(q)\Big). \tag{3}$$

Optimal alignment similarity (OAS). If two data cells are matched, they might have an optimal one-to-one alignment of words, where each word in the first data cell corresponds directly to one word in the other data cell. This similarity function looks for such an optimal alignment between words of P and Q, where the sum of similarity scores between aligned word pairs is maximal. Finding the optimal one-to-one alignment of words is the classical assignment problem. We leverage the Hungarian algorithm [9] to find the optimal one-to-one alignment of words in two data cells. Since the aligning needs both P and Q to have the same length of words, the shorter one is padded with arbitrary out-of-vocabulary words, hence inducing dissimilarity. Let us assume that P is the shorter one and its padded version is P'. Formally,

$$OAS(P,Q) = \frac{\sum_{(p,q)\in L(P',Q)} \text{cosine}\Big(m(p), m(q)\Big) \times (|P| + |Q|)}{2 \times |P| \times |Q|}, \tag{4}$$

where $L(P', Q) = \{(p, q) \mid p \in P', q \in Q\}$ is the optimal one-to-one alignment of words in P' and Q. Note that since this similarity function depends on the word count in P and Q, we normalize its value by the harmonic mean of these word counts, as suggested in literature [4].

Maximum alignment similarity (MAS). Two matching data cells might not necessarily have an optimal one-to-one alignment of words. For example, although the English data value "Purchase Price" is matched to the German data value "Kaufpreis", there is no optimal one-to-one alignment for words. Instead, here we have a two-to-one alignment for the words. Thus, in general, we also need a similarity function that can capture the similarity of m-to-n alignments. This similarity function allows each word in the first data value be aligned to the most similar word in the second data value, regardless of whether these two words are already aligned to any other words or not. Formally,

$$\begin{aligned} MAS(P,Q) = \frac{1}{2}\Big(\frac{1}{|P|}\sum_{p\in P} \text{cosine}\Big(m(p), m(q_p^*)\Big) + \\ \frac{1}{|Q|}\sum_{q\in Q} \text{cosine}\Big(m(q), m(p_q^*)\Big)\Big), \end{aligned} \tag{5}$$

where, $q_p^* \in Q$ is the most similar word to word $p \in P$, i.e., $q_p^* = \max_{q\in Q} \text{cosine}\Big(m(q), m(p)\Big)$.

4 EVALUATION

Experimental setup. We evaluate our approach on six real-world datasets, which are described in Table 2. *Universities* and *Universités* contain information of universities around the world in English and French, respectively. An example of matched universities in these datasets is "Technical University of Berlin" and "Université technique de Berlin". *Movies* and *Películas* contain information on movies in English and Spanish, respectively. An example of matched movies in these datasets is "The Godfather" and "El padrino". *Wikipedia Titles* and *Wikipedia-Titel* contain wider domains including titles of Wikipedia pages in English and German, respectively. An example of matched titles in these datasets is "1982 World Snooker Championship" and "Snookerweltmeisterschaft 1982". We extracted these datasets from the DBpedia knowledge base [10]. We leveraged inter-language links inside DBpedia to obtain the ground truth for these datasets, i.e., the pairs of records that are actually linked. We evaluate our approach with precision $P = \frac{\text{the number of correctly identified linked records}}{\text{the number of all outputted linked records}}$, recall $R = \frac{\text{the number of correctly identified linked records}}{\text{the number of all actual linked records}}$, and F_1 measure $F_1 = \frac{2\times P\times R}{P+R}$. We mainly report only the F_1 measure, which combines the precision and recall, due to the space constraints.

Table 2: Datasets.

Name	Language	#Rows	#Common Attributes	Candidate Set Size	#Actual Linked Records
Universities	English	8758	16	124559	940
Universités	French	3957			
Movies	English	1273	14	59198	72
Películas	Spanish	15334			
Wikipedia Titles	English	1976	2	51211	83
Wikipedia-Titel	German	2159			

We apply cross-validation and report the mean and standard deviation of these measures. As the default parameter setting, we setup our approach with all the introduced features. We also leverage fastText [7] as the cross-language word embedding model and XGBoost [1] as the classifier. Our prototype is available online[1].

Effectiveness versus baselines. We compare the effectiveness of CLRL to the following three baseline approaches:

(1) **Magellan (M).** Magellan is an end-to-end entity matching system that uses monolingual lexical similarity features to learn links between records [8]. In our experiments, we include the following default set of features: Jaccard, Levenshtein, Jaro, Jaro-Winkler, Needleman-Wunsch, Smith-Waterman, and Monge-Elkan similarity measures.
(2) **Machine translation plus Magellan (MT+M).** This approach first translates non-English language datasets into English using the Joshua machine translation toolkit [11] and then applies Magellan on two English datasets.
(3) **Machine translation plus semantic matching (MT+SM).** This approach also leverages machine translation to have both datasets in English. However, instead of using Magellan, it applies a monolingual word embedding model to link records [15].

Figure 2 illustrates the effectiveness of CLRL in comparison to these baseline approaches. CLRL always outperforms the other approaches as it leverages a broad set of features to capture monolingual and multilingual similarities. This superiority is more obvious on *Wikipedia Titles/Wikipedia-Titel* datasets, as they contain more linguistically different content. In fact, in university and movie domains there are many named entities such as "Berlin" and "Brad Pitt" that remain the same in many languages. Therefore, even a traditional record linkage approach, such as Magellan, with lexical similarity measures can capture the similarity. However, in Wikipedia title domain there are fewer named entities, hence cross-language techniques are more promising.

Out-of-vocabulary term expansion analysis. Figure 3 illustrates the influence of out-of-vocabulary term expansion on the effectiveness of CLRL. Leveraging out-of-vocabulary term expansion, CLRL has a higher F_1 measure as the similarly functions can capture the similarities with higher recall, i.e., CLRL can identify more linked records. Again, the improvement is higher on *Wikipedia Titles/Wikipedia-Titel* datasets as the out-of-vocabulary terms in these datasets are mainly morphological and spell errors, which are transformed into in-vocabulary terms.

Feature analysis. Table 3 illustrates the effectiveness of CLRL when it leverages different features separately. In general, all the similarity features are informative for the task as CLRL works best with all the features. Furthermore, the proposed multilingual similarity features provide higher F_1 measure than the traditional monolingual features.

5 RELATED WORK

Cross-language record linkage. There are only few pieces of work on cross-language record linkage because this is relatively a new topic. Song et al. [15] translated the Japanese datasets into English and then applied monolingual word embedding models to identify linked records. As shown in the experiments, CLRL outperforms this approach because of two reasons. First, CLRL does not rely on direct translation of datasets, which can be ambiguous as explained earlier. Second, instead of only one monolingual word embedding-based similarity feature, CLRL leverages various monolingual and multilingual similarity features to capture the similarities of multilingual records more accurately.

Record linkage. Numerous works have tackled the similarity representation challenge of record linkage task by different similarity measures [3]. In addition to these common monolingual similarity measures, CLRL leverages multilingual word embedding-based similarity measures as well-suited similarity features for cross-language setting. We showed the benefit of the new similarity features in our experimental comparison.

Cross-language matching. Cross-language matching has been mainly studied for unstructured text data in tasks such as information retrieval [6] and entity matching [13]. While the entity is usually surrounded with a rich context of words in these tasks, in structured datasets the texts are mainly short, which make the cross-language matching task more challenging. That is why, CLRL leverages cross-language word embedding models to capture the semantic similarity of short multilingual texts accurately.

Out-of-vocabulary term expansion. Out-of-vocabulary term expansion has been addressed for the record linkage problem using the top-K co-occurring words with the out-of-vocabulary term [2]. CLRL does not hold any assumption on the term frequency of the out-of-vocabulary terms in the dataset.

6 CONCLUSION

We addressed the problem of cross-language record linkage. In addition to the monolingual similarity measures, we leverage four novel cross-language word embedding-based similarity measures. As our experiments show, CLRL outperforms three record linkage baseline approaches in cross-language setting. In future, we plan to extend the blocking step. Since the records are in different languages, simple blocking heuristics, such as having a word in common, do not work effectively in cross-language setting.

ABSTRACT

In the last decade we are witnessing a widespread adoption of architectural styles such as microservices, for building event-driven software applications and deploying them in cloud infrastructures. Such services favor the separation of a database into independent silos of data, each of which is owned entirely by a single service. As a result, traditional OLTP systems no longer fit the architectural picture and developers often turn to ad-hoc solutions that rarely support ACID transaction consistency.

At the same time, we are witnessing the gradual maturation of distributed streaming dataflow systems. These systems nowadays have departed from the mere analysis of streaming windows and complex-event processing, employing sophisticated methods for managing state, keeping it consistent, and ensuring exactly-once processing guarantees in the presence of failures.

The goal of this paper is threefold. First, we illustrate the requirements of stateful software services in terms of consistency and scalability. Second, we present how well existing solutions meet those requirements. Finally, we outline a set of challenging problems and propose research directions for enabling event-driven applications to be developed on top of streaming dataflow systems. We strongly believe that streaming dataflows can have a central place in service-oriented architectures, taking over the execution of ACID transactions, ensuring message delivery and processing, in order to perform scalable execution of services.

1 INTRODUCTION

Event-driven Applications (EDA) are software applications that act on incoming events. EDAs nowadays span a multitude of areas. Some very common examples are GUI applications (for web services, gaming, design, etc), complex event processing (for fraud detection, pattern matching, etc.), computations on streaming graphs and machine learning, and analytical queries over streams, such as window aggregation. In this paper we focus on two emerging application types named after the architectural pattern they follow, namely *microservices* [20] and actor-based systems [1], such as Erlang [22], Akka,[1], but most importantly, higher lever abstractions such as Microsoft's Orleans [3]. Our work is motivated by the observation that these emerging architectural patterns do not receive the necessary amount of attention from the database community, although they are extremely ubiquitous and growing in popularity by the day.

Microservices and actors have a surprising number of commonalities. Microservices, like actors, are founded on the principle of separation of concerns: each microservice (or actor) manages its own data and implements a set of endpoints (actors offer function calls). The only way for a microservice to get data from another microservice is to make a call on an endpoint (a function call/shipping for an actor). However, the two have a considerable amount of differences. More specifically, microservices favor communication via synchronous REST API calls[2] and ensure fault tolerance by relying on an external database for persistence. Actors, on the other hand, communicate via asynchronous messages and typically persist state in a local data structure or even in an external storage system [3]. The local state of actors can be used for recovering after failures, but also for migrating to different machines. To alleviate data management and consistency issues from actors, Bernstein et. al. [10] proposed the concept of virtual actors, backed by actor-oriented database systems, with the goal of integrating database concepts inside actor systems.

Stateful microservices can scale particularly well, but almost always implement eventual consistency, such as SAGAS [11]. In case that strict consistency is required, orchestration and Two-Phase Commit (2PC) take place at the application level: users hard-code database logic in their applications, using APIS such as Java XA, by implementing commit, rollback, and prepare for 2PC to work. Worse, transactions today contain more and more complex business logic. However, encoding complex business logic in a stored procedure is not preferred nowadays [2]. As a result, strict consistency – an old and difficult problem that was once only the responsibility of very few database programmers – is now part of daily work for application programmers. Finally, stateful services (including virtual actors) require state locality in order to achieve low latency - not only when writing data, but most importantly when reading data. As applications become more and more interactive, reacting to state changes renders latency requirements even stricter. At the same time, serverless computing [23], an emerging trend allowing the execution of user-supplied functions as a service, is proven to be a bad fit for stateful microservices. This is because it necessitates shipping data to the code and forces communication between executing components through the storage layer, which is slow compared to a direct network connection [14].

The aforementioned shortcomings call for a principled solution that will allow implementing EDAs with innate support for transactions, loose-coupling of service modules with local state, and consistent global state. In this paper we argue that such a fabric can be based on streaming dataflows. More specifically, modern streaming dataflow systems, such as Apache Flink [7] and Samza [17], execute a topology of continuously executing operators with local state and maintain a consistent snapshot of their global state. Operators cooperate to provide analytics on bounded and unbounded data. Moreover, features like Flink's Savepoints [6] or Kafka's Streams offer a deterministic time machine for debugging and replaying dataflow executions, and can be used to hide failures from application developers by offering

[1] https://akka.io

[2] Certain microservice implementations such as reactive microservices opt for asynchronous messaging.

exactly-once processing guarantees. Finally, dataflow systems scale extremely well. As a result, at the time of writing, we are witnessing a trend towards building stateful applications on top of streaming engines.

In this paper we present the vision of *operational stream processing* whose goal is to render stream processors full-fledged data management engines, capable of executing transactions, performing analytics, and embedding complex business logic of stateful services inside dataflow operators. We organize this paper as follows: in Section 2 we focus on current best practices for implementing EDAS and their requirements for scalability and consistency. In Section 3 we review existing possible solutions to fill those requirements. Finally, in Section 4 we argue that streaming dataflow systems, such as Apache Flink [7] and Samza [17], can serve as an efficient, and scalable backend for executing EDAS, given that our community tackles a set of important challenges.

2 REQUIREMENTS OF EDAS

In this section we first briefly outline the main requirements of EDAS with respect to the backend technology required for their execution. We then focus on a set of advanced operational requirements of microservices and actors.

2.1 General Requirements

The following requirements manifest themselves in almost all EDAS. We believe that a fabric that can be used as a backend for EDAS should at least provide support for the following.

Fault-Tolerant State. State is a first-class citizen in virtually every event-driven computation. State in a streaming computation can be counters (e.g., counting elements in a stream), database contents in a microservice or the current computation state of an actor program. At the same time a distributed event-processing application, needs to ensure that, even in the presence of failures, the state of the system remains consistent and the application continues its operations from where it left off. Whenever possible, failures should be transparent to the application programmer.

Event Partitioning & Scaling Out. Computations over partitioned data are typically used for computing aggregates, and for scaling-out actor instances and load-balancing user requests (e.g., by partitioning per user id). Similarly, scalability in microservices can be typically achieved by running multiple service instances, balancing the load among them using HTTP proxies.

2.2 Advanced Requirements

Apart from the general requirements, which are needed by most EDAS, most modern applications demand a special set of requirements for the operation of the services that comprise them.

Transactions. One of the largest problems in running services is the lack of coordination schemes in order to perform *transactions* and retain consistent state across services.

State Locality. Access to local state is important for boosting the performance of services [8], yet it is not always leveraged in microservice or actor architectures in favor of keeping those services stateless. In those cases, the state is offloaded to an external storage system. However, stringent latency requirements of interactive server applications require state to remain embedded in the service.

Global State View & Analytics. Services often need to consolidate data from multiple other services in a bulk fashion. For instance consider the case of joining orders with transactions, in order to obtain insight about sales. Since each service owns its data, consolidating that state via multiple calls to service endpoints is currently slow and cumbersome.

Loose coupling. One of the most important reasons that services are so popular is that they allow developers to develop, test, and deploy them in a loosely-coupled fashion. We consider this a defining trait of services that must be respected.

Debugging and Auditing. Given their distributed nature, services inherit the difficulty to reason, understand, and debug. To this end, services need inherent support for debugging and testing in a reproducible manner.

Dynamic (re)configuration. During the lifetime of a service, the load of the service (e.g., due to churn), its assigned hardware (e.g., due to failures), and even the service itself (e.g. due to updates) can change dramatically. Services need to transparently adapt to those changes without being affected in terms of performance and availability.

3 EXISTING SOLUTIONS

Many existing solutions meet the general requirements presented in Section 2.1. The advanced requirements of Section 2.2 are a lot more challenging to support though. This section presents which of the advanced requirements are fulfilled by existing systems, namely microservices frameworks, OLTP systems, actor programming frameworks, and stream processors.

3.1 Microservices frameworks

Transactions. The most widespread solutions for performing transactions in microservices frameworks are SAGAS [11] and application-level transaction managers implementing the Java Transactions API (JTA). A transaction in the SAGA pattern allows microservices to make local state changes (e.g., book a flight/hotel) independently of the rest of the microservices taking part in the transaction. On failure, all microservices that have already updated their state, need to issue compensating actions (e.g., cancel the flight booking). SAGAS pose two main issues: i) state consistency across microservices cannot be achieved and ii) not every action can be compensated. Various web application development frameworks, such as Spring, offer eXtended Transactions (XA), an implementation of 2PC with ACID-like properties for web applications [18]. The solutions based on application-level transaction managers require a tight coupling of services, and demand from developers to implement 2PC functions (e.g., `prepare` and `abort`) in application-level code which is very error prone and necessitates deep understanding of database concepts.

State Locality. The state locality requirement contradicts the design of stateless microservices, which dictates handing over the responsibility of persisting state to an external database system. Thus, current microservice frameworks fail to fulfill this requirement. Scaling-out microservices requires very sophisticated design of the backing database architecture. The service's state in these cases is external; accessing it requires a call to an external system, introducing latency.

Global State View. Microservices frameworks are not suitable for providing global state views. Since each microservice owns its data and state, having a complete view over the complete system's data state requires manually making a snapshot of all services' individual databases and importing those in a central database to perform analytics. Such a process cannot be done without special software and protocols; naively dumping all individual databases into a data warehouse without taking down all services in advance will most certainly result into data inconsistencies.

Debugging & Auditing. Developing microservices using event-sourcing and Command Query Responsibility Segregation (CQRS) [5] allows developers to replay message exchanges between services and debug their applications by rebuilding the state of an application at the time that a bug occurred.

3.2 Distributed OLTP Systems

Distributed OnLine Transaction Processing (OLTP) systems such as VoltDB [21] and H-Store [15], can be used as a backend for EDAS since they provide scalability, consistency, global view of the application state, and analytics. However, they introduce a number of issues. First, OLTP systems require that transactional code is included in the database as a stored procedure. However, transactional code is often an indivisible part of application code, a microservice's business logic for instance. Pushing the business logic into the database is largely disliked [2]. Second, distributed OLTP systems partition their state as they see fit, yet in order to achieve low latency, the state of each service should be locally available and even in the same memory space as the service itself. Finally, having one distributed database that manages the state of all applications goes against loose-coupling and requires that different services agree on a given schema, database system, etc.

3.3 Actor programming frameworks

Actors are good examples of loosely-coupled systems, that can be reconfigured in the presence of failures and environment changes. In addition, effective debugging can be achieved by use of the event sourcing and CQRS patterns, like in reactive microservices. Erlang, Akka, and Microsoft Orleans are popular actor-based programming frameworks. In the rest of this section, we focus on Orleans, which offers the highest level of abstraction among actor-based systems.

Transactions. Actors in general do not provide means for executing distributed transactions. Orleans appears to be implementing some form of ACID transactions with 2PC based on batching [10].

Global State View & Analytics. Actors can offer state locality but they lack the capability to provide a consolidated view of the global state and perform analytics on that state. For instance, Orleans can save the persistent state of actors locally or in inexpensive cloud storage that can be replicated for scalability and fault tolerance. Adopting the encapsulation principle, each actor has local access to its own data and state and restricted access to the state of other actors as per their public interface. This organization works for established actor-local operations, but leaves much to be desired in terms of a consistent global state view that can be used to answer queries on the complete state of an application. Performing analytics on global state in an actor system would be similar to a microservices.

3.4 Stream Processing Systems

So far stream processors are primarily known for their capacity to support high-throughput and low-latency analytics. However, modern stream processors such as Apache Flink [7], also support distributed state consistency via exactly-once state processing guarantees. Stream processors can serve as a platform for running EDAS in a scalable [16] and consistent fashion [6]. We argue that additional research needs to be performed in order for stream processors to be able to satisfy the operational requirements of EDAS, namely transactions, query-able global state, and loose coupling at the API level. Current stream processors lack appropriate programming models that allow developing microservice architectures. At present, they only offer functional APIS focused on bulk event processing, rather than message exchange that allows for loose microservice coupling. Moreover, stream processor systems need transactional facilities to support advanced business logic and coordination. The only two exceptions that are available at the time of writing are i) a closed-source implementation of multi-key transactions in Apache Flink, as well as S-Store [19], which provides ACID guarantees on shared mutable state on a single machine. Having a global state view of an application is also missing. Apache Flink, for instance, only supports external querying of a single operator's state.

Finally, stream processors can serve as a good basis for debugging distributed services. For instance, message brokers, such as Apache Kafka [17], can be used for storing all messages that are exchanged among microservices and replaying them during debugging. Moreover, Apache Flink's savepoints[3] can be used to replay events from a specific past consistent state of the stream topology in order to debug an application.

4 THE ROAD AHEAD

This section summarizes the research directions our community needs to take in order to realize the operational stream processing vision. We envision EDAS to be authored in a service-oriented API. Such an API would enable a service to have custom business logic, to communicate with other services via (a)synchronous message exchange, and to have access to local state.

A set of services authored in that API can be compiled into a dataflow graph, an example of which is depicted in Figure 1. Edges represent channels of message exchange among services. Vertices execute custom business logic, and are given access to managed local state. The dataflow engine takes care of the state's consistency, as well as the routing and exactly-once processing of messages within services. For the services executing in the dataflow graph to send and receive requests to/from external systems, they have to write or read to a message queue/log (e.g., Apache Kafka). This, not only enables exactly-once processing and delivery of messages, but it can also hide failures from the application programmers who can assume that, if a message has been sent, their application will receive an answer to that message exactly-once. Finally, certain parts of the inputs can be replayed in order to debug/audit a given service deployment.

One would argue that such an architecture could be implemented on existing systems such as Apache Flink, Samza, or Kafka. However, a set of requirements that we introduced in the previous section remain unsatisfied and require further research.

Transactions. Current dataflow systems guarantee consistency of single-event changes on a given partition of state. In order to guarantee consistency during multi-key, multi-partition state changes, we need to extend existing approaches of consistent snapshots [6] drawing ideas from distributed systems [9], and traditional OLTP systems. Some form of timestamp-based concurrency control could be employed [4, 13], especially given that processing- or event-time is a first-class citizen of all events entering a stream processor. Furthermore, we can invent 2PC-like protocols that take advantage of the FIFO connections between computation vertices in dataflow graphs, and ensure the order in which transactions arrive and state changes are applied.

[3] https://ci.apache.org/projects/flink/flink-docs-stable/ops/state/savepoints.html

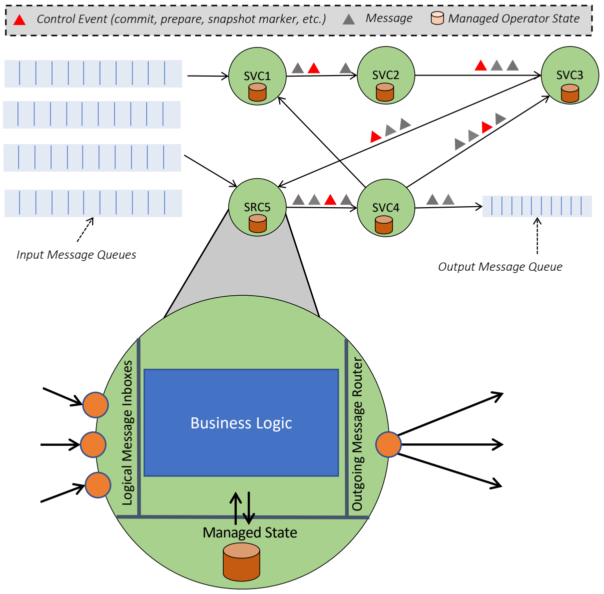

Figure 1: A set of services running inside a streaming dataflow graph. The business logic of services runs as an operator that processes messages and produces responses, the state of the service is managed by the dataflow engine, and all inputs and outputs of a given system are logged.

(Non-Dataflow) APIs for Loosely-coupled Services. Current dataflow systems only allow developers to author data pipelines, by defining data dependencies among operators and user-defined functions such as Map and Reduce in an explicit manner. To allow developers to develop loosely-coupled data-intensive services, we need novel APIs which will allow developers to individually develop, test, and debug services. Those services can be automatically compiled into a single, efficient, and scalable dataflow graph. To this end, we can derive the data dependencies from the defined messages/endpoints that applications send to each other, building the dataflow graph dynamically.

Consistent Access to Global State. Consistent snapshots [6] of transactional dataflows need to provide safe and consistent read access to global state, i.e., we need the means to execute distributed queries over the state of different operators. More specifically, we could provide the means for services to publish (views over) their state on top of which other services can build materialized views. Materialized views can maintain fresh results [12] and guarantee locality.

Dynamic (re)configuration. Currently, dataflow systems build a dataflow graph statically and then parallelize and deploy it, since all the data dependencies among operators are pre-defined. However, frequent and independent updates of services necessitate highly dynamic graphs with network channels that can be created or destroyed at any given time during the execution of a service. The ultimate goal is that the performance of existing services is not affected by changes in the dataflow graph. An important use case of dynamic configuration is the automatic parallelization of services. As we mentioned earlier, each service obtains access to managed local state. However, both the state and the input messages that are directed to a given service should be partitioned whenever possible, in order to ensure parallel execution. To this end, given a key for each state object, we aim at automatically parallelizing and even replicating service deployments and optimizing them for throughput and latency, without sacrificing consistency.

5 CONCLUSIONS & FUTURE WORK

In this paper we made a case for using streaming dataflow systems as a backend for stateful event-driven applications, such as microservices. We listed a set of requirements that include ACID transactions, global state consolidation, and the need for debugging and auditing. We then used those requirements to draw a rough outline of the future work that we believe has to take place, to materialize the vision of operational stream processing.

ABSTRACT

Recently, an optimal probability distribution was proposed to sample vertices for estimating betweenness centrality, that yields the minimum approximation error. However, it is computationally expensive to directly use it. In this paper, we investigate exploiting Metropolis-Hastings technique to sample based on this distribution. As a result, first given a network G and a vertex $r \in V(G)$, we propose a Metropolis-Hastings MCMC algorithm that samples from the space $V(G)$ and estimates betweenness score of r. The stationary distribution of our MCMC sampler is the optimal distribution. We also show that our MCMC sampler provides an (ϵ, δ)-approximation. Then, given a network G and a set $R \subset V(G)$, we present a Metropolis-Hastings MCMC sampler that samples from the joint space R and $V(G)$ and estimates relative betweenness scores of the vertices in R. We show that for any pair $r_i, r_j \in R$, the ratio of the expected values of the estimated relative betweenness scores of r_i and r_j with respect to each other is equal to the ratio of their betweenness scores. We also show that our joint-space MCMC sampler provides an (ϵ, δ)-approximation of the relative betweenness score of r_i with respect to r_j.

1 INTRODUCTION

Centrality is a structural property of vertices (or edges) in a network that quantifies their relative importance. For example, it determines the importance of a person within a social network, or a road within a road network. Freeman [14] introduced and defined *betweenness centrality* of a vertex as the number of shortest paths from all (source) vertices to all others that pass through that vertex. He used it for measuring the control of a human over the communications among others in a social network [14]. Betweenness centrality is also used in some well-known algorithms for clustering and community detection in social and information networks [16].

Although there exist polynomial time and space algorithms for betweenness centrality computation, the algorithms are expensive in practice. Currently, the most efficient existing exact method is Brandes's algorithm [5]. Time complexity of this algorithm is $O(nm)$ for unweighted graphs and $O(nm + n^2 \log n)$ for weighted graphs with positive weights, where n and m are the number of vertices and the number of edges of the network, respectively. This means exact betweenness centrality computation is not applicable, even for mid-size networks. However, there exist observations that may improve the computation of betweenness scores in practice.

- First, in several applications it is sufficient to compute betweenness score of only one or a few vertices. For instance, this index might be computed for only core vertices of communities [23] in social/information networks or for only hubs in communication networks. Chehreghani [9] has discussed some situations where it is required to compute betweenness score of only one vertex. Note that these vertices are not necessarily those that have the highest betweenness scores. Hence, algorithms that identify vertices with the highest betweenness scores [21] are not applicable. While exact computation of this index for one vertex is not easier than that for all vertices, Chehreghani [9] and later Riondato and Kornaropoulos [21] respectively showed that this index can be estimated more effectively for one arbitrary vertex and for k vertices that have the highest scores.
- Second, in practice, instead of computing betweenness scores, it is usually sufficient to *compute betweenness ratios* or *rank vertices* according to their betweenness scores [21]. For example, Daly and Haahr [12] exploited betweenness ratios for finding routes that provide good delivery performance and low delay in Mobile Ad hoc Networks. The other application is handling cascading failures [1].

While the above mentioned observations do not yield a better algorithm when exact betweenness scores are used, they may improve approximate algorithms. In the current paper, we exploit both of these observations to design more effective approximate algorithms. In the first problem studied in this paper, we assume that we are given a vertex $r \in V(G)$ and we want to estimate its betweenness score. In the second problem, we assume that we are given a set $R \subset V(G)$ and we want to estimate the ratios of betweenness scores of vertices in R. The second problem is formally defined as follows: given a graph G and a set $R \subset V(G)$, for any two vertices r_i and r_j in R, we want to estimate the *relative betweenness score* of r_i with respect to r_j, denoted by $BC_{r_j}(r_i)$ (see Equation 8 of Section 4.3 for the formal definition of relative betweenness score). The ratio of the expected values of our estimations of $BC_{r_j}(r_i)$ and $BC_{r_i}(r_j)$ is equal to the ratio of betweenness scores of r_i and r_j.

In [9], Chehreghani presented the optimal probability distribution for estimating betweenness centrality, that yields the minimum approximation error 0. However, this distribution cannot be directly used, as computing the constant factor of probability densities is computationally expensive. A natural solution for this problem is to use Metropolis-Hastings sampling [18]. In this short paper, we investigate the possibility of using such a sampling method for the two aforementioned problems and theoretically analyze the resulted algorithms. More precisely, our key contributions are as follows.

- Given a graph G and a vertex $r \in V(G)$, in order to estimate betweenness score of r, we develop an MCMC sampler

© 2019 Copyright held by the owner/author(s). Published in Proceedings of the 22nd International Conference on Extending Database Technology (EDBT), March 26-29, 2019, ISBN 978-3-89318-081-3 on OpenProceedings.org.

that samples from the space $V(G)$. Unlike existing work, our samples are non-iid and the stationary distribution of our MCMC sampler is the *optimal probability distribution* [9]. We also show that our MCMC sampler provides an (ϵ, δ)-approximation of the betweenness score of r ($\epsilon \in \mathbb{R}^+$ and $\delta \in (0, 1)$).
- Given a graph G and a set $R \subset V(G)$, in order to estimate relative betweenness scores of all pairs of vertices in R, we develop an MCMC sampler that samples from the joint space R and $V(G)$. This means each sample (state) in our MCMC sampler is a pair $\langle \mathfrak{r}, \mathfrak{v} \rangle$, where $\mathfrak{r} \in R$ and $\mathfrak{v} \in V(G)$. For any two vertices $r_i, r_j \in R$, we show that our joint-space MCMC sampler provides an (ϵ, δ)-approximation of the relative betweenness score of r_i with respect to r_j.

Techniques similar to our algorithm (the second algorithm that estimate *relative* betweenness centrality) have already been used in *statistical physics* to estimate *free energy differences* [3]. However, they are new in the context of network analysis. Our current work takes the first step in bridging these two domains. This step can be further extended by proposing algorithms similar to our work for estimating other network indices. As a result, a novel family of techniques might be introduced to the field of network analysis. We leave efficient implementations of our proposed algorithms and evaluating their empirical efficiency for future work.

2 PRELIMINARIES

Throughout the paper, G refers to a graph (network). For simplicity and without loss of generality, we assume that G is an undirected, connected and loop-free graph without multi-edges. Also, we assume that G is an unweighted graph, unless it is explicitly mentioned that G is weighted. $V(G)$ and $E(G)$ refer to the set of vertices and the set of edges of G, respectively. For a vertex $v \in V(G)$, by $G \setminus v$ we refer to the set of connected graphs generated by removing v from G. A *shortest path* between two vertices $u, v \in V(G)$ is a path whose size is minimum, among all paths between u and v. For two vertices $u, v \in V(G)$, we use $d(u, v)$, to denote the size (the number of edges) of a shortest path connecting u and v. By definition, $d(u, u) = 0$ and $d(u, v) = d(v, u)$. For $s, t \in V(G)$, σ_{st} denotes the number of shortest paths between s and t, and $\sigma_{st}(v)$ denotes the number of shortest paths between s and t that also pass through v. *Betweenness centrality* of a vertex v is defined as:

$$BC(v) = \frac{1}{|V(G)| \cdot (|V(G)| - 1)} \sum_{s,t \in V(G) \setminus \{v\}} \frac{\sigma_{st}(v)}{\sigma_{st}}.$$

A notion which is widely used for counting the number of shortest paths in a graph is the directed acyclic graph (DAG) containing all shortest paths starting from a vertex s (see e.g., [5]). In this paper, we refer to it as the *shortest-path-DAG*, or *SPD* in short, rooted at s. For every vertex s in graph G, the *SPD* rooted at s is unique, and it can be computed in $O(|E(G)|)$ time for unweighted graphs and in $O\left(|E(G)| + |V(G)| \log |V(G)|\right)$ time for weighted graphs with positive weights [5]. Brandes [5] introduced the notion of the *dependency score* of a vertex $s \in V(G)$ on a vertex $v \in V(G) \setminus \{s\}$, which is defined as: $\delta_{s\bullet}(v) = \sum_{t \in V(G) \setminus \{v,s\}} \delta_{st}(v)$, where $\delta_{st}(v) = \frac{\sigma_{st}(v)}{\sigma_{st}}$. We have: $BC(v) = \frac{1}{|V(G)| \cdot (|V(G)|-1)} \sum_{s \in V(G) \setminus \{v\}} \delta_{s\bullet}(v)$.

A Markov chain is a sequence of dependent random variables (states) such that the probability distribution of each variable given the past variables depends only on the last variable. An MCMC has *stationary distribution* if the conditional distribution of the $k + 1^{\text{th}}$ state given the k^{th} state does not depend on k. Let $\mathbb{P}[x]$ be a probability distribution defined on the random variable x. When the function $f(x)$, which is proportional to the density of $\mathbb{P}[x]$, can be efficiently computed, the Metropolis-Hastings algorithm is used to draw samples from $\mathbb{P}[x]$. In a simple form (with symmetric proposal distribution), the Metropolis-Hastings algorithm first chooses an arbitrary initial state x_0. Then, iteratively: i) let x be the current state. It generates a candidate x' using the *proposal distribution* $q(x'|x)$, and ii) it moves from x to x' with probability $\min\left\{1, \frac{f(x')}{f(x)}\right\}$. The *proposal distribution* $q(x'|x)$ defines the conditional probability of proposing a state x' given the state x. In the *Independence Metropolis-Hastings algorithm*, $q(x'|x)$ is independent of x, i.e., $q(x'|x) = g(x')$.

3 RELATED WORK

Brandes [5] introduced an efficient algorithm for computing betweenness centrality of a vertex, which is performed in $O(|V(G)||E(G)|)$ and $O(|V(G)||E(G)| + |V(G)|^2 \log |V(G)|)$ times for unweighted and weighted networks with positive weights, respectively. Çatalyürek et. al. [7] presented the *compression* and *shattering* techniques to improve efficiency of Brandes's algorithm for large graphs. The two natural extension of betweenness centrality to sets of vertices are *group betweenness centrality* [13] and *co-betweenness centrality* [8]. Brandes and Pich [6] and Bader et.al. [2] proposed approximate algorithms based on selecting k source vertices and computing dependency scores of them on the other vertices in the graph. To estimate betweenness score of vertex v, Chehreghani [9] presented a non-uniform sampler, defined as follows: $\mathbb{P}[s] = \frac{1/d(v,s)}{\sum_{u \in V(G) \setminus \{v\}} 1/d(v,u)}$, where $s \in V(G) \setminus \{v\}$. Similar to these algorithms, our proposed algorithms are *source vertex samplers*, too. However, they use a new mechanism for sampling which is based on the Metropolis-Hastings algorithm. Riondato and Upfal [22] introduced a *pair sampler* for estimating betweenness scores of all (or top-k) vertices in a graph. Riondato and Kornaropoulos [21] and Borassi and Natale [4] presented *shortest path samplers* for estimating betweenness centrality of all vertices or the k vertices that have the highest betweenness scores. The algorithm of [4] uses balanced bidirectional BFS (bb-BFS) to sample shortest paths. In bb-BFS, a BFS is performed from each of the two endpoints s and t, in such a way that they are likely to explore about the same number of edges. Finally, Chehreghani et.al. [11] presented exact and approximate algorithms for computing betweenness centrality in directed graphs.

4 MCMC ALGORITHMS FOR ESTIMATING BETWEENNESS CENTRALITY

In this section, we present our MCMC sampler for estimating betweenness score of a single vertex; and our joint-space MCMC sampler for estimating relative betweenness scores of vertices in a given set.

4.1 Betweenness centrality as a probability distribution

Chehreghani [9] presented a randomized algorithm that admits a probability mass function as an input parameter. Then, he proposed an optimal sampling technique that computes betweenness score of a vertex $r \in V(G)$ with error 0. In optimal sampling, each vertex v is chosen with probability

$$\mathbb{P}_r\left[v\right] = \frac{\delta_{v\bullet(r)}}{\sum_{v'\in V(G)} \delta_{v'\bullet(r)}} \tag{1}$$

In other words, for estimating betweenness score of vertex r, each source vertex $v \in V(G)$ whose dependency score on r is greater than 0, is chosen with probability $\mathbb{P}\left[v\right]$ defined in Equation 1.

In the current paper, for $r \in V(G)$ we want to estimate $BC(r)$ and also for all pairs of vertices r_i, r_j in a set $R \subset V(G)$, the ratios $\frac{BC(r_i)}{BC(r_j)}$. For this purpose, we follow a *source vertex sampling* procedure where for each vertex r, we consider $\mathbb{P}_r\left[\cdot\right]$ defined in Equation 1 as the target probability distribution used to sample vertices $v \in V(G)$. It is, however, computationally expensive to calculate the normalization constant $\sum_{v'\in V(G)} \delta_{v'\bullet(r)}$ in Equation 1, as it gives the betweenness score of r. However, for two vertices $v_1, v_2 \in V(G)$, it might be feasible to compute the ratio $\frac{\mathbb{P}_r[v_1]}{\mathbb{P}_r[v_2]} = \frac{\delta_{v_1\bullet}(r)}{\delta_{v_2\bullet}(r)}$, as it can be done in $O(|E(G)|)$ time for unweighted graphs and in $O(|E(G)| + |V(G)| \log |V(G)|)$ time for weighted graphs with positive weights. This motivates us to propose Metropolis-Hastings sampling algorithms that for a vertex r, sample each vertex $v \in V(G)$ with the probability distribution $\mathbb{P}_r\left[v\right]$ defined in Equation 1.

4.2 A single-space MCMC sampler

In this section, we propose an MCMC sampler, defined on the space $V(G)$, to estimate betweenness centrality of a single vertex r. Our MCMC sampler consists of the following steps:

- First, we choose a vertex $\mathfrak{v}_0 \in V(G)$, as the initial state, uniformly at random.
- Then, at each iteration t, $1 \le t \le T$:
  - Let $\mathfrak{v}(t)$ be the current state of the chain.
  - We choose vertex $\mathfrak{v}'(t) \in V(G)$, uniformly at random.
  - With probability $\min\left\{1, \frac{\delta_{\mathfrak{v}'(t)\bullet}(r)}{\delta_{\mathfrak{v}(t)\bullet}(r)}\right\}$ we move from state $\mathfrak{v}(t)$ to the state $\mathfrak{v}'(t)$.

The sampler is an iterative procedure where at each iteration t, one transition may occur in the Markov chain. Let M be the multi-set (i.e., the set where repeated members are allowed) of samples (states) accepted by our sampler. In the end of sampling, betweenness score of r is estimated as

$$\ddot{BC}(r) = \frac{1}{(T+1)(|V(G)|-1)} \sum_{v\in M} \sum_{u\in V(G)\setminus\{v\}} \frac{\sigma_{vu}(r)}{\sigma_{vu}}. \tag{2}$$

This estimation does not give an unbiased estimation of $BC(r)$, however as we discuss below, by increasing T, $\ddot{BC}(r)$ can become arbitrarily close to $BC(r)$. In the rest of this section, we show that our MCMC sampler provides an (ϵ, δ)-approximation of $BC(r)$, where $\epsilon \in \mathbb{R}^+$ and $\delta \in (0, 1)$.

Theorem 4.1. *Let $\overline{\delta(r)}$ be the average of dependency scores of vertices in $V(G)$ on r, i.e., $\overline{\delta(r)} = \frac{\sum_{v\in V(G)} \delta_{v\bullet}(r)}{|(V(G)|}$, and $\Delta(r)$ be the maximum dependency score that a vertex in G has on r. Let also $\mu(r)$ denote $\frac{\Delta(r)}{\overline{\delta(r)}}$. Then, for a given $\epsilon \in \mathbb{R}^+$, by our MCMC sampler and starting from any arbitrary initial state, we have*

$$\mathbb{P}\left[|\ddot{BC}(r) - BC(r)| > \epsilon\right] \le 2\exp\left\{-\frac{T}{2}\left(\frac{2\epsilon(|V(G)|-1)}{\mu(r)\Delta(r)} - \frac{3}{T}\right)^2\right\}. \tag{3}$$

Due to space limitations, in this short paper we omit all the proofs. However, the interested reader may find them in a longer version of this text in [10]. In general, our (ϵ, δ)-approximation proofs are based on a theorem presented in [17] for the concentration analysis of MCMC samples and a theorem presented in [19] for the uniformly ergodicity of Independence Metropolis-Hastings algorithms.

Note that Inequality 3 does not depend on the initial state. Furthermore, in Inequality 3 it is not required to discard an initial part of the chain, called *burn-in*. More details on this can be found in [10]. T is usually large enough so that we can approximate $\frac{3}{T}$ by 0. Hence, Inequality 3 yields that for given values $\epsilon \in \mathbb{R}^+$ and $\delta \in (0, 1)$, if T is chosen such that

$$T \ge \frac{\mu(r)^2 \Delta(r)^2}{2\epsilon^2(|V(G)|-1)^2} \ln \frac{2}{\delta} \tag{4}$$

our MCMC sampler will estimate the betweenness score of r within an additive error ϵ with a probability at least $1 - \delta$.

4.3 A joint-space MCMC sampler

In this section, we present an MCMC sampler to estimate the ratios of betweenness scores of the vertices in a set $R \subset V(G)$. Each state of this sampler is a pair $(\mathfrak{r}, \mathfrak{v})$, where $\mathfrak{r} \in R$ and $\mathfrak{v} \in V(G)$. Since this sampler is defined on the joint space R and $V(G)$, we refer to it as *joint-space MCMC sampler*. Given a state $\mathfrak{s}$ of the chain, we denote by $\mathfrak{s}.\mathfrak{r}$ the first element of $\mathfrak{s}$, which is a vertex in R; and by $\mathfrak{s}.\mathfrak{v}$ the second element of $\mathfrak{s}$, which is a vertex in $V(G)$.

Our joint-space MCMC sampler consists of the following steps:

- First, we choose a pair $\langle \mathfrak{r}_0, \mathfrak{v}_0 \rangle$, as the initial state, where $\mathfrak{r}_0$ and $\mathfrak{v}_0$ are chosen uniformly at random from R and $V(G)$, respectively.
- Then, at each iteration t, $1 \le t \le T$:
  - Let $\mathfrak{s}(t)$ be the current state of the chain.
  - We choose elements $\mathfrak{r}(t) \in R$ and $\mathfrak{v}(t) \in V(G)$, uniformly at random.
  - With probability $\min\left\{1, \frac{\delta_{\mathfrak{v}(t)\bullet}(\mathfrak{r}(t))}{\delta_{\mathfrak{s}(t).\mathfrak{v}\bullet}(\mathfrak{s}(t).\mathfrak{r})}\right\}$ we move from state $\mathfrak{s}(t)$ to the state $\langle \mathfrak{r}(t), \mathfrak{v}(t) \rangle$.

Techniques similar to our joint-space MCMC sampler have been used in *statistical physics* to estimate *free energy differences* [3]. Our joint-space MCMC sampler is a Metropolis-Hastings algorithm that possesses a *unique stationary distribution* [15, 20] defined as follows:

$$\mathbb{P}\left[r, v\right] = \frac{\delta_{v\bullet}(r)}{\sum_{r'\in R} \sum_{v'\in V(G)} \delta_{v'\bullet}(r')}. \tag{5}$$

All samples that have a specific value r for their $\mathfrak{r}$ component form an Independence Metropolis-Hastings chain that possesses the stationary distribution defined in Equation 1. Samples drawn by our MCMC and joint-space MCMC samplers are non-iid. In Theorem 4.2, we show how our joint-space MCMC sampler can be used to estimate the ratios of betweenness scores of the vertices in R.

Theorem 4.2. *In our joint-space MCMC sampler, for any two vertices $r_i, r_j \in R$, we have:*

$$\frac{BC(r_i)}{BC(r_j)} = \frac{\mathbb{E}_{\mathbb{P}_{r_j}[v]}\left[\min\left\{1, \frac{\delta_{v\bullet}(r_i)}{\delta_{v\bullet}(r_j)}\right\}\right]}{\mathbb{E}_{\mathbb{P}_{r_i}[v]}\left[\min\left\{1, \frac{\delta_{v\bullet}(r_j)}{\delta_{v\bullet}(r_i)}\right\}\right]} \tag{6}$$

where $\mathbb{E}_{\mathbb{P}_{r_i}[v]}$ (respectively $\mathbb{E}_{\mathbb{P}_{r_j}[v]}$) denotes the expected value with respect to $\mathbb{P}_{r_i}\left[v\right]$ (respectively $\mathbb{P}_{r_j}\left[v\right]$).

The proof of Theorem 4.2 is based on the *detailed balance property* of Metropolis-Hastings algorithms and can be found in [10].

Let $r_i, r_j \in R$, and $M(i)$ and $M(j)$ be the multi-sets of samples taken by our joint-space MCMC sampler whose $\mathfrak{r}$ components are respectively r_i and r_j. Equation 6 suggests to estimate $\frac{BC(r_i)}{BC(r_j)}$ as the ratio:

$$\frac{\frac{1}{|M(j)|} \times \sum_{\mathfrak{s} \in M(j)} \min \left\{1, \frac{\delta_{\mathfrak{s}.\mathfrak{v}}(r_i)}{\delta_{\mathfrak{s}.\mathfrak{v}}(r_j)}\right\}}{\frac{1}{|M(i)|} \times \sum_{\mathfrak{s} \in M(i)} \min \left\{1, \frac{\delta_{\mathfrak{s}.\mathfrak{v}}(r_j)}{\delta_{\mathfrak{s}.\mathfrak{v}}(r_i)}\right\}}. \tag{7}$$

We use Equation 7 to estimate the *ratio of the betweenness scores* of r_i and r_j. We then define the *relative betweenness score* of r_i with respect to r_j, denoted by $BC_{r_j}(r_i)$, as follows:

$$BC_{r_j}(r_i) = \frac{1}{|V(G)|} \sum_{v \in V(G)} \min \left\{1, \frac{\delta_{v \bullet}(r_i)}{\delta_{v \bullet}(r_j)}\right\}. \tag{8}$$

When we want to compare betweenness centrality of vertices r_i and r_j, using *relative betweenness score* makes more sense than using the *ratio of betweenness scores*. In relative betweenness centrality, for each $v \in V(G)$, the ratio of the dependency scores of v on r_i and r_j is computed and in the end, all the ratios are summed. Hence, for each vertex v independent from the others, the effects of r_i and r_j on the shortest paths starting from v are examined. Note that the notion of *relative betweenness score* can be further extended and presented as follows:

$$BC_{r_j}(r_i) = \frac{\sum_{v \in V(G)} \sum_{t \in V(G) \setminus \{v\}} \min \left\{1, \frac{\delta_{vt}(r_i)}{\delta_{vt}(r_j)}\right\}}{|V(G)| \cdot (|V(G)| - 1)}.$$

In the following, we show that the numerator of Equation 7, i.e.,

$$\frac{1}{|M(j)|} \sum_{\mathfrak{s} \in M(j)} \min \left\{1, \frac{\delta_{\mathfrak{s}.\mathfrak{v}}(r_i)}{\delta_{\mathfrak{s}.\mathfrak{v}}(r_j)}\right\},$$

can accurately estimate $BC_{r_j}(r_i)$. We refer to this value as $\ddddot{BC}_{r_j}(r_i)$. For a pair of vertices $r_i, r_j \in R$, in Theorem 4.3 we derive an error bound for $\ddddot{BC}_{r_j}(r_i)$.

Theorem 4.3. *Let $r_i, r_j \in R$, $M(j)$ be the multi-set of samples whose $\mathfrak{r}$ components are r_j, and $\overline{\delta(r_j)}$ be the average of dependency scores of vertices in $V(G)$ on r_j, i.e., $\overline{\delta(r_j)} = \frac{\sum_{v \in V(G)} \delta_{v \bullet}(r_j)}{|(V(G)|}$. Suppose that there exists some value $\mu(r_j)$ such that for each vertex $v \in V(G)$, the following holds: $\delta_{v \bullet}(r_j) \leq \mu(r_j) \times \overline{\delta(r_j)}$. Then, for a given $\epsilon \in \mathbb{R}^+$, by our joint-space MCMC sampler and starting from any arbitrary initial state, we have*

$$\mathbb{P}\left[|\ddddot{BC}_{r_j}(r_i) - BC_{r_j}(r_i)| > \epsilon\right] \leq 2 \exp \left\{-\frac{|M(j)| - 1}{2} \left(\frac{2\epsilon}{\mu(r_i)} - \frac{3}{|M(j)| - 1}\right)^2\right\}. \tag{9}$$

Similar to Inequality 3, Inequality 9 does not depend on the initial state and it holds without need for burn-in. Furthermore, for given values $\epsilon \in \mathbb{R}^+$ and $\delta \in (0, 1)$, if we have

$$|M(j)| \geq \frac{\mu(r_j)^2}{2\epsilon^2} \ln \frac{2}{\delta},$$

then our joint-space MCMC sampler can estimate relative betweenness score of r_i with respect to r_j within an additive error ϵ with a probability at least $1 - \delta$.

5 CONCLUSION

In this paper, first given a network G and a vertex $r \in V(G)$, we proposed a Metropolis-Hastings MCMC algorithm that samples from the space $V(G)$ and estimates betweenness score of r. We showed that our MCMC sampler provides an (ϵ, δ)-approximation. Then, given a network G and a set $R \subset V(G)$, we presented a Metropolis-Hastings MCMC sampler that samples from the joint space R and $V(G)$ and estimates relative betweenness scores of the vertices in R. We showed that for any pair $r_i, r_j \in R$, the ratio of the expected values of the estimated relative betweenness scores of r_i and r_j with respect to each other is equal to the ratio of their betweenness scores. We also showed that our joint-space MCMC sampler provides an (ϵ, δ)-approximation of the relative betweenness score of r_i with respect to r_j. We leave efficient implementations of our proposed algorithms and evaluating their empirical efficiency for future work.

ABSTRACT

Copernicus is the European programme for monitoring the Earth. It consists of a set of systems that collect data from satellites and in-situ sensors, process this data and provide users with reliable and up-to-date information on a range of environmental and security issues. The data and information processed and disseminated puts Copernicus at the forefront of the big data paradigm, giving rise to all relevant challenges, the so-called 5 Vs: volume, velocity, variety, veracity and value. In this short paper, we discuss the challenges of extracting information and knowledge from huge archives of Copernicus data. We propose to achieve this by scale-out distributed deep learning techniques that run on very big clusters offering virtual machines and GPUs. We also discuss the challenges of achieving scalability in the management of the extreme volumes of information and knowledge extracted from Copernicus data. The envisioned scientific and technical work will be carried out in the context of the H2020 project ExtremeEarth which starts in January 2019.

1 INTRODUCTION

Copernicus is the European programme for monitoring the Earth. It consists of a set of systems that collect data from satellites and in-situ sensors, process this data and provide users with reliable and up-to-date information on a range of environmental and security issues. The Earth observation satellites that provide the data of Copernicus are the *Sentinels*, which are developed for the specific needs of the Copernicus programme, and the *contributing missions*, which are operated by national, European or international organizations. The access to Sentinel data is regulated by EU law and it is full, open and free. Information extracted from Copernicus data is made available to users through the *Copernicus services* addressing six thematic areas: land, marine, atmosphere, climate, emergency and security.

The data and information processed and disseminated puts Copernicus at the forefront of the big data paradigm, giving rise to all relevant challenges, the so-called *5 Vs*, discussed below.

Volume: The repository of Sentinel products managed by the European Space Agency (ESA) has so far published more than 5 million products, and it has more than 100 thousand users who have downloaded more than 50 PB of data since the start of the operations of the system. This volume will increase in the following years, as new Sentinel satellites are launched.

Velocity: Copernicus data has to be delivered and processed in a short time frame to allow the provision of 24/7 information to users requiring fast responses. By the end of 2016, 6 TB of data were generated and 100 TB of data were disseminated every day from the Sentinel product repository. These rates will increase in forthcoming years as new Sentinel satellites are launched.

Variety: The Sentinel satellites have different types of sensors (e.g., radar and optical) and different levels of processing (from raw data to advanced products). Moreover, datasets used for geospatial applications can be not only satellite data but also aerial imagery, in-situ data and other collateral information (e.g., public government data). This wealth of data is processed by Earth Observation actors to extract information and knowledge. This *information and knowledge is also big* and similar big data challenges apply. For example, 1PB of Sentinel data may consist of about 750.000 datasets which, when processed, about 450TB of content information and knowledge (e.g., classes of objects detected) can be generated.

Veracity: Decision-making and operations require reliable sources. Thus, assessing the quality of the data is important for the whole information extraction chain.

Value: The extraction of information from the Copernicus data has direct economic benefits for Europe. Several economic studies have concluded that the Copernicus programme has the potential to significantly impact job creation, innovation and growth. The Copernicus Market report of 2016 estimates that the overall investment in Copernicus will reach EUR 7.4 billion in the years 2008-2020, while the cumulative economic value generated by it in the same period will be around EUR 13.5 billion, and it will support 28.030 job years in the Earth Observation sector.

An important activity related to Copernicus is the *thematic exploitation platforms (TEPs)* of the European Space Agency (ESA). A TEP is a collaborative, virtual work environment addressing a class of users and providing access to EO data, algorithms and computing/networking resources required to work with them, through one coherent interface. The fundamental principle of the TEPs is to move the user to the data and tools as opposed to the traditional approach of downloading, replicating, and exploiting data “at home”. Now the user community is present and visible in the platform, involved in its governance and and enabled to share

10.5441/002/edbt.2019.88

and collaborate. There are currently 7 TEPs addressing the following application areas: coastal, forestry, hydrology, geohazards, polar, urban themes, and food security.

Another important development in the context of Copernicus is the implementation of five *Copernicus Data and Information Access Services (DIAS).* The European Commission has awarded in December 2017 four contracts to industrial consortia for the development of four cloud-based platforms for Copernicus DIAS. The fifth DIAS is built by EUMETSAT in collaboration with Mercator Ocean and the European Centre for Medium-Range Weather Forecasts. Like the TEPs, these five platforms will also bring computing resources close to the data and enable an even greater commercial exploitation of Copernicus data.

Although the TEPs and DIAS activities funded by ESA have been welcomed by the EO data user community, they both have a *significant disadvantage:* they target users that are experts in EO data and technologies, and ignore the myriad of software developers that might not be experts in EO but still have a lot to gain by integrating EO data in their applications. Therefore, *opening up the TEPs and DIASs* by extracting information and knowledge hidden in the data, publishing this information and knowledge using *linked data technologies*, and interlinking it with data in other TEPs and DIASs and other non-EO data, information and knowledge can be an important way of making the development of downstream applications easy for both EO and non-EO experts.

In the last few years, there have been four highly successful European research projects that have pursued this idea: the FP7 projects TELEIOS , LEO and Melodies , and the on-going project Copernicus App Lab . These projects pioneered the use of linked geospatial data in the EO domain, and demonstrated the potential of linked data and semantic web technologies by developing prototype environmental and business applications. However, *none of these projects has faced the challenges of big data, information and knowledge that users and application developers are facing in the context of the Copernicus program.* The above four projects have developed tools for knowledge discovery and data mining from satellite images and related geospatial data sets, as well as tools for linked geospatial data integration, querying and analytics. However, *none of these tools scales to the many PBs of data, information and knowledge present in the Copernicus context.* For example, the state-of-the art geospatial and temporal RDF store Strabon implemented in TELEIOS [15] can only handle up to 100 GBs of point data and still be able to answer simple geospatial queries (selections over a rectangular area) efficiently (in a few seconds). Competitor systems like GraphDB by company OntoText performs similarly [2]. If the complexity of geometries in the dataset increases (i.e., we have multi-polygons), not even the aforementioned performance can be achieved for both Strabon and GraphDB.

In addition, contrary to multimedia images, for which highly scalable Artificial Intelligence techniques based on deep neural network architectures have been developed by big North American companies such as Google and Facebook recently [7, 8], *similar architectures for satellite images, that can manage the extreme scale and characteristics of Copernicus data, do not exist today.* The deep neural network architectures can classify effectively and efficiently multimedia images because they have been trained using extremely large benchmark datasets consisting of millions of images (e.g., ImageNet) and have utilized the power of big data, cloud and GPU technologies. *Training datasets consisting of millions of data samples in the Copernicus context do not exist today* and published deep learning architectures for Copernicus satellite images typically run using one GPU and do not take advantage of recent advances like distributed scale-out deep learning [8].

2 MAIN OBJECTIVE AND TECHNICAL CHALLENGES

The main objective of ExtremeEarth is to go beyond the four projects mentioned above by developing *extreme Earth analytics techniques and technologies that scale to the PBs of big Copernicus data, information and knowledge, and applying these technologies in two of the ESA TEPs: Food Security and Polar.* The technologies to be developed will extend the HOPS data platform [9, 12, 13, 17] to offer unprecedented scalability to extreme data volumes and scale-out distributed deep learning for Copernicus data. The extended HOPS data platform will run on a DIAS selected after the project starts and will be available as open source to enable its adoption by the strong European Earth Observation downstream services industry.

The detailed scientific and technical challenges of ExtremeEarth are the following.

Challenge C1. To develop scalable deep learning and extreme earth analytics techniques for Copernicus big data. The constellations of Sentinel-1/2/3 satellites have the important capability to acquire long time series of multispectral and Synthetic Aperture Radar (SAR) images where the temporal dimension plays a very important role for the characterization of the information content of the image (e.g., land cover or sea ice) and its dynamics. Moreover, this results in the availability of very large archives of images covering long time periods. Another key aspect of the Sentinel missions is the multimodal structure of the platforms. Different kinds of sensors (radar, optical, multi/multispectral) are available and can be used in synergy. Each modality provides specific information that can be used to cope with the limitations of another. ExtremeEarth will advance the state of the art in this area [20] by developing distributed scale-out deep learning techniques for the classification of remote sensing images based on architectures that can effectively exploit the spatial, spectral, temporal and multimodal properties of Sentinel data.

Two deep learning architectures for the classification of Sentinel remote sensing images will be developed; one for determining crop boundaries and type, and one for sea ice mapping. These will be used in the two applications described in the Challenges A1 and A2 below. The developed algorithms will be supported by a scale-out open-source platform for distributed deep learning and big data, based on the HOPS data platform [12].

Challenge C2. To develop very large training datasets for deep learning architectures targeting the classification of Sentinel images. In deep learning architectures, the availability of large amounts of high quality training data is equally important to the learning models. Computer vision and other image processing areas have developed during the last few years huge training data sets (e.g., ImageNet) consisting of many millions of objects. Satellite remote sensing is largely lacking this development since the complexity and physical meaning of the sensor data make the generation of training datasets much more complex. Moreover, from an operational viewpoint it is not feasible to assume the availability of enough ground truth or annotated labeled data for training a deep network. In this area, the largest benchmark dataset is Eurosat which was proposed recently [11]. It uses Sentinel 2 data and covers 13 different spectral bands and 10 land cover classes with a total of 27,000 labeled images.

In ExtremeEarth, we will develop tools to generate EO training datasets by enlarging existing datasets currently in development by the German Aerospace Center [4, 18] and by leveraging existing cartographic/thematic products which are now available at continental or planetary scale (e.g., OpenStreetMap). Two training datasets consisting of millions of samples will be developed aimed at the two deep learning architectures of Challenge C1. The datasets will be published as open source to be used by the whole Remote Sensing community.

Challenge C3. To develop techniques and tools for linked geospatial data querying, federation and analytics that scale to big Copernicus data, information and knowledge. The paradigm of linked geospatial data and relevant technologies has been pioneered by previous projects TELEIOS, LEO, Melodies and Copernicus App Lab mentioned above. The technologies developed include state-of-the-art systems for transforming geospatial data into RDF (GeoTriples [16]), interlinking with other geospatial data sources (geospatial/temporal extensions of Silk [21]), visualizing (Sextant [5]), querying, federating (Semagrow [3]) and performing data analytics (Strabon [15] and Ontop-spatial [1]). These systems are open-source and they currently represent the international state-of-the-art in the area of linked geospatial and EO data [6, 14]. In ExtremeEarth, the systems GeoTriples and Strabon will be re-engineered so that they scale to big linked geospatial data and extreme geospatial analytics. In addition, the JedAI linking framework [19] will be extended to enable the scalable discovery of geospatial relations in big geospatial RDF data sources. Finally, the engine Semagrow will be extended so that it can manage efficiently federations of big geospatial data sources and answer extreme geospatial analytical queries. To achieve the required extreme scalability, we will develop these three systems on top of the highly scalable HOPS data platform [12].

Challenge C4. To extend the capabilities for EO data discovery and access with semantic catalogue services that scale to the big data, information and knowledge of Copernicus. Currently, Copernicus data catalogues (e.g., the Copernicus Open Access Hub or the catalogues of the various TEPs) allow a user to access data by drawing an area of interest on the map and specifying search parameters such as sensing date, mission, satellite platform, product type etc. The new semantics-based catalogue we will develop in ExtremeEarth will expose the knowledge hidden in Sentinel satellite images and related data sets, and will allow a user to ask sophisticated queries such as "How many icebergs were embedded in the Norske ÃŸer Ice Barrier at its maximum extent in 2017?" which currently cannot be answered by the catalogue of the Norwegian Meteorological Institute, although all this knowledge is available in the Sentinel archive and related European data sets. We will demonstrate how to develop semantics-based catalogues and how to implement them efficiently for the extreme scale of the Copernicus context using the advances of ExtremeEarth in the area of big linked geospatial data discussed in Challenge C3 above. Two semantic catalogues (one for each TEP) will be developed operating in the selected DIAS platform and scaling to trillions of metadata records.

Challenge C5. To integrate the big data and extreme earth analytics technologies of Challenges C1-C4 in the HOPS data platform and deploy them in the selected DIAS and the two TEPs. The ExtremeEarth technologies presented above will be implemented and evaluated in the elastic cloud environment of the startup LogicalClocks participating in the consortium. This cloud environment is managed by LogicalClocks and currently provides the HOPS data platform [9, 12, 13, 17] together with significant storage, compute and GPU resources that will be made available to the project. Copernicus data will also be made available in the same environment and will be used to develop the ExtremeEarth technologies. The HOPS data platform provides services to move the processing to where the data is and it is based on a cloud computing platform-as-a-service approach. HOPS supports state-of-the-art parallel processing on big data with Apache Spark and deep learning with TensorFlow/Keras , as well as distributed deep learning using TensorFlow's distribution strategies, including collective allreduce and parameter server . HOPS also provides its own libraries for parallel deep learning experiments (hyperparameter search and model-architecture search). Once the ExtremeEarth technologies are integrated in HOPS, they will be deployed in the two TEPs and the selected DIAS.

The technologies discussed above will be demonstrated in two application areas: Food Security and Polar addressed by the relevant ESA TEPs. The challenges to be addressed in these two applications are the following.

Challenge A1. To develop high resolution water availability maps for agricultural areas allowing a new level of detail for wide-scale irrigation support. The maps will be available as linked data together with other geospatial layers (e.g., OpenStreetMap, field boundaries, crop types etc.) and made available to farmers. ExtremeEarth will tackle the combination of hydrological and agricultural monitoring, both in the sense that the thematic areas will be brought together, but also in the sense that the federation of the data sources and the cloud platforms used for the processing will be integrated. Both TEPs are already up and running, with the Food Security TEP, as the youngest of the TEPs, still in its second development phase, and the Polar TEP being in pre-operational mode. On both platforms, the first pre-processing chains for the information needed in ExtremeEarth are already running. These will be the baseline for bringing the two applications together in one combined application for irrigation. In practice this means that processing has to be widened to include whole watersheds (or catchment areas), to include all necessary Copernicus satellite input data from radar and optical imagery and to span the whole year instead of just the winter season or vegetation period. Additionally, scalable deep learning techniques discussed in Challenge C1 will be used to derive field boundaries and crop types, making it possible for the processing chains to include this information as linked data on a large scale (formerly, this information was only available at farm level). This will allow crop type specific deduction of crop variables, and thus a higher degree of accuracy for each field. The information generated with the ExtremeEarth approach will then be fed into the PROMET model [10] to provide high resolution (10m) water availability maps for the agricultural area in the whole watershed, allowing a new level of detail for wide-scale irrigation support. This application, which combines different TEPs, different Earth observation types and remotely sensed information and land surface modelling can be seen as a blueprint for further such applications, where the focus will lie on a federation of specialized knowledge and working environments (data and workflows). This type of federation of TEPs with methods, tools and data specialised for their topic rather than one broad platform for everything is seen by us as the way into the future.

Challenge A2. To produce high resolution ice maps from massive volumes of heterogeneous Copernicus data. The maps will be made *available as linked data and will be combined with other information such as sea surface temperature and wind information for informing maritime users.* The anticipated economic development of the Arctic, partially driven by reductions in sea ice cover, will see an increase in maritime shipping activity. High quality, timely and reliable information about sea ice and iceberg conditions is vital to ensure that vessels navigate efficiently and safely with minimal risk to the environment. This information is required by vessels in many sectors, including cargo transport, fisheries, tourism, research vessels, resource exploration and extraction, destination shipping and national coast guard vessels.

The functionality provided by both the DIAS infrastructure and the ESA Polar TEP as part of the ExtremeEarth infrastructure are well suited to answering the challenges of this application. Access to the required data interfaces is already established for some data sources in Polar TEP and further work to reinforce this will happen with integration of the DIAS infrastructure. Effort will be required to ensure data access is optimised for these purposes, for example ensuring near-real-time access to all required datasets. Building on the Polar TEP and DIAS as part of the ExtremeEarth infrastructure will also provide access to compute resources for processing. Since this is potentially going to be a significant processing load, but for limited periods of time as data is acquired and becomes available, then processing resources will need to be on demand and scalable to ensure efficiency. This will be achived by building on top of the HOPS data platform. Integration of established delivery systems into the ExtremeEarth infrastructure will support delivery of information products to polar users, such as tourist ships and fishing vessels operating in ice infested waters. This will include systems for information delivery and visualisation such as the Polar Code Decision Support System (PCDSS) which is currently being developed by company Polar View. PCDSS is designed to be used over restricted communication links, to bridge between the service production and users onboard ships in the Polar Regions. The scalable deep learning algorithms for sea ice classification, discussed in Challenge C1 above, will be integrated in the HOPS data platform to produce high resolution ice maps from massive volumes of heterogeneous Copernicus data. The aim is to deliver sea ice concentration and type maps, displaying stage of development (in accordance with the World Meteorological Organization - WMO Sea Ice Nomenclature), including fraction of leads and ridges, over the Polar Regions, at a resolution of 1 km or better.

3 THE EXTREMEEARTH CONSORTIUM

ExtremeEarth brings together a consortium of two companies leading the activities of the Food Security and Polar TEPs (VISTA and Polar View), one organization specializing in polar science for the Arctic and the Antarctic (British Antarctic Survey), one company specializing in big data, analytics and deep learning technologies (LogicalClocks), the German Aerospace Center with its TerraSAR-X satellite and expertise in SAR and multispectral EO (DLR), five top European academic institutions specializing in big data, linked data, Artificial Intelligence, deep learning and extreme earth analytics (National and Kapodistrian University of Athens, University of Trento, University of Tromsø, KTH and DLR), one research institute specializing in big data and Artificial Intelligence (National Center for Scientific Research - Demokritos), and one research institute specializing in big data, high performance computing applications, and provision of Metocean information, including sea ice (Norwegian Meteological Institute). The consortium is led by the National and Kapodistrian University of Athens.

ExtremeEarth starts in January 1, 2019 and will have a duration of 3 years. The project consortium is fully aware of the huge challenges that lay in front of us, and it is looking forward to meet them!

4 CONCLUSIONS

We have presented the vision of Horizon 2020 European project ExtremeEarth addressing the challenges of how to extract information and knowledge from the PBs of satellite data of the Copernicus programme using deep learning techniques, how to manage this information and knowledge efficiently using the HOPS data platform, how to develop two applications with economic and environmental importance (Food Security and Polar), and how to deploy these applications on the two relevant ESA TEPs and DIAS.

ACKNOWLEDGMENTS

This project has received funding from the European Union′s Horizon 2020 research and innovation programme under grant agreement No 825258.

Neuromorphic Hardware As Database Co-Processors: Potential and Limitations

Visionary

Thomas Heinis[¶], Michael Schmuker[†]

[¶]*Imperial College, London, United Kingdom* [†]*University of Hertfordshire, Hatfield, United Kingdom*

ABSTRACT

Today's databases excel at processing data using simple, mostly arithmetic operators. They are, however, not efficient at processing that includes pattern matching, speech recognition or similar tasks humans can execute quickly and efficiently. One of the few ways to integrate such powerful operators into data processing is to simulate neural networks or to resort to the crowd.

Neuromorphic hardware will become common-place in complementing traditional computing infrastructure and will, for the first time, enable the time-efficient emulation of neural networks. Given the impact hardware accelerators like FPGAs and GPUs had on querying, the question is if neuromorphic devices can be used to a similar effect by enabling richer database operators.

In this paper we thus discuss how neuromorphic devices can be used as database co-processors. The goal of this paper is to understand their potential as well as limitations, what future developments will make them suitable to accelerate databases and what the research challenges are. We also evaluate a prototype implementation of a query operator on neuromorphic hardware.

1 INTRODUCTION

While today computers have a clear advantage over the brain in terms of raw computing power, the brain is superior in error resilience and speed for approximate tasks like understanding speech or recognizing objects. It is for these reasons but also due to the limitations of current CPU designs (pin bottleneck limiting data transfer, limited heat dissipation, power supply) that scientists have developed neuromorphic devices which for the first time enable the energy and time-efficient simulation of spiking neural networks (SNNs).

The vision is that neuromorphic devices will be as prevalent as FPGAs or GPUs are today: in a first instance neuromorphic chips can be plugged into existing systems and computations are offloaded (e.g., image recognition). Later, neuromorphic chips may share sockets and caches to accelerate exchange of data. With Intel, IBM and others developing neuromorphic hardware, the question is not if, but rather when, it will become commonplace.

Research has developed methods by which hardware accelerators are used to accelerate queries. GPUs are used to offload parallel computation (e.g., joins [14]) while FPGAs are used to compute histograms when data is read from storage [13, 20].

The question we thus ask is how neuromorphic hardware will support query execution in databases. In this paper we first discuss what neuromorphic hardware is and how it can be used to simulate spiking neural networks. We then discuss how neuromorphic hardware has the potential to act as a co-processor for databases to offload computation which is best executed using a SNN. We finally also discuss a prototype application.

2 SIMULATING NEURAL NETWORKS

The simulation of neural networks and neuronal activity is not a new development. Perceptron-based multilayer networks have been used for decades in applications like pattern recognition and memory. With neuromorphic hardware, however, it is for the first time possible to efficiently emulate large SNNs.

In neural networks, neurons communicate via spikes, that is, discrete events that occur at defined times. Depending on the weight of the synapse, these events either increase or decrease the probability that the receiving neuron will produce a spike.

Over time, neuron models of increasing bio-realism and thus complexity have been proposed. Early models did not use voltage spikes, but used neurons as threshold gates that simply add input and fire once the threshold is exceeded [18]. These neuron models only take binary input, produce binary output and can thus be used to compute any boolean function.

Next generation neuron models based on the perceptron [24] use an activation function (typically sigmoid or a linear saturation function) on the sum of weighted inputs to compute a continuous, differentiable output. Concatenated ensembles of perceptron units are able to approximate arbitrary functions and can thus be used as universal classifiers in pattern recognition.

More powerful than this are networks with spiking neurons. They use a model of a neuron that receives several spikes, adds them up to the local potential P over time and fires a spike once P exceeds a given threshold. Information can thus not only be encoded in the number of spikes, the firing rate, but also in the timing of spikes [10]. From an information theory point of view we can encode more information and reduce the number of neurons to perform the same computation with this approach.

Additionally, the time-dependence of spiking neural models enables using additional learning algorithms that operate in the time domain. In neural networks that use non-spiking models, learning is achieved through backpropagation of errors [25], where synaptic weights are iteratively adjusted until the applied stimulus leads to the desired output. In spiking networks, this learning rule is extended with spike timing or spike-timing-dependent plasticity (STDP). In STDP, the weight of a synapse changes as a function of the time difference between spikes produced by the pre- and the postsynaptic neuron (neuron before and after the synapse). In STDP, a synapse is strengthened when the pre-synaptic neuron fired a spike shortly before the post-synaptic neuron fired. Vice versa, the synapse is weakened if the post-synaptic spike precedes the pre-synaptic one [2]. STDP thus extends firing-rate based learning by including spike timing.

3 NEUROMORPHIC DEVICES

The brain is a massively parallel system of highly interconnected but computationally simple neurons. Neurons act entirely event driven and thus operate asynchronously, integrating incoming spikes and sending spikes to other neurons.

Integrating spikes is very efficiently done on von Neumann based hardware (traditional CPUs or GPUs) while other aspects cannot be executed efficiently. First, to simulate, a very high number of very small messages (i.e., spikes) must be sent between neurons. While spikes are encoded with a few bits, most

10.5441/002/edbt.2019.89

communication protocols require an order of magnitude more bits for header and routing information alone. Moreover, today's communication protocols lack efficient means for multi-cast communication which is crucial to send the same spike to a large set of neurons. Second, while neurons are only active when receiving and processing spikes, traditional CPUs or GPUs are always on, rendering the simulation of SNNs energy inefficient.

3.1 Brain-like Hardware

With these challenges, traditional CPUs or GPUs cannot efficiently simulate SNNs. As a consequence, *neuromorphic hardware* is being developed to better support simulation of SNNs. While the design depends on the manufacturer, all proposals are driven by similar ideas.

Computation: Key to neuromorphic hardware is massive parallelism, i.e., a large number of computational units/cores. Each of the cores has the relatively simple task of simulating several neurons and it can thus be comparatively wimpy (few FLOPS).

Communication: Unlike traditional communication between cores or computers, the payload sent between neurons is very small as only the timing of the spike matters. This information can be encoded in a few bits (40-72). Key to neuromorphic hardware thus is an efficient communication optimized for small payloads.

Given the massive number of connections between neurons, multicast communication must also be efficiently supported.

Energy Efficiency: Since the computational requirements to model neurons are modest, the computing infrastructure can be of low complexity. Also, since neurons operate fully event-driven, there is no need for global synchronization. These properties allow for making neuromorphic devices very energy efficient.

3.2 State of the Art Devices

The prototypes developed share key features like a massively parallel infrastructure with a fast interconnect for small messages.

For example, the SpiNNaker architecture is based on a large number of ARM processors [8]. Memory with little capacity is local to each processor (which itself has several cores) while there is also slower, global memory used for communication between processors. More important is a very efficient communication infrastructure for small packets (~24 Bytes for a spike).

IBM's TrueNorth project is a platform with 4096 cores each simulating 256 neurons [19]. Similar to SpiNNaker, memory, computation and networking is handled locally by each core, therefore moving past the von Neumann architecture. With an event driven model where cores are only powered when needed, TrueNorth reduces energy consumption similarly to SpiNNaker.

Intel's design reduces energy consumption by using spin devices to simulate the neurons (thereby restricting the neuron models that can be used) as well as memristor as local memory (to store synapse weight) [27].

Spikey [23] takes energy efficiency even further by using a mixed-signal approach. Neurons are implemented using analog elements. While this makes them more bio-realistic, it limits the flexibility to use arbitrary neuron models. New models cannot simply be implemented through programming, but require changes in the hardware. Nevertheless, Spikey has proven to be versatile enough to implement a wide range of networks [23].

4 APPLICATIONS IN DATA MANAGEMENT

Spiking neural networks are capable of modelling arbitrary complex processes thanks to their ability to represent different information dimensions, such as time, space, frequency and phase.

In this section we discuss applications where neuromorphic hardware can support databases. In the applications we discuss, extracting all features a priori and storing them in a database may at first seem an option but is unfeasible as the feature space will explode, thus requiring excessive storage space.

The simulation of SNNs is thus key. Any application based on a SNN can be simulated on a CPU or GPU but only inefficiently. The benefit of using neuromorphic hardware is that it can run bigger SNNs faster and crucially, substantially more energy efficient.

While there is a plethora of potential applications which can be simulated with SNNs, our discussion is primarily driven by application domains where SNNs are used successfully.

4.1 Multimedia Databases

Neural networks can be used for data classification [26] but they prove particularly useful for recognising media. Several SNNs have been trained based on supervised learning methods [3, 21, 22, 26] and have been tested on imaging benchmarks. SNNs frequently outperformed non-spiking classification methods [3].

Content-based Image Retrieval Research has produced multiple approaches for content-based image retrieval in multimedia databases [4]. Most approaches are based on two phases: feature extraction (i.e., color, shape and others) and the indexing of the features [17]. Feature extraction is application specific [4] while indexing is general and based on high-dimensional indexes for similarity searches (R-Trees [11] and variants).

State-of-the-art approaches generally have two shortcomings. First, the semantic gap [6] means that it is very challenging to determine the semantics of an image from its low-level features, i.e., there is little connection between pixel statistics and the semantics of an image. Second, due to the high number of dimensions of extracted features and the curse of dimensionality, content-based retrieval of images is not efficient and scales poorly [5].

Spiking neural networks, however, are very useful for image and pattern recognition [1]: using a network with spike-timing dependent plasticity, one of the images is presented to a two layer network in the learning phase. The presentation triggers a single spike in each neuron in the first network layer and the incoming activity propagates to the next layer. The first neuron to fire in the second layer inhibits its neighbors and triggers learning. As a result each neuron fires if again presented with the same image. The learning step is substantially faster compared to other methods (particularly backpropagation) as is the recognition step.

Using spiking neural networks for image retrieval in multimedia databases (or databases in general) thus has two major advantages. First, using SNNs, no feature extraction is necessary and the method consequently can work directly on the raw data. By doing so there is less risk of basing retrieval on a highly specific set of features. Whether the use of SNNs bridges the semantic gap, however, has not been determined yet [1] but it decouples image recognition from features. Second, by using SNNs, no high-dimensional indexes are needed and image retrieval is more efficient and scales better. By simulating SNNs efficiently, neuromorphic hardware enables their use for image retrieval.

Audio & Video Retrieval The problem of audio and video retrieval is very similar to image retrieval with the difference that both also have a time dimension, e.g., videos have consecutive different frames. Simple approaches for video retrieval are based on the same ideas as image retrieval with a additional features drawn from changes between frames. By doing so they have the same drawbacks as current image retrieval methods.

Spiking neural networks support time very well. Any stimuli of a SNN is time-based, e.g., even images need to be encoded as a succession of neuron stimuli over time. SNNs and neuromorphic hardware thus lend themselves well for audio or video [28].

4.2 Spatial Indexing

A vast number of spatial indexes has been developed [9]. Many spatial indexes (particularly based on data-oriented partitioning like the R-Tree and variants), however, suffer from limited performance due to overlap and dead space in the index [11].

SNNs have also been used for spatial navigation: through learning mental maps of the environment it enables planning of paths [12]. The particular neuron in the network is activated as a simulated animal explores different locations in the environment and connections between neurons activated in a close temporal proximity are strengthened, i.e, cells representing neighboring locations develop strong synaptic interactions. This mechanism can be used for answering nearest neighbor queries.

A SNN run on neuromorphic hardware thus has the potential to execute nearest neighbor queries and planning paths.

5 CHALLENGES

We propose to use neuromorphic hardware as a co-processor for databases. We use the hardware to efficiently simulate a SNN for a complex query operator, e.g., pattern recognition for image retrieval. The associated research challenges can be identified for neuroscience and data management research alike.

On the level of hardware, while existing neuromorphic hardware already scales substantially better than traditional von Neumann architectures, it has to be investigated how current approaches can scale to simulate SNNs beyond millions of neurons, so that more sophisticated operators can be implemented.

Regarding neuroscience, the challenge lies in finding more SNNs that solve generic computing problems and are amenable to simulation on neuromorphic hardware. Several such SNNs have been developed but more applications from human cognition need to be considered as they are useful as database operators.

On the level of databases the challenges are as follows:

5.1 Data Preparation/Encoding

The data in the database and the query need to be encoded for the neuromorphic hardware. More precisely, as is common for SNNs, the data needs to be encoded as temporal spikes that can be fed into the system. Consider, for example, pattern recognition in images. All images as well as the query need to be encoded as temporal spiking patterns for it to be matched on a SNN.

Encodings for video and audio can be computed very efficiently: because they already have a temporal structure, data like movies or sound are converted to sequences of spikes using little computational effort. Similarly, for imaging data, sensors are available that efficiently produce time series of spikes [16].

As numerous examples of functional SNNs show, it is often possible to convert arbitrary data into spikes. Whether the effort to produce such an encoding is outweighed by the gain in computational power that a SNN will provide over more conventional approaches of data processing, however, is questionable.

Furthermore, while the same encoding can be used for matching different queries, it is very likely that different query operators will benefit from encoding that is tuned to that particular operator. A more difficult challenge thus is to decide what encodings should be stored and the organization in storage. It may suffice to only store the difference between encodings instead of storing one encoding per operator.

The most difficult challenge, however, is how to execute queries on multiple attributes. Going back to the imaging example: a query may restrict the area in which to find a particular pattern. Restricting the area on an already encoded imaging is difficult as all positional information (about the area) is lost in the encoding.

5.2 Query Planning

Current prototypes of neuromorphic hardware have a very limited interface to move data making query execution challenging.

Modelling Execution Cost A crucial question is when SNNs are run faster on neuromorphic hardware compared to the CPU. The query plan has to consider a cost model with the time to transfer data to and from the device and the execution time of the simulation. Execution time, however, is not the only consideration as running an operator on the device is more energy efficient than on the CPU. A second consideration thus has to be the energy needed to move the data and to run the SNN.

Query Optimization Given the high cost of moving data, moving all data to the device should be avoided. Considering the selectivity of predicates other than SNN (e.g., metadata information) early in the query plan is therefore imperative. Further, a crucial research challenge is to investigate if features in the raw data can be identified, extracted and indexed such that they can be used early in the query execution to curb data movement. Selecting the features is very challenging without reintroducing the semantic gap known from image retrieval.

5.3 Query Execution

Setting Up New Operators To define an operator, a network needs to be trained by adjusting synaptic weights. Key to the training phase is to encode the stimulus appropriately and injecting all learning stimulus consecutively to train the network. The learning phase can also be performed in a simulated environment and the resulting weights can be transferred to the hardware.

Swapping Operators One network cannot serve all purposes so operators/networks need to be loaded and unloaded. The state of a SNN or operator is captured in the neurons, their placement, their interconnections and the synaptic weights.

To swap an operator, a new SNN needs to be set up by loading neurons and synapse weights which is a slow process. In many cases, however, it may suffice to only define rules and derive the precise connections/network on the fly.

Interpreting Results Depending on the SNN, the result is indicated differently. In some cases the result is binary, i.e., one neuron being active indicates the result. In other cases, for example in case of the spatial application, the proximity of two points is expressed by the proximity of two active neurons. Each operator must therefore come with an implementation of an interpreter able to understand the result.

The major research challenge is how ambiguous simulation results are interpreted. The result is rarely precise and this ambiguity has to be propagated to the user. One approach is the use of ideas from uncertain databases, e.g., attribute-level uncertainty.

6 CURRENT LIMITATIONS

Neuromorphic hardware still is a new proposition and most available prototypes focus on the efficient execution of SNNs as a proof of concept whereas the programmability, data transfer and others are currently only second order considerations.

Moving Data: Current hardware, in particular the SpiNNaker system, has a very limited interface to move data to and from the device (Ethernet interface with 100MBps). The issue of bandwidth will, however, be addressed if neuromorphic hardware demonstrates its usefulness.

Simulation Size: The current challenge for hardware developers is increasing the capacity of neuromorphic systems. The largest systems today can simulate at most millions of neurons. Nevertheless, it is believed that scaling the number of neurons up to the human brain (i.e., 10^{10} neurons) will give neuromorphic systems the ability to infer relationships in data of a complexity that is inaccessible to conventional computers [7].

7 PROTOTYPE IMPLEMENTATION

To show the basic feasibility of using neuromorphic hardware as a database co-processor, we implement a proof of concept based on a simple application. Clearly this is only an example with several obvious optimizations which we address in future work.

7.1 Sample Application

As our sample application we use the recognition of digits in images [26]. Images containing hand written digits are stored as bitmaps in the database and a users query to find images containing a particular digit. To answer a query, a SNN run on neuromorphic hardware infers the digit in the image. The SNN is trained offline by showing sample digits (0 - 9) from MNIST [15].

In the current implementation we use the same digits for learning and querying. We do so to avoid the challenge of interpreting the result — an open research challenge as we discussed. Hence, when training we store the response (active neurons) to the stimulus for a particular digit. When asking what images contain a particular digit, we present the stored images to the SNN and compare the stimulus response (active neurons) with stored responses. Due to the nondeterminism of SNNs, the stored and the current result may not be identical. We thus compute the share of active neurons the current and the stored response agree on and consider the result a match if it exceeds a predefined threshold.

Compared to preprocessing all data and storing the result, we remain flexible as the SNN can be updated and ran on the hardware to query the data (with potentially more accurate results).

7.2 Setup

For the current implementation we use Postgres. Given the images from MNIST are stored as bitmaps, we store them as two dimensional arrays without need for transformation.

We use a user defined C function in Postgres: given a number *n* and a images stored in a table *t*, the UDF presents all images in *t* to the classifier and returns the ones likely to contain *n*.

For the experiments we use a 4 chip SpiNNaker board [8], the smallest board but adequate for a proof of concept. The board has 72 identical Arm968 processors (18 per SpiNNaker chip) operating at 200MHz. The SpiNNaker board currently only provides an Ethernet interface which connect to the host running Postgres.

7.3 Experimental Analysis

Training the SNN takes on average 68.2 seconds. The vast majority (95.5%) of time is spent transferring data: images to the device (8.4%), reading the stimulus responses (29.2%) and reading the trained SNN (57.9%). Learning only takes 3.1 seconds as each of the hundred digits is exposed to the SNN for 20ms.

Querying for one number — classifying all images and finding the ones matching the user input — takes on average 52.5 seconds. Most time is spent on moving data, i.e., moving the trained SNN (84.4%) and sending all images (10.5%) to the device. Classification on the device takes 0.2s while the time spent in the UDF is 2.48s.

Clearly, querying (as well as learning) suffers from loading (and storing) the SNN — the main bottleneck. Even without, however, moving the images is a very costly operation. The time for learning and classifying, on the other hand, is insignificant.

7.4 Open Challenges

As simple as the example used is, it shows some of the challenges discussed. A major challenge is the transfer of data. Currently this can only be done through Ethernet and is slow but future versions will have SATA and TrueNorth, for example, uses PCI.

Related to the limited bandwidth is the challenge of reducing the data moved: only images which contain the digit with high probability should be moved. Means to index the stimuli need to be devised so that a preselection of images can be performed.

Finally, scoring the result (and the inherent uncertainty) is a challenge which we worked around. Clearly, better approaches need to be devised for more sophisticated applications.

8 CONCLUSIONS

While neuromorphic hardware systems are still maturing, the high-level design is well-defined and the benefits are clear. It is thus the right time to start assessing the viability of neuromorphic applications. In this paper we have sketched the research challenges for query execution. Some challenges are implied by the prototypic nature of the hardware, but most are due to more fundamental reasons (e.g., query planning). By addressing these challenges we believe neuromorphic hardware will enable the efficient execution of more sophisticated query operators.

ABSTRACT

Data has become a major priority for customer facing businesses of all sizes. Companies put a lot of effort and money into storing, cleaning, organizing, enriching and processing data to better meet user needs. Usually in large scale systems such as big e-commerce sites these tasks involve machine learning methods, relying on training data annotated by domain experts. Since domain experts are an expensive resource in terms of monetary costs and latency, it is desired to design algorithms that minimize the interaction with them.

In this paper we address the problem of minimizing the number of annotation tasks with respect to a set of queries. We present a dedicated algorithm based on efficient labeling, that dictates the strategy for constructing a minimal set of classifiers sufficing to answer all queries. Our approach not only reduces monetary costs and latency, but also avoids data redundancy and saves storage space. We first consider a typical scenario of two expressions per query, and further discuss the challenges of extending our approach to multiple expressions. We examine two common models: *batch* and *stream* configurations, and devise *offline* and *online* algorithms, respectively. We analyze the number of annotations, and demonstrate the efficiency and effectiveness of our algorithm on a real-world dataset.

1 INTRODUCTION

Data has become a major priority for customer facing businesses of all sizes. Companies put a lot of effort and money into storing, cleaning, organizing, enriching and processing data to better meet user needs. For example, news articles published on news websites, are often annotated, e.g., tagged with "World Cup 2018" or "Elections in the United States", enabling readers to easily consume relevant content, hereby improving personalization and accessibility. E-commerce websites invest in generating a reliable catalog of products combining human and machine intelligence [4, 10, 17]. This allows potential customers to find the best matching product either by navigating through faceted categories, or by executing search queries. Since catalogs are often huge and cannot be maintained solely by human experts, automatic solutions based on machine learning (ML) are also employed. Combining both experts and ML is a widely-used approach also in fraud detection applications [9], text categorization [15] and other classification tasks [19, 20]. One of the most common usages of ML with *human in the loop* is harnessing domain experts to generate adequate labeled data as a baseline for supervised learning. Thus, generating sufficient annotations, while minimizing domain experts' effort, is highly desired. This trade-off between high quality and low cost is the holy grail of training data preparation. Much research has been devoted in the literature to minimizing the interaction with regular crowds [8, 12, 20]. However, these techniques are best suited for mundane classification tasks, whereas for questions that require particular expertise, as shown in [6], gathering multiple answers from various crowd workers does not always produce a desired accuracy level. In light of this, we present a novel query driven approach with *human experts* that avoids redundant labeling tasks and finds the minimal set of necessary tasks. We note that our approach may be combined in a regular crowdsourced schema with probabilistic settings. To illustrate our approach, consider the following example.

Example 1.1. A database *Products* contains a relation *Shirts* with attributes *product_id*, *product_title*, *product_description*, *product_image*, *product_price*, *color* and *material*. This relation contains a list of shirts sold on an e-commerce website. While the product title and description are provided by the seller, its color and material are usually missing and should be automatically extracted from the title, description or image using ML classifiers. Assume a customer performs a keyword-based search for orange cotton shirts, which translates into the following SQL query via NLP-based methods[1]:

```
SELECT * FROM Shirts
WHERE `color` = 'Orange'
AND `material` = 'Cotton';
```

Providing an answer to such queries, should rely on correctly enriched color and material attributes values for every product. Toward this end, one may train various classifiers with respect to suitable labeled data. Classifiers shall be incorporated to answer "Is this product's color is X and material is Y?". Given that any classifier needs N labeled examples for training, in order to answer the query above one can either train *two* classifiers: one for detecting orange shirts and one for detecting cotton shirts, and separately apply them for each product. This requires $2N$ labeled examples. Alternatively, one could train a more specific classifier that detects orange cotton shirts, using only N labeled examples. Clearly, for this specific case, it is better to choose the latter. However, given a general list of queries with different values of colors or materials, minimizing the number of classifiers may be difficult.

In this paper we propose an algorithm that minimizes the number of classifiers (labeling tasks) that are sufficient to answer all queries. We focus on the case of having at most two expressions per query, which is the most common case in e-commerce search [3]. The extension of our approach to multi-criteria queries is discussed in the future work section. We present a dedicated algorithm based on efficient labeling, that dictates the strategy for constructing a minimal set of classifiers sufficing to answer all queries. Our approach not only reduces monetary costs and latency, but also avoids data redundancy and saves storage space entailed in the enriched attribute values. The contributions of this paper can be summarized as follows:

- We formulate the problem of experts labeling effort minimization with respect to a database and a list of queries.

[1] This methods involve NER-based solutions and assumed to be given, hence it is out of the scope of this paper.

SELECT * **FROM** `Shirts` **WHERE** `color` = 'Red' **AND** `material` = 'Linen'
SELECT * **FROM** `Shirts` **WHERE** `color` = 'White' **AND** `material` = 'Linen'

Figure 2: Queries and their graph representation.

- We propose an algorithm that solves the special (yet highly common) case of having at most two expressions per query and provide theoretical analysis of this algorithm.
- We extend the solution to a streaming scenario, where queries are processed piece-by-piece in a serial fashion, and provide approximation guarantees for our approach.
- We conduct an experimental evaluation with a real-world setting, demonstrating the efficiency and effectiveness of our approach, with respect to the number of annotation tasks and the additional storage required.

The paper is organized as follows. The next section defines the model and the problem statement and describes the technical details of the solution (Section 2). We then present our experimental evaluation (Section 3). Finally, we discuss related and future work (Sections 4-5).

2 OUR APPROACH

We start by explaining the data model composed of queries and attributes, followed by the description of the algorithm and its online fashion variant for the streaming scenario.

2.1 Preliminaries and Model

Data: Our model consists of a database $\mathcal{D}$ with relation $\mathcal{R}$, a set of attributes F occupied with values for all $t \in R$ and a set MF of attributes with missing values for some (or all) $t \in R$. Each of the attributes has its domain, the set of all possible values per attribute, i.e., $dom(A_i) = \{v_i^1, v_i^2, ..., \}$.
Binary Classifier: Missing attribute values can be discovered with full certainty by constructing a proper *binary* classifier based on labeled data generated by domain experts[2]. Formally, a binary classifier maps every tuple $t \in R$ with its predefined attributes values to $\{0, 1\}$, and can be used for filling holes in missing attribute values. For example, followed our running example, the predefined attributes F are all the $product\_*$ attributes (title, image, price, etc.) while two missing attributes are *color* and *material*. In order to reveal missing values for colors, one can learn binary classifiers for various colors that indicate whether a tuple t has the objective color, e.g., $C_{red}(t) = 1$ if t is red. Figure 1 depicts a small sample of such relation that contains products from "Shirts" category. Note that since data is provided by various sellers, the information is concealed within different patterns, usually semi-structured or free-text fields. In some cases the relevant missing values exist only in the title, in other in the description, or in a combination of both. Hence, extracting the desired attributes is a difficult task, which needs well-trained classifiers. We assume that the construction of every classifier is the same. We discuss how to relax this assumption in Section 5, which is a part of our ongoing work.

Queries: In addition to the information stored in $\mathcal{D}$, there is a set of queries Q that is used to extract the relevant tuples from $\mathcal{D}$. The queries assumed to be only over missing attribute values[3]. Formally, the query is of the following form:

```
SELECT * FROM R WHERE `A_1` = 'v_1_j1' AND
`A_2` = 'v_2_j2' AND ... AND `A_n` = 'v_n_jn';
```

We denote the queries that specify all the attributes from MA as *full queries*, while the queries that specify only subset of MA as *partial queries*.
Query Expressiveness: We assume that queries may specify up to two equality expressions over a set of missing attributes values MF. While this sounds limiting, having one or two tokens is the most common case both in e-commerce [3] and general purpose search engines [7]. Extending our solution to multi-criteria queries is a part of the open problems and ongoing effort discussed in Section 5.
Graph Model: We represent the set of queries in an undirected graph $G = (V, E)$, where the vertices V are the values that appear in the queries (unique per attribute) and the edges E correspond to the queries such that if a query clause consists of two equality expressions with values v_1^j and v_2^l of attributes A_1 and A_2, resp., we construct an edge between their corresponding nodes in the graph. To support partial queries with one equality expression, we use self edges on the corresponding node. Figure 2 illustrates the set of unique queries and their corresponding graph representation. The graph consists of 6 nodes, 3 unique value per each of the attributes and 5 edges (the number of queries). Note that the graph is not necessarily connected. For example, removing in the mentioned example the "white linen shirt" query, splits the graph into two separate connected components. In addition, the provided example has no self-loops since all queries have two expressions. Adding a query such as:

```
SELECT * FROM `Shirts` WHERE `color` = 'Black';
```

generates a self-loop in the graph ("B" node).

2.2 The Algorithm

We start by presenting the *offline* algorithm assuming the set of queries is given as a whole. We extend our solution to support streaming fashion in the next subsection. Considering the general case, the algorithm should determine the set of suitable binary classifiers: either a *query-oriented* classifier corresponding to specific query (denoted by "label the edges") or a *predicate-oriented* classifier corresponding to single attribute value (denoted by "label the nodes"). The goal is to minimize the number of classifiers that are sufficient to answer all queries. Note that in order to answer all queries, our algorithm must determine which edges and nodes to assign a classifier.

Assuming a relation $\mathcal{R}$ and a set of queries Q. The algorithm first constructs a graph representation of the queries, as described

[2] A common method of *multi-label classification* amounts to independently training one binary classifier for each label [16]. There are other solutions, e.g., reduction to the *multi-class classification* problem or adaption methods, which are out of the scope of this work.

[3] Clauses that involve F attributes can be filtered without any classification.

in previous section. For every connected component C in the graph, the algorithm determines whether labeling edges or nodes (in accordance with query-oriented and predicate-oriented classifiers, resp.) by calculating $|E_C|$ and $|V_C|$. If $|E_C| \geq |V_C|$, the algorithm labels nodes[4] and edges otherwise. Since we focus on connected components, the number of edges $|E_C|$ is at least $|V_C| - 1$. Therefore, the algorithm labels edges if and only if $|E_C| = |V_C| - 1$, i.e., if the connected component is a tree.

Lemma 2.1. *Given a relation $\mathcal{R}$ and a set of queries Q with a corresponding graph $G = (V, E)$, the algorithm minimizes the number of classifiers that are sufficient to answer all queries.*

Proof. Since connected components are independent, it suffices to prove correctness with respect to a single connected component C. Assume that there is a better solution with a set of classifiers T, $|T| < min(|E_C|, |V_C|)$. If C is a tree with $|E_C| = |V_C| - 1 < |V_C|$ then there is an edge (v_{q_i}, v_{q_j}) with no query-oriented classifier from T and at least one of v_{q_i} or v_{q_j} does not have a predicate-oriented classifier in T. Thus, the query corresponds to this edge is insoluble. On the other hand, let $|V_C| \leq |E_C|$, then some v_{q_i} does not have a predicate-oriented classifier in T, thus all $(v_{q_i}, u) \in E$ must have query-oriented classifiers, $d = |(v_{q_i}, u) \in E|$. Since a query-oriented classifier matches a single edge, the number of edges is reduced by d while the number of nodes is reduced by at most d, since otherwise v_{q_i} and its neighbours form a tree. Thus, applying these query-oriented classifiers induces a sub-graph $C' \subset C$ with at least $|V| - d$ nodes and $|E| - d$ edges. Since $min(|V| - d, |E| - d) > |T| - d$ it follows, by induction, that the set of classifiers is insufficient to answer all queries. □

Corollary 2.2. *Let q be a partial query, v_q its corresponding vertex and C_{v_q} the connected component containing v_q, then the set of classifiers derived by labeling all nodes in C_{v_q} is a minimal set that suffices to answer all queries projected to C_{v_q}.*

Proof. Since partial query with one attribute corresponds to a self-loop in a graph, a cycle is created. Therefore, the connected component is not a tree and its nodes should be labeled. □

2.3 Online Algorithm

We now assume that the queries arrive in a streaming manner, i.e., piece-by-piece in a serial fashion, and the algorithm makes a decision based on limited information.

The practical motivation for this setting is the common scenario where the already existing classifiers are not sufficient to provide accurate answers to users' query, thus a deficient result is retrieved based on a simple full-text query against a text index. to improve for future times where such a query will be issued, suitable labeling tasks are generated.

Here again we assume a relation $\mathcal{R}$ and a set of queries Q arriving in a streaming manner, one at a time, and our algorithm makes labeling decisions that may later turn out to be sub-optimal. Our algorithm initializes an empty graph and for every query q being processed, it updates (or creates) the connect component C_q with the corresponding edge and nodes. Similar to the offline version, it labels the new edge if C_q is a tree, and the nodes o/w.

Lemma 2.3. *Given a query q being processed from a stream of queries, v_q its corresponding vertex and C_{v_q} the connected component containing v_q. If the algorithm decides to label the node v_q, the optimal strategy henceforth w.r.t to C_{v_q} is labeling nodes.*

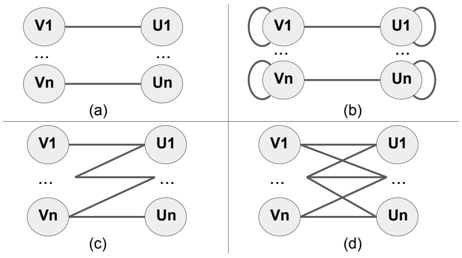

Figure 3: Worst case analysis of "label the edges" strategy.

Proof. Given a query q with vertex v_q within connected component C. Assume that $|E_C| \geq |V_C|$ for the first time immediately after updating the graph, and the algorithm decides to label v_q. Now, since every processed query q' with v'_q in C contributes at most one vertex and at least one edge to C, it follows that $|E_C| - |V_C|$ can only increase and $|E_C| \geq |V_C|$ holds. □

For every connected component C, we refer to the point when C abandoned its tree structure, as the *swapping point*, since our strategy swapped from label edges to label nodes.

Relative Bounds Analysis: First, as proven in Lemma 2.3, once we have swapped strategy from labeling edges to labeling nodes, the optimal strategy is labeling nodes henceforth. Thus, our error derives in between those states, if exist. Till the swapping point $|V_C| - 1$ edge classifiers were generated and in the worst case, each one of them turns out to be redundant. On the other hand, since every solution must contain at least $|V_C| - 1$ classifiers, our approximation ratio is at most 2.

We now illustrate two unfortunate cases. In Figure 3a there are $|E|$ connected components, each consists of two nodes and one edge. Figure 3b makes the original strategy sub-optimal, where each connected component has one redundant edge classifier. In this case, the ratio is $(n + 2n)/(2n) = 3/2$. Figures 3c and 3d present the worst case scenario where the graph is a tree till the swapping point. Therefore, the approximation ratio in the case is $(|V_C| - 1 + |V_C|)/|V_C| = 2 - 1/|V_C|$, demonstrating we can make the relative error as close as we like to 2.

3 EXPERIMENTAL EVALUATION

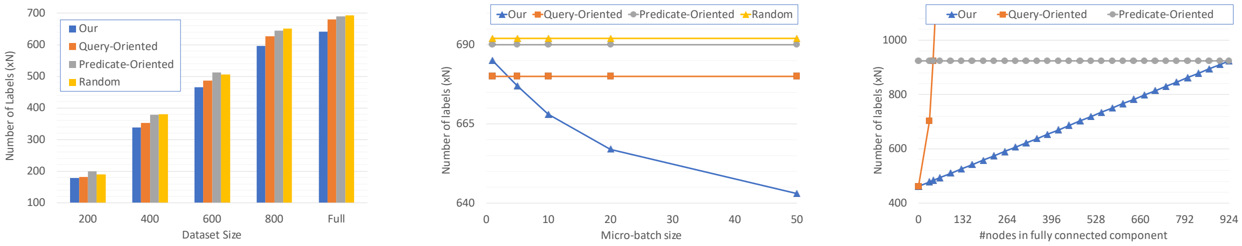
3.1 Experimental setup

Competitors: To evaluate our approach we implemented our algorithm and its three natural competitors. Given a query graph:

- **Predicate-Oriented** - Regardless of any relationships among the queries, the algorithm always labels nodes.
- **Query-Oriented** - Regardless of any relationships among the queries, the algorithm always labels edges.
- **Random** - The algorithm randomly decides whether to label nodes or edges, till it has sufficient information to answer all queries.

Dataset: The dataset contains a real-world public dataset taken from BestBuy with around 1000 search queries over the electronics domain [1]. Each query is written in a structured format, e.g., the query "LG TV" is represented as {"*Brand*" : "*LG*", "*Category*" : "*TV*"}), which allows a straightforward execution of our experiment. The dataset contains 7 different attributes (Category, Model, Brand, ScreenSize, Price, Storage, RAM) with 97% of the queries specify up to 3 attributes: Category, Model, Brand. Out of this subset, around 95% of the queries are of length one or two (66.5% and 29.2% respectively), which corresponds to our assumption on the number of attributes in the e-commerce search queries being small. Interestingly, the longest query in the dataset contains only four attributes (Category, Brand, Model, ScreenSize).

[4] This decision has no effect in the offline case, but helps in the streaming scenario.



(a) Offline results. **(b) Online results.** **(c) Effect of queries dispersion.**

Figure 4: Experimental results.

3.2 Evaluation results

We evaluate our algorithm and its competitors with respect to two configurations: offline and online. Considering the offline configuration, we first execute the algorithms against two types of sets: (i) the full set of relevant queries (that contain one or two expressions), and (ii) randomly selected subsets of varying sizes (200, 400, 600, 800). Considering the online configuration, we simulate random arrivals of successive queries from a stream of queries, and measure the number of classifiers generated by every competitor. Furthermore, we evaluate a *micro-batching* approach, where each iteration is executed with respect to a window of queries with varying sizes (5, 10, 20, 50).

Offline Evaluation: Results are depicted in Figure 4a. As expected, our algorithm outperforms the competitors and reduces the number of classifiers as the dataset size increases. Observe that the query-oriented algorithm is constantly superior to the predicate-oriented algorithm. In general, the predicate-oriented algorithm performs better when there is a small set of attributes which covers multiple queries. On the other hand, for queries that do not share many attributes the query-oriented algorithm performs better. Since our algorithm decides the best strategy per connected component, it outperforms both competitors. While reducing “only” 5%, it may save hundreds of thousands of dollars annually in workers cost [2] and terabytes of storage (entailed in the labeled data and the additional attributes in the relation).

Streaming Scenario Evaluation: Results are depicted in Figure 4b. We can see that even in small micro-batches of size 5, our algorithm outperforms all competitors, and significantly surpasses the competitors for larger windows. Observe that only in the extreme case of completely online scenario it is sub-optimal.

Queries Dispersion Evaluation: In this set of experiment, we examine the effect of attributes overlapping between queries on the number of labeling tasks. To examine it, we fix the size of the graph with n nodes and vary its density by increasing the size of connected components, from 2 to n, which corresponds to the queries dispersion. Figure 4c depicts the results for our algorithm and its two deterministic competitors: predicate-oriented and query-oriented algorithms. First, we can see that our algorithm is consistently superior with comparable competitors in the two extreme cases. In between those cases, our algorithm beats the competitors by large margins and when $|E| = |V|$, it conducts approximately two times less labeling tasks.

4 RELATED WORK

In recent years, crowd workers and human experts are widely employed with various tasks to amend the performance of supervised ML models, e.g., contributing to feature selection [13], learning of semantic attributes [18] and others. Several systems propose hybrid mechanisms [5, 14, 17] that interweave humans and machines. One family of algorithms focus on reducing the error of crowd annotators [4, 8], e.g., combining crowd and machines for multi-predicate classification tasks [11]. In contrast to the probabilistic models employed in these algorithms, they are less suitable for the experts-based setting. To the best of our knowledge, this is the first attempt that aim at minimizing the effort of experts in annotation tasks and the required storage entailed by obtaining classifiers sufficing to answer a set of queries.

5 FUTURE WORK

The most intriguing direction is extending our approach to support longer queries, which is our main ongoing process. Simply extending our graph representation to queries with multiple equality expressions results in a hypergraph representation, thus other approaches might be more suitable. In addition, supporting general weights for various classification tasks, is interesting. Finally, extending our evaluation to additional datasets with different types of queries is a part of our future work.

Short Paper

A Galaxy of Correlations

Detecting Linear Correlated Clusters through k-Tuples Sampling using Parameter Space Transform

ABSTRACT

In different research domains conducted experiments aim for the detection of (hyper)linear correlations among multiple features within a given data set. For this purpose methods exist where one among them is highly robust against noise and detects linear correlated clusters regardless of any locality assumption. This method is based on parameter space transformation. The currently available parameter transform based algorithms detect the clusters scanning explicitly for intersections of functions in parameter space. This approach comes with drawbacks. It is difficult to analyze aspects going beyond the sole intersection of functions, such as e.g. the area around the intersections and further it is computationally expensive. The work in progress method we provide here overcomes the mentioned drawbacks by sampling d-dimensional tuples in data space, generating a (hyper)plane and representing this plane as a single point in parameter space. By this approach we no longer scan for intersection points of functions in parameter space but for dense regions of such parameter vectors. By this approach in future work well established clustering algorithms can be applied in parameter space to detect e.g. dense regions, modes or hierarchies of linear correlations in parameter space.

1 INTRODUCTION

Typing into Google Scholar [1] the query **"linear correlation between"** yields around 343.000 scientific works from various domains such as medical science, chemistry, biology, pharmacology, electric engineering, economics, physics. Further limiting the search by adding "multivariate" to the previous query reduces the results down to around 20 scientific works. The insights are here twofold: first, there is a demand for detecting linear correlations in various domains and second, as for now only few scientific works have investigated linear correlations between multiple variables. One real-world example for linear correlations among multiple features is in the wages data set[2]. It contains the statistics of potentially influencing factors of wages from 1985 Current Population Survey. Visualizing the data reveals that there are linearly correlated clusters among the features "years of education", "years of work" and age. As a second example in the scientific domain of water research in a work by [4] the authors revealed a linear correlation between the hydroxyl-radical concentration and the inactivation time of E.coli in a photocatalytic disinfection substance.

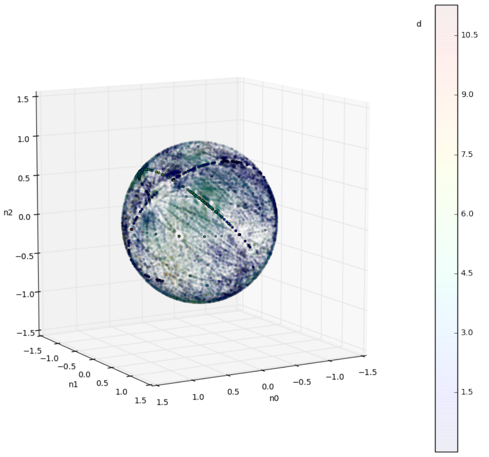

Figure 1: Triple of 3D data points sampled in data space yield this spherical galaxy of correlations in a Hessian Normal Form parameter space. Highly dense regions represent areas with high correlations between data points.

Among the various methods for detecting linear correlated clusters in high dimensional data there is one particular method which relies on parameter space transform: CASH [1]. This method comes, compared to its competitors, with advantages that it is highly robust against noise and detects global linear correlated clusters, being independent of any kind of locality assumption. As we shall elaborate more in detail in section 3 this method works by projecting data points from data space to parameter space becoming a data point functions. The parameter space is then scanned for intersections of such data point functions which represent data points being linearly correlated. However the scan for intersections in parameter space is computationally expensive and the capabilities to further analyze the area around the intersection areas are not given by this approach. We provide the following two major contributions in this work:

- Providing a novel approach for detecting regions of intersection by generating d-dimensional samples from which a linear function is derived. This linear function is then represented in parameter space as a vector eliminating the need to scan for intersections resulting in galaxy-like shapes as seen in Figure 1 and
- An opportunity to analyze further aspects on the detected clusters such as e.g. different densities and thus variances

Table 1: Selected Parameter Transform Methods

Method	Strategy	Strengths	Weaknesses
Hough Transform	grid-based (accumulators)	Simple strategy	No pruning
CASH	iterative parameter axis splitting	efficiency from DFS	Slow on high-noise data
D-MASC	De-noising with Mean-Shift, Rasterization of functions	Effective against high levels of noise	slow on low-jitter and low-noise data

of linear correlated clusters as well as density connected clusters and their semantics.

2 RELATED WORK

The parameter transform, which is also known as Hough transform, has been first introduced in a patent by Paul V.C. Hough in [6] in context of edge detection on images. The first application of parameter transform in context of detecting (hyper)linear correlated clusters was in the work by [1]. This approach despite its high level of sophistication suffered regarding its runtime if the data has a high amount of noise and jitter. To approach this issue in a recent work [7] the authors provide a method in which the data is pre-aggregated using Mean Shift [3] in data space which yields modes. These modes are transformed into mode-functions in parameter space, which then are rasterized into cells. Those cells from mode functions which are overlapping most with other mode-function cells are considered as candidates for linear correlated clusters. All the mentioned related works aim primarily at finding intersections in parameter space at a specific resolution. The intuition behind this resolution is that the smaller the detected cells in parameter space, the more are the points located on a specific line, plane or hyperplane. An overview on the mentioned linear parameter transform methods are provided in Table 1. It would be of interest to detect e.g. chains of dense regions by applying DBSCAN [5], or centroids by applying centroid or mode based methods such as e.g. MeanShift, or determining hierarchies of linear correlated clusters by applying e.g. single-link to the parameter space. Since we are dealing with functions and not with points in parameter space, we can not apply the mentioned methods.

3 PROJECTING SAMPLED K-TUPLES TO PARAMETER SPACE

Having given an overview on the related work, we elaborate in this section on our work in progress in more detail and compare it to the currently used approach. In the methods described in the related work section, each data point p_i in data space $\mathbb{D}$ is projected to parameter space $\mathcal{P}$ as a data point function $p_i \mapsto f_{p_i}$ where $f_{p_i} := b = y - m \cdot x$, where m represents the slope of a line and b the intercept. An intersection of several of such data point functions at a specific point (m_s, b_s) means that their corresponding data points are located on a line with a common slope and common intercept as it can be seen in Figure 2. Since data points are rarely located perfectly on a line, in the related work it is looked for at least *minpoint* data point functions intersecting within a maximum (m, b)-range. Here *minpoint* is a hyperparameter set by the domain experts. Further regarding the range, the intuition is the following: the smaller the range for the slope and intercept, the more precise are the data points located on an explicit line, and the higher the linear correlation.

In contrast to the related work, in our method all k-Tuples (here all pairs) of data points are taken. From these tuples (p_i, p_j), for each of them a line with a specific slope and intercept is calculated. From the lines we obtain the slope and intercept for each tuple which is a point in parameter space. A point or region in parameter space where these slope-intercept coordinates are densely located represent a correlation in data space as it can be seen in Figure 2. In a formalized manner:

$$\forall (p_i, p_j), where p \in \mathcal{D} : (p_i, p_j) \mapsto f_{p_i, p_j} = (m_{p_i, p_j} . b_{p_i, p_j}) \in \mathcal{P} \tag{1}$$

,

For detecting the dense regions in parameter space we apply density based clustering algorithms such as DBSCAN [5] and OPTICS [2]. In DBSCAN we have two hyperparamters, namely *minpoints* which defines the minimum number of data points which are expected to be located within an *ϵ-neighborhood*. In context of the parameter space, the effects of controlling minpoints and ϵ are the following:

$$\begin{aligned} minpoints &\mapsto |S| \in Corr_{(m,b)}, \\ where \quad S &:= \{(p_0, p_1), ..., (p_i, p_j)\} \subseteq DB \\ and \quad \epsilon &\mapsto \sigma(Corr_{(m,b)}) \end{aligned} \tag{2}$$

Here the intuition is as follows: the minpoints in DBSCAN represent the minimum number of data point tuples which are expected to have the same parameter values (or value ranges) and thus belonging to the same linear correlation. The ϵ hyperparameter represents the variance σ or resolution we allow for the data points around a linear correlation.

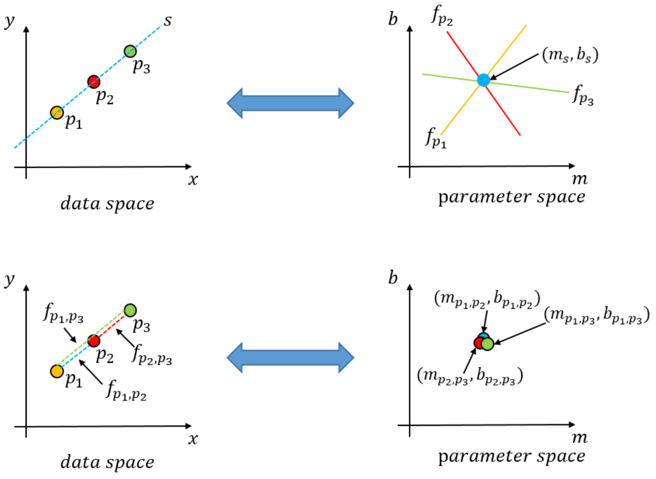

Figure 2: Comparison of current parameter space transform approaches (top) to our method (bottom).

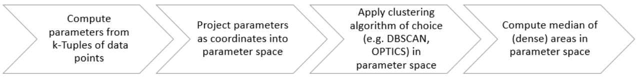
At this point we have to highlight that a question which may rise immediately is: how do we choose the two parameters? This can be partially addressed by using OPTICS which eliminates mostly the issue of determining a proper ϵ value and enables the detection of density hierarchies. Having determined the dense regions or sampled linear correlations, our method computes the median of such regions. The median comes with a pleasant effect that it weeds out the influence of outlier k-tuple correlations in parameter space. As for now our method can be summarized into the following steps as it can be seen in Figure 3



Compute parameters from k-Tuples of data points
Project parameters as coordinates into parameter space
Apply clustering algorithm of choice (e.g. DBSCAN, OPTICS) in parameter space
Compute median of (dense) areas in parameter space

Figure 3: Pipeline with its single stages of our method.

The parameter space provided in our example is the slope-intercept form. There is a variety of linear parameter space representations. Since the slope-intercept form comes with various drawbacks (unbounded dimensions, unable to project y-axis parallel linear correlations, non-ambiguous representations in higher dimensions etc.) we use in this work the Hessian Normal Form (HNF) since it comes with the advantages of the slope-intercept and other representations but with none of their disadvantages as stated in [8]. In the HNF representation a line or (hyper)plane is represented through:

$$\begin{aligned} \delta =< p, n >, where p := (p_0, p_1, ..., p_d) \in \mathcal{D}^d, \\ and \quad n := (n_0, n_1, ..., n_d) \in \mathcal{P}^d \end{aligned} \tag{3}$$
,

Here n represents the normal vector and δ represents the distance from origin orthogonal to the hyperplane.

Further we shall see in the complexity section why a full k-Tuple construction is computationally infeasable, especially in higher-dimensional settings.

4 COMPLEXITY

The runtime complexity of the related work CASH is in worst case $O(s \cdot c \cdot n \cdot 2^d)$ where s reflects the number of intersections and thus the resolution of the grid, c denotes the number of found clusters, n represents the number of data points in the data set and d stands for the dimensionality of the data space. In comparison D-MASC has a runtime complexity of $O(Tn\log(n)+(\frac{len(bounds_d)}{w})^d m^2)$ with T denoting the number of iterations of the MeanShift algorithm for initially reducing noise and jitter in data space, $len(bounds_d)$ representing the range of the parameter space range in which we are looking for intersections, w standing for the width of the cells being generated in a rasterization process and m for the number of resulting modes after applying MeanShift. Our method requires for computing the parameter coordinates for all data point all k-tuples, where k corresponds to the dimensionality d of the original data set. With regards to the dimensionality, we require in a 2D data set all two-tuples, in a 3D data set all three-tuples etc. This yields a runtime of $O(\binom{n}{d})$. DBSCAN requires with an indexing structure that executes the neighborhood query an overall runtime of $O(n\log(n))$. Thus we get for our method in total a runtime of $O(\binom{n}{d} + n\log(n))$. From a runtime point of view, our method has an exponential runtime with regards to the dimensionality like CASH and D-MASC. However instead of generating all $\binom{n}{d}$ tuples, one strategy is to sample over the data points. In some preliminary experiments we could observe that sampling yielded in most cases as accurate results as performing a full enumeration of all k-tuples. As for now, our assumption is, that if data points are correlated in data space, so do their samples reflect the correlation up to a certain extent. However, since this is a work in progress, an exhaustive analysis on theoretical as well as on experimental level is required to prove the assumptions.

5 EXPERIMENTS AND DISCUSSION

Now that we have elaborated on our method and its runtime complexity we provide here experiments which focus on the quality of the detected clustering results. As a first experiment we take one of the data sets which is used in D-MASC. The two-dimensional data set consists of 100 data points contributing to three linear correlated clusters with irregular densities. To these 100 data points 90% noise is contributed. According to the pipeline mentioned in section 3, first all 2-tuples of data points are created, then projected into the parameter space. In the parameter space we can already observe dense regions. Applying OPTICS we get the following plot as seen in Figure 4.

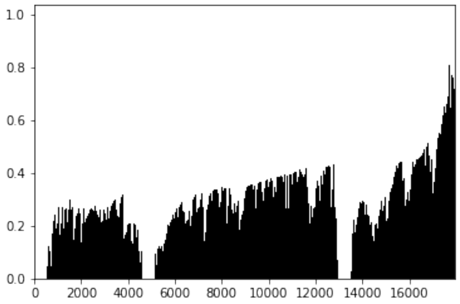


Figure 4: OPTICS plot of the parameter vectors in parameter space.

The three valleys indicate three almost equally high-dense regions in parameter space. As a result of DBSCAN with $minpoints = 33$ and $\epsilon = 0.015$ we obtain the following regions in parameter space which are marked with an 'x' in Figure 5

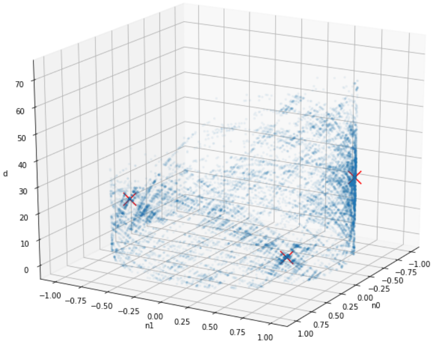

Figure 5: Detected three high-density regions in parameter space.

After having computed the median from each of the dense regions, our method was capable of detecting all three linear correlated clusters with all the data points being assigned to their respective cluster as it can be seen in Figure 6.

As a teaser for its performance on data sets with a dimensionality higher than two, we have a three dimensional data set

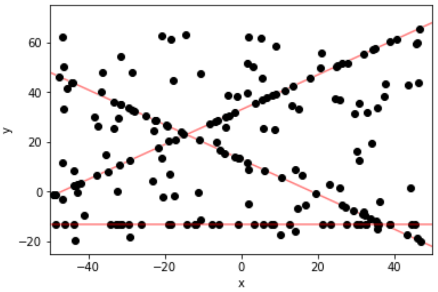

Figure 6: Detected three linear correlated clusters in data space.

consisting of 66 data points. From which 36 data points belong to planar correlations and 30 data points are randomly generated noise. The 36 data points belong to two planar correlated clusters, with 18 data points per correlation. In parameter space we generate thus $\binom{66}{3} = 45760$ parameter vectors in parameter space. Our method detects in parameter space two clusters as it can be seen in Figure 7 where two very deep valleys can be seen. The first figure in the introduction of the paper is the actual parameter space of this data set. The three axes represent each a dimensional of the normal vector. The color (black) represents the distance δ. The parameters for the density based clustering were $minpoints = 250$ and $\epsilon = 0.01$.

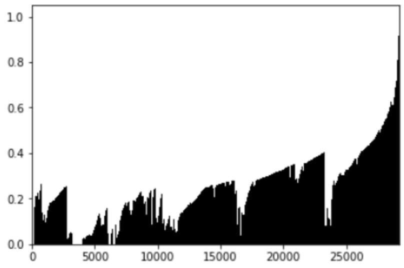

Figure 7: OPTICS plot of the 3D data set with two highly-dense clusters.

As an result we get both planes detected correctly and all points assigned to their corresponding planar correlated clusters as seen in Figure 8.

6 CONCLUDING REMARKS AND FUTURE PROSPECTS

In this work in progress, we have provided a first concept for a different approach in detecting (hyper)linear correlated clusters in parameter space by sampling k-Tuples in data space, generating k-dimensional (hyper)planes. The parameters of these (hyper)planes are projected to parameter space. In the parameter space we used as an example density based methods for detecting highly dense regions. This approach of dealing with points in parameter space instead with (hyper)linear functions opens new possibilities of analysis. Primary targets for future work are evaluating sampling strategies, applying the experiments to high-dimensional and also real world data and evaluating different clustering models in parameter space (hierarchical, centroid-based, subspace etc.). We hope to encourage with this paper to

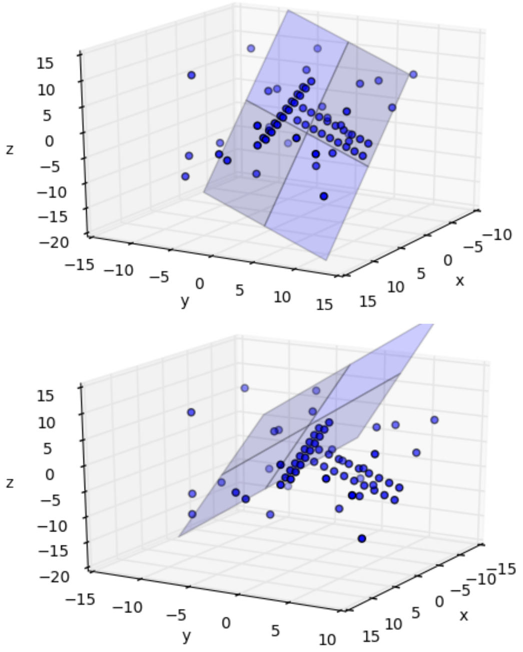

Figure 8: Two planar correlated clusters

not only develop different approaches for clustering using parameter transform itself, but also fostering the research of parameter space transformation based methods making discoveries in the galaxies of correlations.

ABSTRACT

In recent years the demand for having algorithms which provide not only their results, but also add explainability up to a certain extent increased. In this paper we envision a class of clustering algorithms where the users can interact not only with the input or output but also intercept within the very clustering process itself, which we coin with the term process-aware clustering. Further we aspire to sketch the challenges emerging with such type of algorithms, such as the need of adequate measures which evaluate the progression through the computation process of a clustering method. Beyond the explainability on how the results are generated, we propose methods tailored at systematically analyzing the hyperparameter space of an algorithm, determining in a more ordered fashion suitable hyperparameters rather then applying a trial-and-error schema.

1 INTRODUCTION

Performing a query to the computer science bibliography search engine dblp with the keyword "explainable"[1] delivers an interesting insight looking at the "refine by year" area of the search result as it can be seen in Figure 1 . As for now (November 2018) the number of publications dealing with the aspect of explainability increased from 33 in 2017 up to 101 in 2018. However the scientific works are tailored towards deep learning systems. Since it can be agreed on that deep learning systems have some kind of black box character as stated in e.g. [8], classical clustering methods are fairly transparent regarding the way they generate the clustering results. In the majority of publications dealing with clustering, the whole system can be represented as in Figure 2. Data is given to a clustering algorithm additionally with hyperparameters. The algorithm of choice is executed on that data and yields a clustering result. If clustering methods are already transparent and so easy to comprehend, why should we bother then with the aspect of explainability? Despite the fact that we know how a clustering algorithm works, questions arise like e.g. "what is a good hyperparameter setting?", or "how do my clusters change (or not change) with different hyperparameter settings?", "why did the clusters change that particular way choosing different settings?". Only because we know how the clustering algorithms work, we do not yet fully utilize the potential of this knowledge. Having algorithms like e.g. MeanShift [3] domain experts may want to know what happens with the emerging clusters during the clustering process to understand the resulting clusters. In this vision paper we elaborate in the upcoming sections more in detail on different aspects which are ultimately connected to the idea of including insights from the clustering process itself. For this we address in our vision targets such as points of interaction, hyperparameter analysis, methods and measures as well as potential impacts of our vision on areas such as explainability and didactics. During our tour through these targets we will mention the current related work, and highlight potential difficulties and needs motivating the need for process-aware clustering.

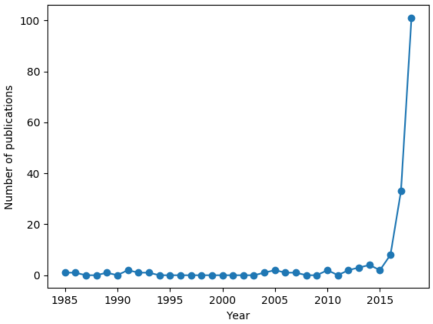

Figure 1: Number of publications indexed at dblp for the keyword explainable from 1985 to 2018.

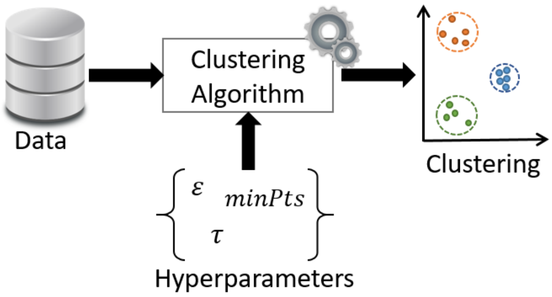

Figure 2: A classic clustering pipeline.

2 INTERACTION TARGETS

In context of interactiveness a rich body of literature is present. Exemplarily we mention iPCA as an interactive tool for PCA-based visual analytics [5]. Despite its high level of sophistication regarding the used visualization techniques, it enables the user to interact with the system *after* a PCA has been performed. The users can not browse through some imtermediate computation steps of PCA and intercept. Also advanced interactive clustering tools like VISA [2] enable human interaction for inspecting the detected clusters and subspaces but do not facilitate to intercept within the clustering process itself. Even in a more recent work

[1] https://dblp.uni-trier.de/search?q=explainable

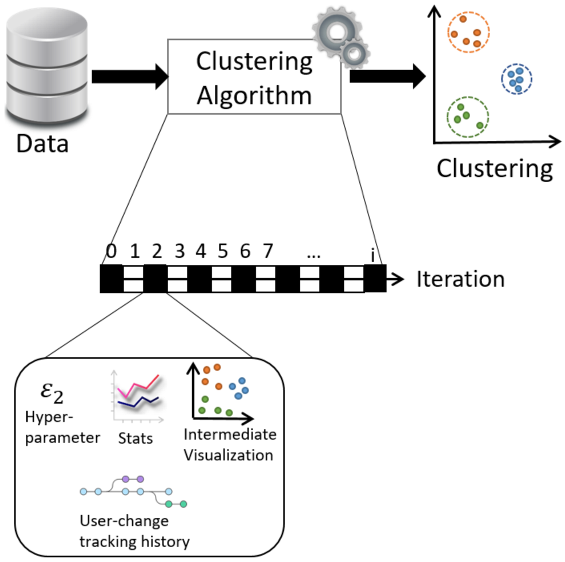

Figure 3: Clustering pipeline in an interactive setting where the users can intercept within each of the steps of the clustering.

[9] , the users can decide on modifying the results in context of hierarchical clustering, yet they do not offer a history of steps which the utilized hierarchical clustering has performed so far.

In a more recent work, a simple but also limited tool PARADISO [6] provides the users the opportunity to explore and intercept within the clustering process itself. In PARADISO our classic clustering pipeline from Figure 2 is re-defined to a pipeline as seen in Figure 3. Here the users can intercept at each of the iterations of a MeanShift algorithm. In this algorithm data points roam within a specific bandwidth (also known as Parzen window) to their mean with regards to the position of other data points located within the bandwidth. The data points thus roam themselves towards their respective mode. In PARADISO the bandwidth hyperparameter can be modified, stats regarding the current clusters are provided, and visualizations for intermediate results at each iteration step are given.

2.1 Multi-instance hyperparameter settings

One aspect from PARADISO which we'd like to emphasize on, is the capability to assign at any iteration step of the algorithm a different bandwidth value, which we coin with the term multi-instance hyperparameter setting, where multi-instance refers to either the iteration step or in general the steps of a clustering algorithm. Going beyond the classical setting where the users provide in the beginning one fixed (set of) hyperparameter(s) which remain(s) valid until the end of an algorithms run, leads us to the case of intercepting within the clustering process and deliberately changing the hyperparameter values at different times. This method becomes even more significant in streaming context. By the simple fact that in a stream setting the data changes over time, a hyperparameter which has been selected in the beginning may no longer be suitable. Thus we may need different hyperparameter values at different times while a clustering algorithm is computing at each iteration on different snapshots of the data.

Further in context of multi-instance hyperparameter settings it is vital to keep track of which changes the users have made. Similar to a version control system, the users shall be given a tool at hand to keep track of the history of changes they have made. By knowing which changes have been made at which iteration, the users can move arbitrarily through the iteration timeline and create alternative branches of changes. Despite giving new targets of interaction, like changing at arbitrary iterations the hyperparameters, the concepts of interactivenes as described so far do bare their own problems which need to be addressed: While on small amounts of data the intermediate computations can be stored, it is in-feasible to store each of the iteration steps at larger data sets. Here potential research targets are e.g. compression strategies and significance measures to determine which of the iteration steps are relevant (enough) to be kept in memory. Such measures could indicate e.g. at which iterations the most changes are taking place.

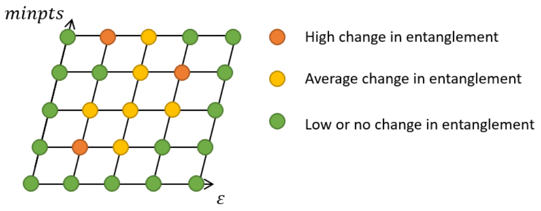
One question which may arise in context of multi-instance hyperparameter settings is: what are the implications of such an approach? What would it change if we choose different bandwidths *within* a MeanShift run vs. re-running MeanShift multiple times with different bandwidths? Suppose we are given a data set and apply the MeanShift algorithm with a specific bandwidth (e.g. 0.7) in the beginning. Depending on the data set it may happen that a subset of points collapses after a few iterations into one mode. Intercepting a few iterations beforehand by choosing a much smaller bandwidth (e.g. 0.2) may prevent the collapse to one singular mode, leading to multiple modes. Depending at which iteration the interception has taken place, a re-run of MeanShift with a bandwidth of 0.2 may not lead to the same result as in the variant where we start with 0.7 and change it after i-iterations to 0.2. However a proof for this claim is required, which is subject of future works further investigating the multi-instance hyperparameter settings aspect. Yet, we'd like to provide a brief intuition for why it can lead to different results using different bandwidths at different iterations. We envision that MeanShift executed in two instances with each having a bandwidth b_0 and b_1 is like two objects moving among distinct trajectories where time is represented through the single iteration steps. Intercepting in the MeanShift with b_1 is comparable to deflecting the object b_1 leading to a potentially different trajectory than its original path by forces from other modes acting on the object. It may lead to the same destination as MeanShift executed with b_0 but can as well have its destination at a different positions in data space.

3 MEASURING METHODS

Besides the concept of intercepting into the clustering process itself and assigning multiple instances of hyperparameters at different iteration steps, there is a need for measuring methods which are suitable in context of process-aware clustering. The requirements to such measures would be e.g. to capture the dynamics within the clustering process like data points being assigned to specific clusters or subspaces and the change of such over the course of a clustering run.

3.1 Entanglement

The first propositions for such a measure were made in [7]. Here the concept of entanglement has been raised which is intended to support interactive data clustering with the purpose to supply additional information to users. In [7], the entanglement between



minpts
ε
High change in entanglement
Average change in entanglement
Low or no change in entanglement

Figure 4: Parameter grid, with the parameters of DBSCAN. Each point represents the entanglement difference computed to its previous entanglement values.

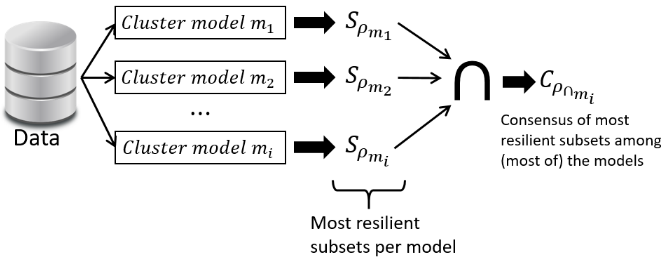


Figure 5: Resilience in context of ensemble clustering.

two data points is defined as the dynamic time warp distance between the trajectories of both points roaming over time to their modes in a MeanShift clustering algorithm. If those data point trajectory pairs are sufficiently similar to each other over the iterations, they are considered as entangled. This definition is however limited to centroid-based approaches like in MeanShift. In our vision we aspire to provide such entanglement definitions for various clustering models (e.g. density-based, hierarchical, spectral, subspace, correlation etc.) and, if possible, a more generalized definition of it.

3.2 Resilience

The entanglement of two data points can be highly varying or remaining stable. This stability depends on the chosen hyperparameters. In [7] the so called resilience has been defined, which computes the variation of the entanglement over different hyperparameter settings. The lower the variance of the entanglement at different hyperparameters, the more resilient is the specific subset of data points. However the work in [7] is highly limited to the MeanShift setting. In our vision auspicious directions include the research of resilience in context of other clustering models, especially also in context of subspaces where the resilience and entanglement is not only determined among subset of data points but also among a subset of subspaces. It remains for future work to investigate in how far the concepts of entanglement and resilience can be applied to different clustering models (e.g. density based, hierarchical, subspace, correlation, spectral etc.) and with which kind of adaptations.

3.3 Hyperparameter Analysis

The research on entanglement and resilience bares potential for the aspect of hyperparameter analysis. In many of the publications on clustering so far, the hyperparameters in e.g. the conducted experiments were chosen on an experience basis. Different settings are tried out until a good (enough) clustering result is achieved. We envision that measures like e.g. resilience can be used together with more systematic approaches in determining the quality of parameters. For example in context of density based clustering like in DBSCAN [4], where we have a minpnts and ϵ parameter, a grid-based approach can prove effective as seen in Figure 4.

Here the granularity of the grid is set by the users on how fine they want to sample the grid. It is advised to start with a coarse grid first. In an initial step, one computes for each of the (minpnts, ϵ) combinations the entanglement. Then the resilience over different parameter settings is computed. Those points on the grid (which represent (minpnts, ϵ) hyperparameters) which have the highest difference in resilience can be considered as interesting, since this specific hyperparameter setting impacts the entanglement of subsets of points. Then in a follow-up step, the grid is refined around such interesting points on the grid. The users can thus successively explore the impact of the hyperparameters. In this context the users can use clusering with a different goal in mind: given a subset of points S_{in} where we want them to be in the same cluster, and further we are given a subset of points S_{not-in} which we do not want to be in the same cluster. Under which parameter settings do we get a clustering fulfilling these constraints? In this setting it is also of interest for future research to approach the scientific problem: how can the users be informed on how "unintuitive" it would be for the clustering algorithm with its underlying model to respect the given constraints as in S_{in} and S_{not-in}?

3.4 Ensemble Settings

The concept of resilience can further be used as a measure for ensembles of clustering models. Given a dataset, in an ensemble setting, the most resilient subsets are considered per model. The intersection of the resulting resilient subsets over all the models yields a subset which is highly resilient among all (or most) of the clustering models which can be seen in Figure 5. The intuition of this intersection subset is, that it is a consensus of different cluster models at different hyperparameter settings, yielding clusters or at least subsets of clusters being valid among different cluster models. On the contrary, removing the consensus subset, leaves subsets which may be (a) not resilient among their respective models, or (b) are highly resilient, but only within their models. The latter case is exciting since this potentially facilitates the extraction of highly *model specific subsets* of data points.

4 IMPACTS

Having elaborated on interaction targets, and measuring methods, we now discuss potential impacts of our vision within the upcoming subsections providing some outlook on the potential magnitudes that this vision may trigger.

4.1 Explainability

Since we have mentioned in the beginning of this vision paper the aspect of explainability we now elaborate on this aspect as a potential impact. The propositions for methods and measures so far enable to look at different parts of an clustering algorithm. The entanglement supports to look into the clustering process itself detecting data points which have the same trajectories or are assigned to the same clusters, subspaces etc. Resilience enables to understand which data points remain (based on entanglement) together even over different hyperparameter settings. The interaction concept of multi-instance hyperparameter setting permits the users to intercept and explore the effects of choosing different values for hyperparameters during the clustering process. Each of the mentioned methods and aspects can reveal information which can, best to our knowledge, not be gained by simply adding data and some chosen hyperparameter values for a clustering algorithm that once executed only returns the clustering results. However, words of caution are also need to be stated here, since questions that remain open are e.g.: How are the information from the clustering process itself best being presented to the users, and in which form? Which other forms of interaction-tracking may be required, since with increasing number of interaction targets, also the complexity of what can be changed and observed increases.

4.2 Didactics

A connection which may not be obvious on first sight, but becomes rather evident when thinking more from an educational perspective is the relation between explainability and didactics. Besides the theory and exercises in tutorials, demonstrations of the discussed clustering algorithms significantly contribute to the understanding. For such purposes tools like e.g. ELKI [1] exist which can also be used to demonstrate how datasets are clustered and to explore the effects of different hyperparameters by re-running the algorithm every time with a different parameter setting. We are convinced that in our vision process-aware clustering can enable even more insights into the clustering process itself, understanding the behavior, the strengths and also limitations of the process-aware clustering models. It may further aid graduate students which are writing their bachelor or master thesis to evaluate the effects of potential enhancements that they develop and apply to the clustering models they are working with, providing a different approach to evaluate.

5 CONCLUSIONS

In this vision paper we have elaborated on the idea of process-aware clustering, and on its concepts which can be seen summarized in Figure 6. Regarding interaction targets, we have the pillar of multi-instance hyperparameter settings and the pillar of hyperparameter-change tracking with history. While the first pillar enables the interception into the clustering process, the latter provides the capability to track changes and explore different settings. The pillars of entanglement and resilience from the aspect of measuring methods provide the very basis for (a) hyperparameter analysis, which itself serves as the foundation for (b) ensemble settings. All the mentioned fields pose the very foundation for explainability and didactics in the field of interactive process-aware clustering. Further ideas regarding the vision would be to connect process-aware clustering with the research field of process mining. Since various methods are developed for the analysis of processes, some of them (with or without adaptations) may be beneficial to the process-aware clustering concept. Since this vision aims to reveal what happens within the clustering process itself, we conclude this vision paper with a quote from Dr. Faust from a tragic play by Johan Wolfang von Goethe:

That I may understand whatever
Binds the world's innermost core together,
See all its workings, and its seeds,
Deal no more in words' empty reeds.
−−Faust, lines 382–385.

Interpolation-friendly B-trees: Bridging the Gap Between Algorithmic and Learned Indexes

Ali Hadian

Thomas Heinis
Imperial College London
t.heinis@imperial.ac.uk

ABSTRACT

Index structures such as B-trees and bloom filters are the "petrol engines" of database systems, but these structures do not fully exploit patterns in data distribution. To address this, researchers have suggested using machine learning models as "electric engines" that can entirely replace index structures. Such a paradigm shift in data system design, however, opens many unsolved design challenges, e.g. more research is needed to understand the theoretical guarantees and design efficient support for insertion and deletion.

In this paper we adopt a different position: index algorithms are good enough, and that instead of going back to the drawing board to fit data systems with learned models, we should develop lightweight "hybrid engines", where a *helping model* "boosts" classical index performance using techniques from machine learning.

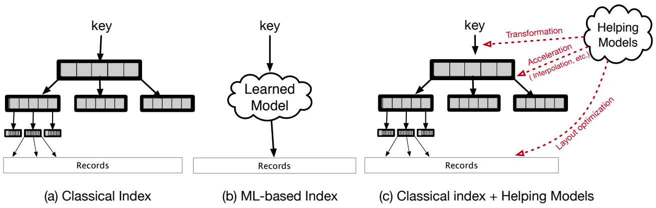
As a case study, we show how interpolation techniques can be integrated with a B-trees with negligible change to the structure and memory footprint of the base algorithm. We show that such a simple helping model, called Interpolation-Friendly B-tree (IFB-tree), can boost the speed of B-trees by up to 50%.

1 INTRODUCTION

Data engines exploit efficient implementations of algorithmic index structures, such as hash tables, B-trees, radix-trees, bloom filters, etc. Index structures fit different tasks and workloads, e.g. B-trees are efficient for range lookups and hash tables are the tool of choice for point queries. Different aspects for each of these indexes have been studied for decades. Many tuning suggestions exist, for example, for B-trees to efficiently fit hardware specifications including the latency/bandwidth ratio and cache-sizes, and various extensions have been suggested to improve the performance even further. [4, 5, 11, 12].

Recently, it was suggested that general-purpose index structures such as B-tree cannot exploit common patterns in data distribution of the real-world data, hence proposing the use of machine learning (ML) models [9]. In this approach, a learned model entirely replaces a classical index and learns how to perform the same behavior. For example, a B-tree can be replaced by a learned index (based on deep learning models) that takes the key as input and *estimates* the position of the corresponding data record in a sorted set, i.e., a clustered index or sorted list of keys.

Learned indexes can be effective for read-only lookups over many data distributions. However, lack of theoretical performance guarantees for a learned model and the challenges for handling update operations in a learned model has lead to an extensive debate in the community. In general, and similar to the analogy of 'petrol vs electric' engines, adopting machine learning techniques could yield elegant methods in data management but the design and maintenance of an ML-enhanced DBMS opens numerous challenges that require comprehensive research. In the meantime, we need hybrid engines that do not render current algorithms and indexes unnecessary. We refer to the hybrid engines as "helping models". Figure 1 illustrates a classical B-tree index (a) vs a learned index (b), the hybrid approach (c) where helping models improve a classical index on different stages.



(a) Classical Index (b) ML-based Index (c) Classical index + Helping Models

Figure 1: Alternatives for classical indexes

In this work, we try to bridge the gap between traditional index structures and the ML approach, suggesting that a helping model can be *integrated* with a traditional index without incurring undue overhead. We suggest that the ability of an ML model to make *distribution-aware* indices is not a rival for classical indexes, but indeed complements them.

We therefore present the *Interpolation-Friendly B-tree* (IFB-tree), which sticks with the traditional B-tree structures to enjoy their performance guarantees, yet is able to exploit the basic ideas of a learned index such as *bounding error-windows* for intra-node lookups. More specifically, we demonstrate how linear interpolation can be integrated with a B-tree index to reduce unnecessary operations with a negligible memory footprint. The process can be done by analyzing a B-tree and labeling *interpolation-friendly* nodes, so that further access to such nodes can be accelerated using interpolation. Our experiments show that the Interpolation-Friendly B-trees (IFB-trees) gives up to 50% improvement over B-trees.

2 TO B-TREE OR NOT TO B-TREE?

2.1 B-tree overview

The B-tree is a generic data structure. State-of-the-art B-trees are n-ary binary trees, i.e., generic data structures that do not assume any specific pattern in the underlying key distribution [4, 5, 11, 12]. B-tree lookup time consists of the time to search within each node, plus the time to follow the pointers and load the next nodes in bottom levels. This takes time and requires keeping a portion of data (inner nodes) in memory.

One of the key issues in a B-tree is that, to locate an item in each of the B-tree nodes, the entire node should be searched, either by linear scan or binary search.

In the following, we consider the alternative approaches that provide "smarter" methods for looking up keys in B-trees. The general solution for a more targeted lookup in a B-tree node (i.e., a sorted list of keys) is to use a method that effectively leverages the underlying key distribution.

2.2 Learned indexes

Machine learning provides various tools for learning a distribution. Recently, Kraska et al. [9] suggested that if a machine learning model can fully learn the CDF of the key distribution, it can directly predict the location of the queried keys in the table pages. They exploited a hierarchy of deep learned models to help shrink the problem space. Since all predictions in machine learning are susceptible to errors, the *maximum error* for the models needs to be computed in advance. Once the position is estimated, we can scan a *range* around the estimated position in the table pages. This is called the *error window*, i.e. $[\hat{pos}(key) - MaxErr_{\text{Left}}\ ,\ \hat{pos}(key) + MaxErr_{\text{Right}}]$. As shown in Figure 1(a,b), a learned index entirely replaces a classical data structure (like B-tree). If the prediction error is small enough, a learned model can ultimately beat B-tree's lookup time.

Challenges of learned indexes. A learned index can learn many complex distributions and locate the position of the key with a considerably low error margin. The idea of ML-indexes is be very effective for modeling some specific CDFs, yet ML models are not efficient for every key distribution. Moreover, state-of-the-art learned models are mostly suitable for read-only data. Despite that these models can handle a few insertions and deletions by reserving empty spaces in the sorted list, more update requests require re-training the model, which is computationally expensive. Since the model is bound to the mapping between the key's value and the position's offset, any changes to this mapping, such as inserts and deletes, make the learned model ineffective. Moreover, learned indexes require that the table pages be stored in a continuous block of memory so that records can be retrieved once the position is estimated. This assumption does not hold when the keys are not sorted, e.g. in a secondary (non-clustered) index, hence limits the applicability of a learned index.

2.3 IFB-tree

We believe that the main issue behind the challenges in a learned index is that it "replaces" an algorithmic data structure, but cannot deliver all the same operations. Alternatively, we suggest that a similar ideas of a learned index can be embedded within a data structure, such as the B-tree. Unlike the ML index approach which entirely replaces conventional index structures with a learned model over the sorted page of keys, we stick with the genuine structure of the B-tree. In fact, the B-tree itself is very effective in modeling the CDF of the key distribution by repeatedly breaking it into smaller parts. We consider the fact that a considerable share of B-tree lookup time is spent on intra-node search, i.e., to find the smallest value in a B-tree node that is larger (or equal) to the query point q. If we manage to outperform the intra-node search in a B-tree, the efficiency of B-trees can be improved without changing its theoretical performance guarantees.

Learning node distribution. Since keys are sorted in each B-tree node, we can think of a smarter lookup instead of naively doing a linear or binary search over all keys in the node. Similar to the learned indexes, a tiny model can predict the position of a key in each node, which reduces the search space within each B-tree node. However, even the simplest models (e.g. linear regression) requires keeping model parameters for each node in memory, and the cost of managing and loading the parameters does not lead to any performance improvements.

Node interpolation. Following the general idea of ML indexes, our solution is to estimate a range that guarantees the target key resides in. While *interpolation* looks like a naive approach, it could be very effective and has near-zero cost: it simply requires one bit per key, and the computation is very fast and simple. Figure 2b illustrates how interpolation can be done in a B-tree node. If the queried key v_q is between the two keys in a B-tree node, say v_i, v_{i+1} , it should be located on the next level, which could be the next node in the tree or a node in the physical table pages if the current node is a leaf. The interpolated index of the entry corresponding to v_q is: $\hat{p_q} = \left\lfloor \frac{v_q - v_i}{v_{i+1} - v_i} \times \texttt{node\_size} \right\rfloor$

The interpolation has an error, unless the keys follow an exact arithmetic progression, which is almost never the case in real-world except in case of auto-generated key sequences. Let's assume the maximum error for any value in a node is $\text{MaxErr}_{\text{Left}}$ and $\text{MaxErr}_{\text{Right}}$, respectively. This means that the area between $\hat{p_q} - MaxErr_{\text{Left}} + \hat{p_q} + MaxErr_{\text{Right}}$ should be scanned to find the actual position corresponding to v_q.

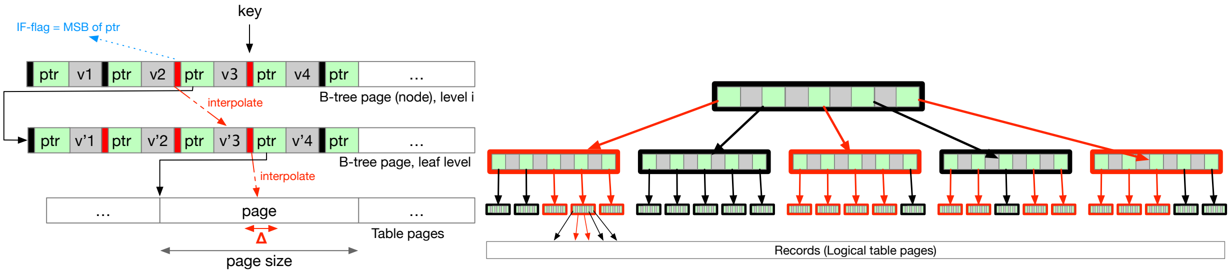
Global error window. Storing the errors values $\text{MaxErr}_{\text{Left}}$ and $\text{MaxErr}_{\text{Right}}$ alongside the keys in the B-tree node will increase the memory footprint and hence greatly reduces the performance. Moreover, having variable error values for each node makes it challenging to exploit the SIMD capabilities for interpolation and search. We prefer not to store any extra information in each node and keep the structure of B-tree untouched to the extent possible. Therefore, we define a *global* threshold for error for the entire B-tree, called the *interpolation diameter* Δ. We call a B-tree node "*interpolation-friendly*" if any key can be found with interpolation error of at most Δ, i.e. $\Delta \geq max(MaxErr_{\text{Left}}, MaxErr_{\text{Right}})$. If a node is interpolation-friendly, we can estimate the location corresponding to the query point q, say $\hat{p_q}$, and then search the area $\left[\hat{p_q} - \Delta, \hat{p_q} + \Delta\right]$, as the result is guaranteed to be in this area. Another advantage of having a pre-defined value for Δ, is that the length of the loop for searching in a node is defined in compile time, hence the program can be efficiently optimized using efficient branch-free and/or loop-unrolled code for either linear or binary search [2].

Marking IFB-tree nodes. Building an IFB-tree involves two steps. The first step is to build a simple B-tree. In the second stage, we analyze all nodes in B-tree to find which nodes are interpolation friendly. More specifically, a node is interpolation-friendly if $|p_{\text{key}_i} - i| < \Delta, \forall\ 0 \leq i \leq K$. Once a node is identified as interpolation-friendly, it should be flagged somewhere. In case that the interpolation error for a node is above Δ, the default search procedure should be used without interpolation, which can be done by either linear or binary search.

A typical B-tree node consists of a list of keys and pointers to next nodes. However, the MSB of the 64-bit pointer is rarely used in practice, because the memory address in commodity operating systems is less than 2^{64-1} bytes = 2 Exabytes. Therefore, we can use the MSB of the pointer to flag if the node is interpolation-friendly. To use the pointer, we need to mask the MSB of the pointer value before using it. Figure 2a shows the layout of an IFB-tree node. Note that if IFB-tree is used as a primary index, the data tables are sorted too, hence interpolation can be also done on the leaf node to predict the position of the result in physical table pages. Moreover, marking an IFB-tree is a lightweight process compared to B-tree build time, but it can be easily parallelized as well.

2.4 Complexity analysis

The complexity of IFB-tree is the same as the B-tree for all operations. Whenever an IFB-tree node is created or modified, the interpolation error must be re-computed for all values in the



(a) Interpolation in IFB-tree

(b) Overall layout of IFB-tree. IF nodes are marked in red.

Figure 2: Interpolation in IFB-tree

node. For a node with node size of p, the time taken to find the maximum interpolation error for all values in the node is $O(p)$. In the following, we analyze the time taken to build and update the IFB-tree and show that none of the theoretical complexities are different than that of B-tree.

Build time. . Bulk-loading data in a B-tree takes $O(n \log_p n)$ time. In IBF-trees, there is a second phase for evaluating the nodes and marking interpolation-friendly nodes, which takes $O(n)$. The complexity of bulk insertion thus is $O(n \log_p n + n) = O(n \log_p n)$.

Update time. For insertion and deletion, the complexity of the B-tree is $O(p \log_p n)$, which consists of $O(\log_p n)$ access/modification of nodes times $O(p)$ time for modifying each node. When using IFB-trees, we simply re-evaluate the interpolation-friendliness of each node when an element in the node is modified. The complexity of accessing a node thus still is $O(p + p) = O(p)$, leaving the overall $O(p \log_p n)$ complexity unchanged for update operations.

Lookup time. Finding the position corresponding to the query in each node takes $O(t)$ time if the node is interpolation-friendly (t=interpolation diameter), and $O(p)$ otherwise. Depending on how many of the nodes are interpolation-friendly. As $t < p$, the lookup time is between $O(t \log_p n)$ if all nodes are interpolation-friendly and $O(p \log_p n)$ in the worst case.

3 EVALUATION

In this section we compare the performance of the IFB-tree for both synthetic and real-world data to analyze its lookup time and the effectiveness of interpolation.

Experimental Setup. IFB-tree and B-tree are implemented in C++ and compiled with gcc (7.3.0). Note that all data resides in main memory. The range index finds the first the first indexed key that is equal or higher than the lookup key. Also, the keys on the physical layout are sorted (i.e. it is a clustered index), so that the entire result set can be returned once the first key is found.

Datasets. We used three datasets for performance evaluation, namely accessLog, lognormal, and longitudes. The accesslog data contains web-server log records from a hotel booking website. Lognormal is a synthetic data generated from lognormal distribution. Longitudes are sampled without replacement from the longitudes of over 1.5 billion locations extracted from the OpenStreetMap database [17].

Implementation details. For both B-tree and IFB-tree, we used 64-bit keys and 64-bit payload. Scanning in each node can be done by either linear or binary search. When the baseline methods use linear search, the performance improvements of IFB-trees are expected to be higher and more predictable, because shrinking the scan area will linearly reduce the lookup time in nodes. However, it is generally reported that binary search is more effective on new hardware, even for medium-sized nodes [2, 7]. We consequently use binary search for both IFB-tree and the baseline B-tree methods.

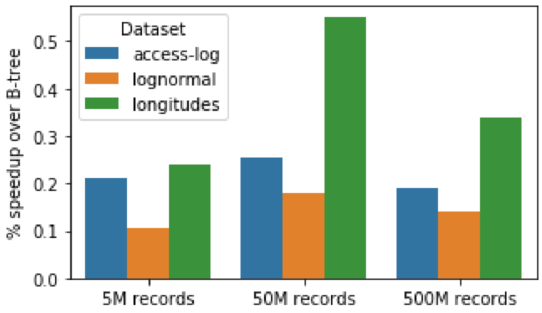


Figure 3: Speedup gained by interpolation (IFB-tree)

Speedup. Figure 3 shows the speedup obtained by the IFB-tree over the B-tree on different datasets with 5M and 500M keys. After tuning the parameters for both indexes (i.e., page size and interpolation diameter), the IFB-tree improves the performance by 10% to 55%.

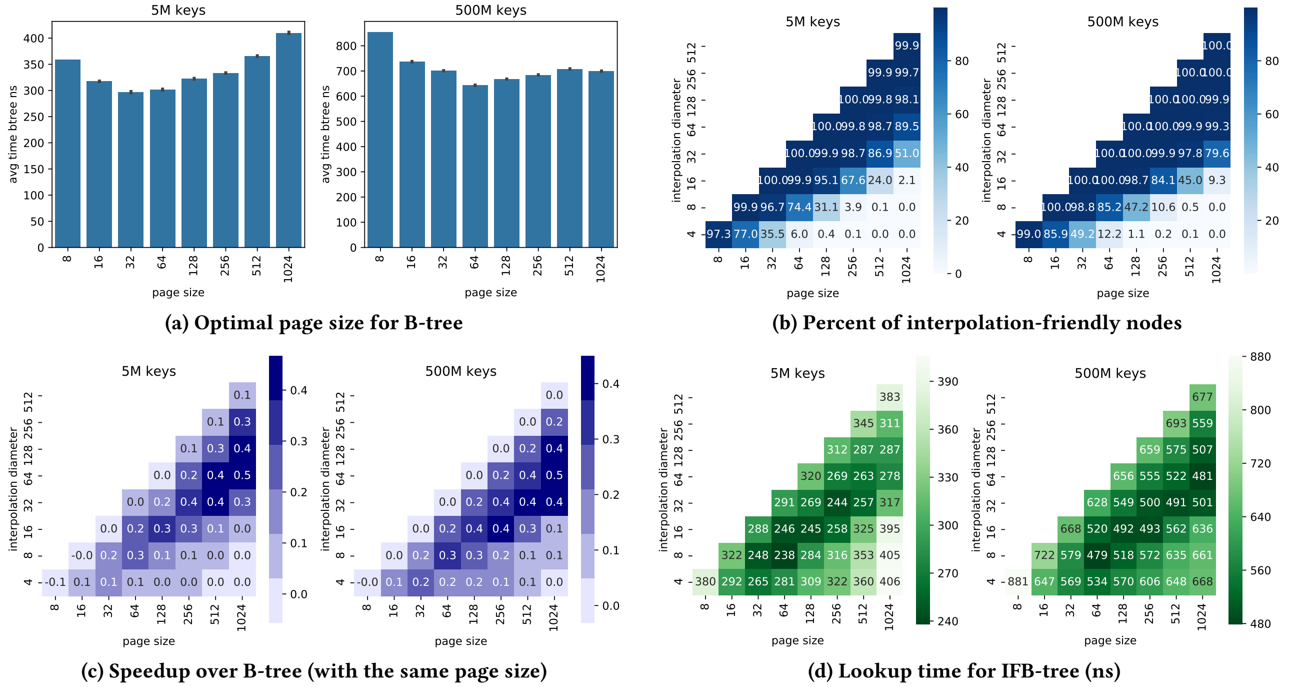
Effect of page size. The key parameter in a B-tree is the page size (= node size). Figure 4a shows how the B-tree lookup time is affected by the page size. Choosing a large page size decreases the branching factor and the tree depth, but searching through each nodes takes more time.

Speedup analysis. The performance speedup of the IFB-tree depends of B-tree nodes that are interpolation-friendly, as well as the interpolation diameter (the area that should be searched within each page). As shown in Figure 4b, the number of interpolation-friendly nodes is almost proportional to $\frac{\Delta}{\text{page size}}$, i.e., to interpolate the majority of nodes on large pages, we need a larger error window. However, a larger error window also decreases the speedup gained by interpolation. Figure 4c shows the speedup of IFB-tree against a B-tree with the same page size, suggesting that the best error window is obtained when $\Delta = \frac{1}{4} \times$ page size. The lookup times (in nanoseconds) are depicted in Figure 4d.

4 RELATED WORK

Interpolation search. Interpolation is an alternative to index structures for estimating the location of records in a clustered index. The technique is known to be very effective when the underlying data distribution is close to uniform [4].

Learning database engine. The use of machine learning on learned indices is just recently proposed. Kraska et al. suggested a learned index based on a hierarchy of deep models, called the *Recursive Model Index* (RMI) [9]. Further research is done on linear learned indexes [3], inverted indexes [18], and enhanced learned bloom filters [15, 18]. Moreover, some theoretical analysis is done on the maximum *capacity* of deep learning models for



(a) Optimal page size for B-tree

(c) Speedup over B-tree (with the same page size)

(d) Lookup time for IFB-tree (ns)

Figure 4: IFB-tree analysis on Longitudes dataset

keeping index key information [20]. Machine learning has been also adopted for other database operations [6, 8, 10, 13, 13, 16, 19].

Data transformation. Following a different line of work, it is suggested that the performance of index structures can be greatly improved by pre-processing the input data and transforming the keys using a mapping function, in a way that the index structure be more efficient for indexing the distribution of the transformed keys. This idea is exploited for bloom filters [14] and multi-dimensional data [1]. Interestingly, a data transformation that makes the key distribution closer to uniform can benefit IFB-tree and further decreases the interpolation error, hence boosting the speedup of an IFB-tree against its B-tree equivalent.

B-tree enhancement techniques. Several suggestions have been made to design B-trees efficient for the modern hardware. For example, Levandoski et al. suggested BW-trees, a latch-free and cache-friendly B-tree that is used in several Microsoft data engines [12]. Optimizing B-trees can involve compression techniques such as prefix-based splitting. Leis et al. suggested Adaptive Radix Trees, which consumes less memory especially on top levels of the tree. Since all tree-based data structures follow the basic principles of B-trees, such as maintain data in sorted order and splitting the distribution using hierarchies of the table, IFB-tree can be customized for these variants, too.

5 CONCLUSION AND FUTURE WORK

We suggest that the ideas behind learned indexes can be integrated with classical index structures to make them aware of the distribution, hence boosting the performance of the current algorithm. By adopting a computationally lightweight method like interpolation, we boosted the performance of B-trees by up to 50% without modifying the overall structure of B-trees or deteriorating their theoretical performance guarantees. The intra-node interpolation idea is indeed independent from the layout of the tree and hence can be integrated in different extensions to B-tree, including B+-trees, BW-trees [12], and radix trees [11].

Short Paper

SynthEdit: Format transformations by example using edit operations

ABSTRACT

Format transformation is one of the most labor intensive tasks of a data wrangling process. Recent advances in programming by example proposed synthesis algorithms that showed promising results on spreadsheet data. However, when employed on repositories consisting of multiple sources and large number of examples, such algorithms manifest scalability issues. This paper introduces a new transformation synthesis technique based on edit operations that enables efficient learning of transformation programs. Empirical results show comparable effectiveness and dramatic improvements in efficiency over the state-of-the art.

1 INTRODUCTION

Format transformation is a sub-task of data wrangling ([3], [8]) that carries out changes to the representation of textual information, with a view to reducing inconsistencies. Such tasks are typically coded manually by experienced users through scripts that change the representation of data. Recent advances in Programming By Example (PBE) led to algorithms such as *FlashFill* [4] and *BlinkFill* [11] that synthesize transformation programs from user given input-output examples. These algorithms represent important steps towards automatic format transformation in the fields for which they have been devised: spreadsheets. Spreadsheet processing often involves datasets of manageable size, a small number of examples and active user involvement in providing additional example data when needed. In contrast, in areas of data wrangling and data analysis, the task of format transformation is applied repetitively on large datasets from many sources, where more examples are available and user supervision is impractical [2]. Increased volume of example data reveals the opportunity for taking the human factor out of the synthesis process. Automating format transformation by increasing the number of examples represents a challenge for current synthesis algorithms due to their high complexity: exponential in the number of examples and highly polynomial in the length of the examples [10].

In this paper we contribute a solution, which we call *SynthEdit*, to the problem of automatic format transformation. We are motivated by the high computational cost of current state-of-the-art techniques when the number of available examples increases, and propose an approach based on finite state automata that scales better than algorithms such as *FlashFill* when there are more than a few examples available - typically tens or hundreds. The improved efficiency comes at the expense of expressiveness, but allows *SynthEdit* to benefit from substantial example data when available, and, therefore, to cover many inconsistency cases and to eliminate the need for user involvement.

Related work: The problem of learning transformations from examples has been addressed in a number of settings ranging from restructuring of textual information [4], [11], to table formatting [6], and text extraction [1]. More complex systems such as TDE [5] embody a wider range of transformations using external information in addition to user-provided examples.

The closest to our work are algorithms such as FlashFill which have specifically been designed for spreadsheets, assume high user involvement and use DAG-based synthesis solutions that aim to cover the entire space of possible transformations between two given strings. The user's main task in such systems is to provide additional examples for cases not covered by the previous instances. The resulting algorithms have exponential complexity w.r.t. the number of examples [10].

While recent works [2], [7] have proposed techniques that minimize the user involvement in generating examples, *SynthEdit* aims to fully automate the task of format transformation for larger repositories such as data lakes, richer in potentially useful example data, and challenging to address through manual authoring of scripts due to their size and diversity.

2 PRELIMINARIES

We start by describing a representative example where our algorithm can be employed, inspired by web real world data.

Example 2.1. 1900s NY state governor names and term years:

Source	Target
Hugh Leo Carey (74-82)	Hugh L. Carey (1974-1982)
Jay Henry Lehman (33-42)	Jay H. Lehman (1933-1942)

In Example 2.1, the task is to derive a transformation that can generate the *Target* values using the *Source* values. In this paper we refer to such pairs of strings as *example instances.*

Tokens: We view a string s as a collection of *tokens*, where each token represents a sub-string of s. Similarly to existing algorithms for format transformation, e.g., *FlashFill*, *SynthEdit* supports three types of tokens: (i) regular expression tokens - that match a predefined regular expression pattern; (ii) constant string tokens - with a value equal to the corresponding constant string, and (iii) special tokens - beginning/end of a string.

Regular expression primitives: Obtaining the set of tokens for a string s builds on a set of primitive lexical classes defined by regular expressions. The regular expression primitives we use are notated as follows: N = [0-9]+, U = [A-Z]+, L = [a-z]+, A = [A-Za-z]+, Q = [A-Za-z0-9]+, P = [.,;: /-_?!&$]+, W = \\$s$+.

Transformations: Going back to Example 2.1, we can express the source string in the first row as a collection of token types, henceforth called a *token-type representation*: A W A W A W P N P N P. Such representations will be used to derive a transformation that will produce the target string from the source string. One simple such transformation would have the following English language specification: *Replace "Leo", "74", and "82" from the source with "L", "1974", and "1982" from the target, resp.*. Although such

Figure 1: Transformation language syntax

a transformation is consistent with the first example instance, it is too specific to correctly transform the string in the second row. Fortunately, we can generalize the transformation by using token types instead of actual sub-string values: *Replace the second* A*-type token, the first* N*-type token, and the second* N*-type token from the source with the first* U*-type token, the first* N*-type token, and the second* N*-type token from the target, resp.*. Now, the same transformation is consistent with both example instances.

3 TRANSFORMATION LANGUAGE

In this section we propose a transformation language that is expressive enough to describe the previous transformation using simple edit operations: *Insert* (referred to as *INS*), *Delete* (referred to as *DEL*), and *Substitute* (referred to as *SUB*). The complete syntax of the transformation language is in Figure 1, while the semantics are described below. We use the notation ϵ to denote an empty string, $len(s)$ for the length of a string s, $s[i : j]$ for the sub-string that starts at index i in s and ends at index j, and c to denote the c^{th} occurrence of a token type in a string[1].

The semantics of a position expression, $Pos(\mathtt{r}_1, \mathtt{r}_2, c)$, is to evaluate to a sub-string $s[j : k]$ of a given string s, such that $\exists\, i, j, k, l\ 0 \leq i < j < k < l \leq len(s) - 1$, where $s[i : j]$ matches $\mathtt{r}_1$ and $s[k : l]$ matches $\mathtt{r}_2$. Furthermore, $s[j : k]$ is the c^{th} such sub-string in s. If such a sub-string does not exist then the expression evaluates to ϵ. Such an expression allows us to uniquely identify each token in a given string using its neighbour tokens and, at the same time, ensures that the expression will (likely) evaluate to ϵ when applied on strings with different format representations. We can now redefine a token $\mathtt{t}$ as a pair consisting of a token type $\mathtt{r}$ and a position expression $\mathcal{P}$. Note that $\mathtt{t}$ only exists if the string value returned by $\mathcal{P}$ matches $\mathtt{r}$.

The *Copy*($\mathtt{t}$) expression evaluates to the string value of $\mathtt{t}$. *Const*($\mathtt{s}$) evaluates to a constant string s. $Substr(\mathtt{t}, i, j)$ returns the sub-string that starts at position i and ends at position $j - 1$ of the string value of $\mathtt{t}$. $Concat(\mathcal{E}_1, \ldots, \mathcal{E}_n)$ performs string concatenation on the results of the underlying string expressions $\mathcal{E}_1, \ldots, \mathcal{E}_n$. The edit operations $INS(\mathcal{E})$, $DEL(\mathtt{t})$, and $SUB(\mathtt{t}, \mathcal{E})$ perform insertion, removal, and replacement, resp. of some string resulting from the expressions given as parameters, on a given string s. Lastly, $\mathcal{T}$ is a sequence of edit operations applied on s.

Figure 2 shows 5 operations (from a total of 12) of a transformation that can be used to edit both source strings from Example 2.1 into their corresponding target strings. Considering the first row from Example 2.1, the intuition in (1) and (2) is to replace the first occurrences of an A-type token, i.e., *Hugh*, and the first white space with a copy of themselves. Similarly, in (3), the token *Leo* from the source string is replaced with the first letter of itself. In (4), a dot, ".", is inserted after the result of operation (3).

$$
\begin{aligned}
&SUB((\mathtt{A}, Pos(\hat{}\,, \mathtt{W}, 0)), Copy((\mathtt{A}, Pos(\hat{}\,, \mathtt{W}, 0)))); && (1)\\
&SUB((\mathtt{W}, Pos(\mathtt{A}, \mathtt{A}, 0)), Copy((\mathtt{W}, Pos(\mathtt{A}, \mathtt{A}, 0)))); && (2)\\
&SUB((\mathtt{A}, Pos(\mathtt{W}, \mathtt{W}, 0)), Substr((\mathtt{A}, Pos(\mathtt{W}, \mathtt{W}, 0)), 0, 1)); && (3)\\
&INS(Const(".")); && (4)\\
&SUB((\mathtt{N}, Pos(\mathtt{P}, \mathtt{P}, 0)), Concat(Const("19"), Copy((\mathtt{N}, Pos(\mathtt{P}, \mathtt{P}, 0))))); && (5)
\end{aligned}
$$

Figure 2: Transformation for Example 2.1

Operation (5) replaces the first number between two punctuation tokens, i.e., *74,* with the result of the concatenation of a constant string, *19*, and the same number to obtain *1974*. Note that the transformation in Figure 2 is applied on a copy of the source, as opposed to modifying the string in-place. This ensures that source tokens used by later operations are not lost if an early operation deletes/substitutes them.

4 SYNTHESIS ALGORITHM

In this section we describe an algorithm that, starting from the example instances provided in Example 2.1, learns the transformation from Figure 2. Given an example instance, the algorithm consists of 4 phases: 1) tokenize the source and target strings; 2) synthesize edit operations; 3) synthesize string expressions; 4) merge the results of 2) and 3) to create a transformation.

Tokenization: Both *source* and *target* strings are split into tokens using a function `Tokenize`. Specifically, the function searches for sub-strings that match one of the regular expression primitives defined in Section 2. Each such match represents a new token t_i. Next, by looking at the neighbouring matches, the function learns a position expression which uniquely identifies t_i in the parent string. Tokenizing the source string of the first row in Example 2.1 returns: $(\mathtt{A}, Pos(\hat{}\,, \mathtt{W}, \mathtt{0}))$, $(\mathtt{W}, Pos(\mathtt{A}, \mathtt{A}, 0))$, $(\mathtt{A}, Pos(\mathtt{W}, \mathtt{W}, 0))$, $(\mathtt{W}, Pos(\mathtt{A}, \mathtt{A}, 1))$, $(\mathtt{A}, Pos(\mathtt{W}, \mathtt{W}, 1))$, $(\mathtt{W}, Pos(\mathtt{A}, \mathtt{P}, 0))$, $(\mathtt{P}, Pos(\mathtt{W}, \mathtt{N}, 0))$, $(\mathtt{N}, Pos(\mathtt{P}, \mathtt{P}, 0))$, $(\mathtt{P}, Pos(\mathtt{N}, \mathtt{N}, 0))$, $(\mathtt{N}, Pos(\mathtt{P}, \mathtt{P}, 1))$, $(\mathtt{P}, Pos(\mathtt{N}, \$, 0))$

Edit operation synthesis: The top-level transformation is a collection of edit operations parameterized with tokens and/or string expressions. Given an example instance, with its corresponding token-type representation of source (T_s) and target (T_t) derived from the token sets obtained at the previous step, a function `EditSynthesis`(T_s, T_t) generates a sequence of edit operations that edits T_s into T_t. This can be done using an edit distance algorithm, such as the one proposed in [9], where the composition operation on weighted finite state automata (WFSA) is used to generate all possible edit operations that transform the source into the target. By assigning equal weights to each edit operation, the shortest path of the lattice of operations returned by the composition of WFSA denotes the simplest way to obtain the token-type representation of the target. Note that each path of the obtained lattice denotes a valid sequence of edit operations which would produce the target string, but we are only interested in the simplest one. As an example, consider again the first row from Example 2.1 with the token-type representations $T_s = \mathtt{A\ W\ A\ W\ A\ W\ P\ N\ P\ N\ P}$ and $T_t = \mathtt{A\ W\ U\ P\ W\ A\ W\ P\ N\ P\ N\ P}$. `EditSynthesis`$(T_s, T_t)$ can produce the following sequence of edit operations[2] that transform T_s into T_t:

$$
\begin{aligned}
&SUB(\mathtt{A}^{\mathtt{s}}_{\mathtt{0}}, \mathtt{A}^{\mathtt{t}}_{\mathtt{0}});\ SUB(\mathtt{W}^{\mathtt{s}}_{\mathtt{0}}, \mathtt{W}^{\mathtt{t}}_{\mathtt{0}});\ SUB(\mathtt{A}^{\mathtt{s}}_{1}, \mathtt{U}^{\mathtt{t}}_{\mathtt{0}});\ INS(\mathtt{P}^{\mathtt{t}}_{\mathtt{0}});\\
&SUB(\mathtt{W}^{\mathtt{s}}_{1}, \mathtt{W}^{\mathtt{t}}_{1});\ SUB(\mathtt{A}^{\mathtt{s}}_{2}, \mathtt{A}^{\mathtt{t}}_{1});\ SUB(\mathtt{W}^{\mathtt{s}}_{2}, \mathtt{W}^{\mathtt{t}}_{2});\ SUB(\mathtt{P}^{\mathtt{s}}_{\mathtt{0}}, \mathtt{P}^{\mathtt{t}}_{1}); \qquad (6)\\
&SUB(\mathtt{N}^{\mathtt{s}}_{\mathtt{0}}, \mathtt{N}^{\mathtt{t}}_{\mathtt{0}});\ SUB(\mathtt{P}^{\mathtt{s}}_{1}, \mathtt{P}^{\mathtt{t}}_{2});\ SUB(\mathtt{N}^{\mathtt{s}}_{1}, \mathtt{N}^{\mathtt{t}}_{1});\ SUB(\mathtt{P}^{\mathtt{s}}_{2}, \mathtt{P}^{\mathtt{t}}_{3});
\end{aligned}
$$

$\mathtt{A}^{\mathtt{s}}_{\mathtt{i}}/\mathtt{A}^{\mathtt{t}}_{\mathtt{j}}$: the i^{th}/j^{th} token of type A from source/target, $i, j \geq 0$.

Note that Expression (6) denotes the transformation between a given source and a given target, but it cannot be used directly

[1] All string positions, i.e. indexes, start from 0.

[2] Expression (6) omits the *Pos* constructors for clarity.

Algorithm 1 String expression synthesis

```
Input: Index entry: $t_i \rightarrow pairs_{t_i}$
Output: A string expression $\mathcal{E}$
 1: function ExpressionSynthesis
 2:     if $pairs_{t_i}$ == [] then return $Const(t_i)$ end if
 3:     $(s_j, lcs_j) \leftarrow$ best_pair(pairs$_{t_i}$)
 4:     if $s_j == lcs_j == t_i$ then $\mathcal{E} \leftarrow Copy(s_j)$
 5:     else if $lcs_j \subset s_j$ && $lcs_j == t_i$ then
 6:         $\mathcal{E} \leftarrow Substr(s_j$, indexOf$(lcs_j, s_j))$
 7:     else
 8:         $\mathcal{E} \leftarrow Concat($ConcatSynthesis$(t_i, pairs_{t_i}))$
 9:     end if
10:     return $\mathcal{E}$
11: end function
```

Algorithm 2 *Concat* expression synthesis

```
Input: Index entry: $t_i \rightarrow pairs_{t_i}$
Output: A list of string expression $exp$
 1: function ConcatSynthesis
 2:     $exp \leftarrow [\,]$
 3:     for all $(s_j, lcs_j) \in pairs_{t_i}$ do
 4:         if $s_j == lcs_j$ then $exp \leftarrow exp + [Copy(s_j)]$
 5:         else $exp \leftarrow exp + [Substr(s_j$, indexOf$(lcs_j, s_j))]$
 6:         end if
 7:         $t_i \leftarrow$ replace$(t_i, lcs_j$, "")
 8:     end for
 9:     if len$(t_i) > 0$ then $exp \leftarrow exp + [Const(t_i)]$ end if
10:     return $exp$
11: end function
```

when the target is not given. As such, our next objective is to express each target token in Expression (6) as a string expression applied on some source token, e.g., Figure 2. This will allow us to apply the newly obtained operations on new input strings.

String expression synthesis: Expressing a target token t_i as a processing of some source tokens requires the identification of the source token (or the group of source tokens) whose value(s) are the closest to t_i. To this end, we create an inverted index $\mathcal{I}$ in which each target token value t_i identifies a list of pairs of the form (s_j, lcs_j), where lcs_j is the *longest common sub-string* between a source token value s_j and t_i. The first two columns from Table 1 depict three index entries obtained for the first row of Example 2.1. The third column indicates the type of string expressions that can be applied on the source tokens to obtain t_i, as described next.

For each entry of I, we can apply a function `StringSynthesis` (defined in Algorithm 1) to synthesize a string expression that uses some source tokens to obtain the target token. The function at line 3 in Algorithm 1 returns a pair (s_j, lcs_j) where s_j is the source token value that best covers the target token value. Note that we only process the best such pair because its source token has the most useful value to derive the target token. For when the best pair is not the desired one, i.e. the target token has to be obtained from a different source token, we rely on multiple example instances to disambiguate and to generalize a transformation. The `indexOf`(lcs_j, s_j) function at line 6 returns the start and end indexes of lcs_j in s_j.

When there is no source token that can be used to obtain t_i, `ExpressionSynthesis` returns a *Const* expression. Alternatively, when the longest common sub-string, the source and target token values are all identical, the result is a *Copy* expression, e.g., Row 1 in Table 1. If the longest common sub-string is only equal to the target token value, it means that t_i can be obtained from the source token using a *Substr* expression, e.g., Row 2 in Table 1.

Finally, a *Concat* expression is synthesized, using Algorithm 2, when the source token value is a sub-string of the target token value. The `ConcatSynthesis` function processes all pairs of the current index entry, as opposed to only the best pair, and consumes the target token value as soon as it is able to derive a sub-string of it. For example, for Row 3 in Table 1, *74* is a source token and, therefore, the condition at line 4 in Algorithm 2 is met. At the next iteration t_i = "19" (because we consume the previous value) but there are no pairs in $pairs_{t_i}$ that cover the new value which means that the condition at line 9 evaluates to true and the next expression learned is *Const*.

Transformation synthesis: The last step of the algorithm replaces the target tokens in Expression (6) with the corresponding string expressions learned by Algorithm 1. The result, listed below, is a transformation consistent with the example instance and applicable on new input strings, similar in format representation with the source string of the example instance.

Table 1: Index entries

	t_i	$[(s_j, lcs_{(s_j,t_i)})]$	Expression
1	Hugh	[(Hugh, Hugh)]	*Copy*
2	L	[(Leo, L)]	*Substr*
3	1974	[(74, 74)]	*Concat*

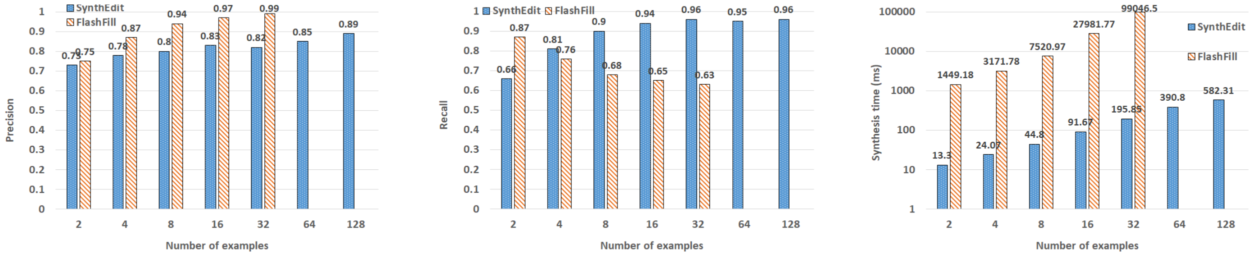
$SUB(\mathtt{A}^s_0, Copy(\mathtt{A}^s_0))$; $SUB(\mathtt{W}^s_0, Copy(\mathtt{W}^s_0))$; $SUB(\mathtt{A}^s_1, Substr(\mathtt{A}^s_1, 0, 1))$;
$INS(Const(".")); SUB(\mathtt{W}^s_1, Copy(\mathtt{W}^s_0))$; $SUB(\mathtt{A}^s_2, Copy(\mathtt{A}^s_2))$;
$SUB(\mathtt{W}^s_2, Copy(\mathtt{W}^s_0))$; $SUB(\mathtt{P}^s_0, Copy(\mathtt{P}^s_0))$;
$SUB(\mathtt{N}^s_0, Concat(Const("19"), Copy(\mathtt{N}^s_0)))$; $SUB(\mathtt{P}^s_1, Copy(\mathtt{P}^s_1))$;
$SUB(\mathtt{N}^s_1, Concat(Const("19"), Copy(\mathtt{N}^s_1)))$; $SUB(\mathtt{P}^s_2, Copy(\mathtt{P}^s_2))$;

Learning from multiple examples: *SynthEdit* assumes the existence of several example instances from which it can learn multiple transformations. Although it is possible for a valid transformation to be synthesized from a small sample of the examples, it is not always possible to automatically identify the relevant sample and, therefore, all examples have to considered. Synthesizing transformations from multiple example instances that follow more than one format representation results in a *conditional transformation program.* To create such a program, we first partition the example instances into groups with source strings that follow the same format representation and synthesize a transformation for each partition[3]. Before transforming a new input string, we match its format representation against the ones for which we have synthesized transformations and apply the transformation of the matching format. If such a format representation does not exist the input string is left unchanged.

Complexity: There are two dominant tasks in *SynthEdit* in terms of complexity. Firstly, *EditSynthesis* runs in $O(m \times n)$ time [9], where m is the length of the source string and n is the length of the target string. Secondly, the generation of inverted index I implies the identification of the longest common sub-string between two token string values which is a dynamic programming problem that runs in $O(k \times l \times u \times v)$, where k is the number of source tokens, l is the number of target tokens, u is the source token value length, and v is the target token value length.

Synthesizing string expressions using `Expression Synthesis` only for the simplest token-based transformation, previously obtained using `EditSynthesis`, gives *SynthEdit* a computational

[3] If more than one transformation is possible per partition, we pick the one consistent with the majority of the example instances of that partition



(a) Average precision

(b) Average recall

(c) Average synthesis time

Figure 3: Experimental Results

advantage over algorithms such as *FlashFill* which considers all possible transformations that are consistent with the examples before ranking them and choosing the best one.

5 EVALUATION

In this section we perform a comparative evaluation[4] involving *SynthEdit* and an implementation of *FlashFill* from PROSE SDK[5], using 33 real world datasets[6], used in a related work [12]. Each dataset consists of up to 200 example instances from several domains such as person names, websites, songs, etc.

We report the average precision, recall and synthesis time over all datasets computed using k-fold cross-validation ($k = 10$) and various number of examples. At each iteration (fold), we synthesize a transformation program from n randomly picked example instances and test on the remaining instances. For the purposes of computing precision and recall, we count as a *true positive* any input string that is correctly transformed, i.e., the result of the transformation is similar to the expected output; as a *false positive* any input string that is incorrectly transformed; and as a *false negative* any input string that is left unchanged, i.e., there is no transformation synthesized for its format representation.

Comparative effectiveness: Avg. precision and recall as the number of examples varies. The precision results are shown in Figure 3a. *SynthEdit* achieves lower precision compared with *FlashFill* for the different numbers of examples. The difference can be explained by the ability of *FlashFill* to better generalize transformations as more examples are added by using a classifier trained on example instances. This allows it to correctly transform strings with format representations not covered by the examples. Conversely, *SynthEdit* performs a strict mapping between format representations and transformations and, therefore, requires at least one example instance for each format representation it transforms. For the last two cases, i.e., 64 and 128 examples, *FlashFill* required more RAM memory than was available.

The classifier employed by *FlashFill* to pick the right transformation given a new input string can become confused when some examples are too similar to each other in terms of the features used during learning. This means that for some input strings *FlashFill* fails to identify an appropriate transformation or the transformation picked is not consistent with the input, e.g., the transformation expects a type of token that is not present in the input. The consequence is a drop in recall visible in Figure 3b as the number of examples increases. By contrast, *SynthEdit* achieves better recall because more examples enables it to better differentiate between transformation cases.

Comparative efficiency: Avg. synthesis time as the number of examples varies. Figure 3c confirms the high complexity of *FlashFill* when the number of examples increases. Conversely, *SynthEdit* proves more than two orders of magnitude faster in synthesizing transformations. As opposed to *FlashFill*, *SynthEdit* does not aim to exhaust the search space of transformations for each example instance. Our algorithm uses edit distance computations to find the shortest path between the token-type representations of the source and target strings. Consequently, the transformation language is simpler but more efficient to learn.

6 CONCLUSIONS

We have contributed an effective and efficient solution to the problem of automating format transformation given input-output examples. We have used an edit distance based approach that identifies the shortest path from a source string to a target string and uses fuzzy matching of source and target tokens to generalize transformations applicable on new input strings, similar in format representation with the examples. Results from a comparative evaluation provide evidence that *SynthEdit* performs substantially more efficiently than the state-of-the-art while achieving better recall at the cost of slightly reduced precision.

ABSTRACT

Triad enumeration yields more detailed information than triangle enumeration. However, triad enumeration is more complex as it has to list the edges as well as the nodes of the triads. Furthermore, it is challenging to do on large graphs because of two reasons: how to deal with large amounts of data using limited memory, and how to do the computation in a reasonable amount of time. While distributed computing can take care of both problems, it requires large investment and high operating cost, as well as a distributed algorithm design which is not always possible. In this paper we show that triad enumeration of very large graphs at the web-scale can actually be done on a single commodity machine. Memory space limitation can be overcome by using data compression and partial loading. Performance can be greatly improved through optimized preprocessing and parallelization.

1 INTRODUCTION

Triangles play an important role in network analysis. For example, the presence of triangles is an indicator of communities in the network [13]. Triangles are also central to computing the connectivity of a graph [2], the clustering coefficient [18], and the transitivity [11]. There are many practical applications of these, for example, detecting fake users in social networks [19] and uncovering hidden thematic layers in the Web [9].

Most real world networks have directed relationships, and therefore we should consider directed graphs for better representations of those networks. A triad is a subgraph of three nodes in a directed graph [1, 8]. When each pair of the nodes is connected we have a closely connected triad. Since we are only interested in closely connected triads we will simply call them triads in this paper. There are seven types of triads, called by some authors as seven types of triangles [14, 16]. They are shown in Fig. 1. Note, however, that we define our own numbering here.

Enumerating triads means listing the edges as well as the nodes inside every triad. Triad enumeration would reveal a more detailed picture of the network, and hence opening up more possible applications. For example, transitivity can be more accurately analyzed by using triads [2], and directed clustering coefficient can be used as a measure of systemic risk in complex banking networks [15]. Also, triad enumeration is an important element in social network analysis [17].

Nonetheless, triad enumeration is more complex than triangle enumeration. The general belief is that it is considerably more difficult [14] and that it would take much longer running time. We found that this is not necessarily the case. Although there are some challenges, it is possible to devise an efficient algorithm which, combined with a compression framework such as WebGraph, is able to enumerate triads on a graph with a billion nodes and billions of edges using a single commodity machine.

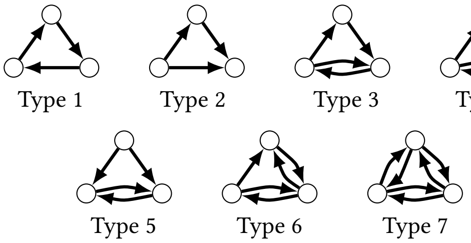

Figure 1: Seven types of triads.

1.1 Related Work

Pajek is a well known graph analysis software for triad enumeration. The triad census algorithm by Batagelj and Mrvar [1], which is employed in Pajek, has been known as the standard algorithm to enumerate triads for several years. However, this program is not suitable for very large graphs with millions of nodes and edges.

Chin et al. [7] proposed a compact data structure where both outgoing and incoming edges are listed in the same adjacency list, and the edge direction is encoded using the 2 lowest bits out of the 32 bits (i.e., using `int`) in each entry. This data structure is suitable for parallel computation using shared memory architectures.

This idea was further refined by Parimalarangan et al. [12], who proposed two types of algorithms, intersection based (AI) and marking based (AM), as the most efficient algorithms to enumerate triads on shared memory platforms.

While those ideas significantly improve the running time, there is a cost on the scalability. With two bits used for edge direction, the order of the graphs that can be processed is reduced. This becomes a problem when we want to analyse a graph of a billion nodes. Theoretically, we can switch to 64-bit integers and the problem should be moot. Practically, however, this would at least double the memory requirement. With limited memory budget, space is already a problem for analysing very large graphs.

1.2 Contributions

1. We implemented Parimalarangan et. al. AI algorithm in Java. We chose AI over AM because it uses less memory. AM is unable to work in a consumer-grade machine of 32GB memory even for graphs of moderate size. Our code is designed for execution on a single machine with parallel threads. Together with optimized preprocessing on the input graphs, we were able to run triad enumeration faster than the ones reported in Parimalarangan's paper, hence raising the known record.

2. For enormous graphs, such as ClueWeb12, AI is not able to work in a consumer-grade machine of 32GB memory. In order to address the case of such graphs we propose another algorithm, which has better scalability. It uses both the graph and transpose graph as input, and computes the node connections on the fly.
3. We are able to employ WebGraph compression which archives a more than 7-fold compression ratio and thus allows loading big graphs (or significant parts of them) in main memory. This enables our new algorithm to complete triad enumeration on ClueWeb12 in the aforementioned machine.

2 TRIAD ENUMERATION

The Batagelj and Mrvar triad census algorithm [1] assigns a code to each pair of nodes to represent the directed edges between them. For each triple of nodes it then uses a table to find the triad types based on the combined codes. Although this algorithm can do triad enumeration in subquadratic time, it is not fast enough for very large graphs with millions of nodes and edges.

Chin et al. [7] developed a compact data structure which makes it easier to parallelize the computation. They combined the adjacency list to contain both outgoing and incoming edges. The edge information or the link is coded using 2-bits: 01 (forward), 10 (backward), and 11 (both), embedded in the neighbour node labels inside the list. Suppose the nodes were labeled by using 32-bit integers. The bits are shifted to the left by two, and the two lowest bits are then used for the edge direction. Thus, only 30 bits can actually be used to label the nodes.

Parimalarangan et al. [12] took on this idea and combined it with the most efficient algorithms known for triangle enumeration on single machines [10]. They came up with two algorithms, the AI algorithm which is intersection based, and the AM algorithm which is marking based. Although AM can in some cases be faster it requires more memory than AI. Therefore, we chose AI and implemented it in Java for our base comparison. We use parallel streams introduced in Java 8 to make use of the multiple threads in our machine.

In our experiments, we use directed networks and their transpose in compressed WebGraph format. For our implementation of AI, we first build the compact data structure (of edges and their direction 2-bit-encoding) from these datasets and save it in plain text format, which is then used as input to the AI program.

The WebGraph framework [5, 6] provides compression schemes suitable for graph adjacency lists. The compression factor can be more than seven-fold, significant in saving disk space. The framework also provides some tools to work with files in WebGraph format. One of them is the `loadMapped`, which allows partial loading of the dataset using memory-mapped files. As we will see later, this is one of the key tools that enable us to process very large graph such as ClueWeb12. Note, however, that using WebGraph comes with the cost of decompressing the dataset.

To improve the performance, we did some preprocessing on the graphs (before building the compact data structure). First, note that each triad should be iterated only once. To avoid multiple counting, we assert condition $u < v < w$ for a triad (u, v, w). Consequently, we only need to consider bigger neighbours. Also, permutation on the labels should not change the number of triads in a graph. Thus, we first sort the nodes according to degrees from lowest to highest, relabel them, and then cut out smaller neighbours from the adjacency list. That is, suppose N_u is the set of neighbours of u after relabelling, then after the cut the adjacency list only contains $N_u \setminus \{v | v < u\}$. This is done simultaneously for the graph and its transpose as the relabelling must be the same for both. After this preprocessing, a node which originally has the highest degree would have zero/no neighbours. The degree distribution in the new adjacency list would have a hill shape with highest (effective) degrees gathered in the middle. When we parallelize on the first node iteration, this distribution can lead to imbalanced workload among the threads. To alleviate this, we do a further preprocessing which redistributes the nodes in steps of 10,000. That is, we pick the nodes and rearrange them in order (0, 10000, 20000, ..., 1, 10001, 20001, ...), and then relabel them as (0, 1, 2, ...).

Algorithm 1 Four Pointers Triad Enumeration

```
Input: A directed graph $G = (V, E)$ and its transpose $G^T$
Output: The number of each type of triads in $G$, $\Delta_i$.
$\Delta_1 \leftarrow 0, \ldots, \Delta_7 \leftarrow 0$
for all $u \in V$ do                                    ▷ Parallelize
    while there is next do
        Find next neighbour in $N^+(u)$ and/or $N^-(u)$: $v$.
        Code the link $uv$ as $e1$: either 01, 10 or 11
        while there is next do
            Find next common neighbour of $u$ and $v$: $w$, in $(N^+(u), N^-(u))$ and $(N^+(v), N^-(v))$.
            Code the links $vw$ as $e2$, and $wu$ as $e3$.
            Look up triad type $i$ using $e1, e2, e3$.
            enum(u,v,w,e1,e2,e3)
            $\Delta_i \leftarrow \Delta_i + 1$
return $\Delta_1, \ldots, \Delta_7$
```

The drawback of the compact data structure solution is that it leads to a reduced scalability. In Java, the 32-bit integer data type can be used to label up to 2^{31} nodes (because we can have only signed integers), but with 2 bits used for edge information, it can label only up to 2^{29} (or about 1/2 billion) nodes. This becomes problematic when we want to analyze a graph such as ClueWeb12 which has almost a billion nodes and about forty two billion edges. Theoretically, we can switch to 64-bit long data type and be able to do ClueWeb12. However, we still need to overcome the memory limitation problem. With ClueWeb12, forty two billion edges translates to more than 300GB RAM if we use 8 bytes for each, which is way beyond the typical amount of RAM in current commodity machines.

In order to process ClueWeb12, we tried several modifications of the AI algorithm, separating the edge direction information from the node labels in the adjacency list. For instance, we put it in separate list of bytes, where each byte encoding a link. We also tried to use BitSet to more compactly encode the edge and save the space, and WebGraph for the combined adjacency list. However, none of our attempts succeeded in running on ClueWeb12 using 32GB RAM.

To this end, we develop a new algorithm which computes the type of connections between each pair of nodes on the fly, using both the graph and its transpose as input. Using this algorithm, and partial loading method of WebGraph , we were able to process ClueWeb12 on our machine with a budget of 32GB RAM. The algorithm, in a simplified version, is shown in Algorithm 1. We call this Four Pointers Triad Enumeration algorithm due to the fact that we use four pointers: one on each of $N^+(u)$, $N^-(u)$, $N^+(v)$, and $N^-(v)$. Here, $N^+(u)$ is the set of out-neighbours of u

in G, while $N^-(u)$ is the set of out-neighbours of u in G^T. This algorithm is an expansion of the 2-pointer algorithm commonly used for set intersections.

Algorithm 1 iterates over the first node u. This iteration can easily be parallelized. For each, it checks both $N^+(u)$ and $N^-(u)$ to find the neighbours of u and their respective links. For each neighbour of u, v, it finds their common neighbours using four pointers. For each, w, it looks up the triad type based on the links among the three nodes (u, v, w). In line 10, `enum()` is a space holder for an enumeration or listing function.

3 EXPERIMENTS AND DISCUSSIONS

3.1 The Setup

We ran our experiments on a machine with dual Intel Xeon E5620 CPUs and 64GB RAM. Its price is less than $3K, qualifying it as a commodity machine. However, to make a better comparison with other papers, we allowed only 32GB of RAM to be used by the Java virtual machine. The Xeon CPU has a clock speed of 2.40 GHz and 8 threads (16 threads total for the dual). The OS is Linux Ubuntu 14.04.5. We used Java 8 and the WebGraph 3.6.1.

We have five programs to run, listed in Table 1. Both AI and 4P are parallelized on the first node iteration.

Name	Description
SC	Sort and cut preprocessing
RD	Node redistribution
CDt	Build compact dataset
AI	Our AI implementation
4P	Four pointers enumeration

Table 1: The programs used in this experiment.

3.2 The Datasets

We applied our algorithms on five networks in compressed WebGraph format. The datasets were downloaded from the WebGraph website [4] (http://law.di.unimi.it/datasets.php). For each, we downloaded both the graph and the transpose graph.

Here are our selection of networks:

1. **cnr-2000**: a small crawl from the Italian CNR (Consiglio Nazionale delle Ricerche).
2. **ljournal-2008** (abbreviated as **ljournal**): a snapshot from LiveJournal (https://www.livejournal.com/) in 2008.
3. **arabic-2005** (abbreviated as **arabic**): a of websites that contain arabic, performed by UbiCrawler [3] in 2005.
4. **uk-2005**: a shallow crawl of .uk domain, performed by UbiCrawler [3] in 2005.
5. **clueweb12** (abbreviated as **clueweb**): a crawl of English webpages, created by the Lemur Project (http://www.lemurproject.org/clueweb12/index.php), with outlink nodes removed.

The statistics of these datasets are listed in Table 2. Notice that G and G^T can have different sizes because the results of the compression can be different. The smallest dataset, `cnr-2000`, has 3.2M edges, while the largest dataset, `clueweb`, has more than 42B edges. The degree statistics are listed in Table 3. The statistics of the resulting graphs after preprocessing are listed in Table 4. Note that redistribution will not change these statistics.

3.3 Results

We ran the AI, and 4P triad enumeration programs on the chosen datasets. We verified that we got the same numbers from both programs, when run with or without pre-processing. The numbers of triads for each types are listed in Table 5.

In Table 6 we list the running times. The graphs had been preprocessed by the SC program (sort and cut) before being used as input, but without node redistribution. The running times on graphs without preprocessing are not shown here. However, note that this preprocessing is important in keeping the running time low. The CDt program takes the graph and its transpose in the compressed WebGraph format and produces a compact dataset written into a plain text file which is then used as input by the AI program. The 4P program takes the WebGraph files directly as input. Therefore, we compare 4P with AI+CDt. Except for `cnr-2000`, AI+CDt is faster than 4P. This is due to repeat decompression cost in 4P. However, AI+CDt is unable to process `clueweb` for the reason that is explained in the previous section (inability to represent 1 billion nodes using 29 bits for each), while 4P can. Notice that our AI implementation can process `arabic` in a shorter time than the one reported in Parimalarangan's paper [12] (In that paper they did not report the time to build the compact data set, CDt, and excluded the loading time. Our numbers here for AI include the loading time.).

Next, we checked whether redistribution can improve the performance. In Table 7 we list the running times on the graphs that had been preprocessed and which nodes had been redistributed. The cost of redistributing the nodes is listed as RD. We see that this RD cost can be quite significant. Taking this cost into consideration, it is not always worth it to do redistribution. For example, on `ljournal`, the 4P time without RD is 81 seconds, while RD +

uk2005	311	354	319	673	796
clueweb	12,870	-	-	-	115,960

Table 6: The running time (in seconds) of triad enumeration using Four Pointer algorithm (4P), and AI algorithm (AI). Also listed are the preprocessing time (SC), and the time to build the compact dataset (CDt). Since, 4P does not need compact dataset, we compare 4P with AI+CDt.

$4P^{RD}$ is 86 + 30.5 = 116.5 seconds. For `arabic`, though, the RD is helpful in bringing the overall cost down.

Name	RD	AI^{RD}	CDt^{RD}	$AI+CDt^{RD}$	$4P^{RD}$
cnr-2000	3.7	0.98	1.49	2.5	3.2
ljournal	86	18.4	22.8	41.2	30.5
arabic	453	215	154	369	483
uk2005	632	312	248	560	366
clueweb	30,413	-	-	-	-*

Table 7: The running time (in seconds) of triad enumeration using Four Pointer algorithm (4P), and AI algorithm (AI) on redistributed graphs. *The run on `clueweb` cannot be done in a reasonable amount of time.

Notice that with RD our 4P becomes competitive to AI+CDt. This can be understood from the fact that workload imbalanced affects 4P more than AI since 4P has to do decompression on the adjacency list, and hence RD benefits 4P more as it reduces the imbalance. It is faster on `ljournal` and `uk2005`, and just a bit slower on `cnr-2000` and `arabic`.

The redistribution, however, has an unwanted effect on WebGraph compression. The compression works best if the distances among the neighbour nodes are not large. With redistribution, there are large distances within a neighbour set, which in turn lower the overall compression ratio. As such, we do not advise performing redistribution on very large graphs such as `clueweb`. For such graphs sort-and-cut preprocessing is all what is needed for our algorithm 4P to complete in reasonable time.

4 CONCLUSIONS

We have shown that through optimized preprocessing and parallelization we are able to run triad enumeration on very large graphs using a single commodity machine in reasonable time. We also designed an algorithm, 4P, with better scalability than the state-of-the-art, which, with some trade-off on the performance, can run on graphs of a billion nodes and billions of edges, counting trillions of triads. In our solution, the WebGraph framework plays an important role in alleviating the memory problem. In conclusion, our results show that triad enumeration can be done on a commodity machine even for very large graphs such as ClueWeb12.

Fast Truss Decomposition in Large-scale Probabilistic Graphs

Fatemeh Esfahani, Jian Wu, Venkatesh Srinivasan, Alex Thomo, and Kui Wu
{esfahani,wujian,srinivas,thomo,wkui}@uvic.ca

ABSTRACT

Truss decomposition is popular for finding dense substructures in graphs. Discovering trusses in deterministic graphs has been widely discussed in the literature. However, with the intrinsic uncertainty in many networks such as social, biological, and communication networks, it is of great importance to study truss decomposition in a probabilistic context, but this has received much less attention till now. Furthermore, due to computation challenges of truss decomposition in probabilistic graphs, the state-of-the-art approaches are not scalable to large graphs.

Given a user-defined threshold, we are interested in finding all the maximal subgraphs which are a k-truss with high probability. The most important challenge, which distinguishes truss decomposition in probabilistic graphs from deterministic graphs, is computing tail probabilities of edge supports. We employ a special version of the Central Limit Theorem (CLT) to obtain the tail probabilities efficiently. Based on our CLT approach we propose a peeling algorithm for truss decomposition of a probabilistic graph that scales to very large graphs and offers significant improvement over state-of-the-art. Our extensive experimental results confirm the scalability and efficiency of our approach.

1 INTRODUCTION

Probabilistic graphs are graphs in which each edge has an existence probability [2]. Many real-world networks, such as social, trust, communication, and biological networks, feature uncertainty and thus can be modeled as probabilistic graphs.

Dense subgraph mining is an important way to analyze the structure of networks [7]. A popular notion of cohesive graph is the k-truss, which is defined as a maximal subgraph in which each edge participates in at least $(k-2)$ triangles within that subgraph. The k-truss features a variety of applications [5]. For instance, k-truss is a useful tool for visualization of complex networks [12]. Also, k-trusses are the basis of several community models [8]. It is thus important to discover k-trusses in probabilistic graphs.

Truss decomposition in deterministic graphs is a straightforward task and has been broadly studied in the literature [4, 9, 11]. However, in probabilistic graphs, truss computation is challenging and has received much less attention. We use the notation of local probabilistic (k, η)-truss introduced in [5], and will be explained in more detail in the next section.

Challenges and contributions. Probabilistic truss decomposition is associated with significant challenges due to intrinsic uncertainty in probabilistic graphs. Thus, the general idea of iterative edge removal in deterministic graphs does not work by itself in probabilistic graphs. For instance, counting the number of triangles which contain an edge is straightforward in deterministic graphs. But, in probabilistic graphs, the triangles in which an edge might participate have combinatorial nature [5]. As a result, the most difficult task is computing edge support probabilities efficiently. This becomes particularly important when the input graph is huge. In [5], support probability of an edge $e = (u, v)$ is computed using dynamic programming (DP), which has a complexity of $O((\min\{d(u), d(v)\})^2)$, where $d(u)$ and $d(v)$ is deterministic degree of u and v, respectively. Unfortunately, the values of $d(u)$ and $d(v)$ can be in the millions in many real-world social and web networks, and quadratic time complexity of DP makes it impractical for huge graphs.

Realizing the fact that each triangle in probabilistic graph can be defined as a Bernoulli random variable with an existence probability, we design a novel approach based on Lyapunov's special version of the Central Limit Theorem [6] to approximate probability distribution of the support of an edge. We show that the proposed approximation is accurate for our problem when the number of triangles is big. In addition, we derive an error bound on the approximation to ensure that the output probabilities are very close to the values obtained through exact computation.

We design a peeling algorithm for probabilistic k-truss decomposition. Our algorithm takes advantage of the fast calculation of edge support probabilities in time $O(\min\{d(u), d(v)\})$ using central limit theorem. It also uses optimized array-based data structures for storing edge information of the graph.

In summary, our contributions are as follows.

- We introduce an efficient approach based on Lyapunov's central limit theorem to compute support probabilities of edges in the input graph (Section 3.1).
- Using theoretical analysis, we obtain error bound of the approximation, which shows that the higher the number of triangles, the higher the accuracy of the approximation results (Corollary 1).
- We develop a peeling algorithm based on recursive edge deletions (Section 3.2), which, by utilizing central limit theorem and additional data structures, is able to calculate truss decomposition in very big probabilistic graphs not possible with the pure DP approach (Section 4).

2 BACKGROUND

Trusses in deterministic graphs. Let $G = (V, E)$ be an undirected graph with no self-loops. For a vertex v, let $N_G(v)$ be the set of v's neighbors in G. A triangle in the input graph is defined as a cycle of length 3, denoted by $\triangle_{uvw}$, where $u, v, w \in V$. Given an edge $e = (u, v)$, the *support of* e in G is the number of triangles that contain e. Formally, $\text{sup}_G(e) = |N_G(v) \cap N_G(u)|$.

The k-truss of G is defined as the maximal induced subgraph $T_k(G) = (V', E_{V'})$ in which each edge $e \in E_{V'}$ has support of at least $(k-2)$. The set of all k-trusses forms truss decomposition of G, where $2 \leq k \leq k_{\max}$, and $k_{\max}$ is the largest support of any edge.

Probabilistic graphs. A probabilistic graph is defined as $\mathcal{G} = (V, E, p)$, where V and E are as before and $p : E \rightarrow (0, 1]$ is a function that assigns existence probability $p(e)$ to edge e. In the most common probabilistic graph model [2], the existence probability of each edge is assumed to be independent of other edges.

To analyze probabilistic graphs, we use the concept of *possible worlds*, which are deterministic graph instances of $\mathcal{G}$. For each

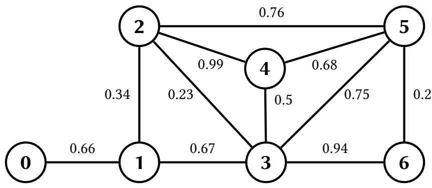

Figure 1: A probabilistic graph.

possible world $G = (V, E_G) \sqsubseteq \mathcal{G}$, where $E_G \subseteq E$, the probability of observing that possible world is obtained as follows: $\Pr(G) = \prod_{e \in E_G} p(e) \prod_{e \in E \setminus E_G}(1 - p(e))$.

Given an edge $e = (u, v)$, let $k_e = |N(u) \cap N(v)|$. We define the notion of *η-support*, denoted by *η-sup$_{\mathcal{G}}(e)$*, as the maximum k for which $\Pr_{G \sqsubseteq \mathcal{G}}[\mathrm{sup}_G(e) \geq k] \geq \eta$, where $k = 0, \ldots, k_e$, and the probability is taken over all the possible worlds $G \sqsubseteq \mathcal{G}$. In the rest of the paper, we use $\Pr[\mathrm{sup}_{\mathcal{G}}(e) \geq k]$ to denote $\Pr_{G \sqsubseteq \mathcal{G}}[\mathrm{sup}_G(e) \geq k]$.

For instance, consider Figure 1, edge $e = (2, 5)$, and $\eta = 0.5$. With the assumption that e exists (with probability $p(e) = 0.76$), edge e has support at least 2 with probability $0.76 \cdot (0.99 \cdot 0.68) \cdot (0.23 \cdot 0.75) = 0.0883$ (product of the probabilities that triangles $\triangle_{245}$ and $\triangle_{235}$ exist in a possible world), and it has support at least 1 with probability $0.76 \cdot \big(1 - (1 - 0.99 \cdot 0.68) \cdot (1 - 0.23 \cdot 0.75)\big) = 0.5545$ (complementary probability that none of the two triangles are in a possible world). Since 0.5545 is greater than the threshold η, the η-support of edge e is 1.

In probabilistic context, $\mathrm{sup}_{\mathcal{G}}(e)$ is a random variable which can take on integer values form zero to k_e. Furthermore, as k increases, the value of $\Pr[\mathrm{sup}_{\mathcal{G}}(e) \geq k]$ decreases.

Trusses in probabilistic graphs. In order to compute truss decomposition in probabilistic graphs we follow the local (k, η)-*truss* model defined in [5]:

Definition 1. *Let $\mathcal{G} = (V, E, p)$ be a probabilistic graph. Given threshold $\eta \in [0, 1]$, the local (k, η)-truss is the maximal induced subgraph $T_{(k,\eta)}(\mathcal{G}) = (V', E_{V'}, p)$ in which the η-support of each edge $e \in E_{V'}$ is at least $(k - 2)$. The set of all the local (k, η)-trusses forms the local truss decomposition of $\mathcal{G}$.*

Similar to deterministic case, local (k, η)-trusses are unique and nested into each other. The highest value of k for which e belongs to a local (k, η)-truss is called *η-truss* number or probabilistic trussness of e.

Computing η-supports using Dynamic Programming. Support probabilities are computed using $\Pr[\mathrm{sup}_{\mathcal{G}}(e) \geq k] = 1 - \sum_{i=0}^{k-1} \Pr[\mathrm{sup}_{\mathcal{G}}(e) = i]$. One way of calculating $\Pr[\mathrm{sup}_{\mathcal{G}}(e) = i]$ is to use dynamic programming as proposed in [5]. Given an edge $e = (u, v)$, time complexity of this method of computation is $O(k_e^2)$. Since $k_e \in O(\min\{d(u), d(v)\})$, where $d(u)$ and $d(v)$ are deterministic degree of u and v in $\mathcal{G}$, respectively, this method of computation is not practical when the minimum degree of two neighbors is big, say over 100, which is quite common in all our datasets. In addition, web-scale graphs have millions of such edges, and as a result, if DP is applied to each edge the total processing time increases considerably. In the next section we propose an alternative approach for fast computation of η-support of an edge e using Lyapunov central limit theorem.

3 PEELING ALGORITHM FRAMEWORK USING CENTRAL LIMIT THEOREM

We describe a CLT-focused algorithm to compute truss decomposition in probabilistic graphs. The pseudocodes/proofs are omitted due to page limit.

3.1 Computing η-Supports using Central Limit Theorem

We first show how a special version of Central Limit Theorem (CLT) can be applied to accurately estimate $\Pr\big[\mathrm{sup}_{\mathcal{G}}(e) \geq k\big]$. Then, we show theoretical bounds on the accuracy of this approximation. Specifically, we show that CLT can produce a very accurate approximation to tail probabilities of the support edge.

Based on CLT, the distribution of properly scaled sum of a sequence of random variables converges to normal distribution under specific conditions. In this paper, we consider a variant called Lyapunov CLT that can be applied when random variables are independent, but not necessarily identically distributed. Lyapunov CLT can be formally stated in the following:

Theorem 3.1. ***Lyapunov CLT.*** *Let $\zeta_1, \zeta_2, \cdots, \zeta_n$ be a sequence of independent, but non-identically distributed random variables, each with finite expected value μ_k and variance σ_k. Let*

$$s_n^2 = \sum_{k=1}^{n} \sigma_k^2, \tag{1}$$

Lyapunov CLT states that if

$$\lim_{n \to \infty} \frac{1}{s_n^{2+\delta}} \sum_{k=1}^{n} \mathrm{E}[|\zeta_k - \mu_k|^{2+\delta}] = 0, \tag{2}$$

for some $\delta > 0$, then $\frac{1}{s_n} \sum_{k=1}^{n} (\zeta_k - \mu_k)$ converges in distribution to a standard normal random variable.

Equation (2) is called Lyapunov's condition which in practice is usually tested for the special case $\delta = 1$. The proof for this theorem can be found in [3].

Computing η-supports using Lyapunov CLT. Given an edge e, to compute $\Pr\big[\mathrm{sup}_{\mathcal{G}}(e) \geq k\big]$ we assume that e exists. Thus, the true edge support probability is obtained by multiplication of $\Pr\big[\mathrm{sup}_{\mathcal{G}}(e) \geq k\big]$ with $p(e)$.

Each edge e_j in probabilistic graph has existence probability of $p(e_j)$, which is independent of the other edge probabilities. As a result, associated with each edge e_j we can define a Bernoulli random variable ζ_{e_j} which takes on 1 with probability $p(e_j)$ and 0 with probability $(1 - p(e_j))$. Since each edge is assumed to exist independently of other edges, ζ_{e_j}'s are independent. Given an edge $e = (u, v)$, let $\mathcal{T}_e$ be a set of all the common neighbors of u and v in $\mathcal{G}$. We have,

$$\mathcal{T}_e = N(u) \cap N(v) = \left\{t_1, \cdots, t_{k_e}\right\}.$$

For each common neighbor t_i, let ζ_{u,t_i} and ζ_{v,t_i} be the corresponding Bernoulli random variables to the edges (u, t_i) and (v, t_i), respectively. Let $X_i = \zeta_{u,t_i} \cdot \zeta_{v,t_i}$. The following observations hold for each random variable X_i: **(1)** X_i's are independent, since ζ_{u,t_i} and ζ_{v,t_i} are independent random variables. **(2)** X_i's are Bernoulli random variables which take on 1 with probability $p(u, t_i) \cdot p(v, t_i)$. This is because X_i can be equal to 1 when both $\zeta_{u,t_i} = 1$ and $\zeta_{v,t_i} = 1$, with probability $p(u, t_i) \cdot p(v, t_i)$. Otherwise, if at least one of them is 0, the value of X_i will become zero. The probability that at least one of these random variables become zero is $1 - (p(u, t_i) \cdot p(v, t_i))$.

Now, let us consider the triangle $\triangle_{uvt_i}$. It should be noted that only common neighbours can create a triangle containing edge e. With the assumption that e exists, the triangle $\triangle_{uvt_i}$ exists if both edges (u, t_i) and (v, t_i) exist, which is associated with $X_i = 1$. On the other hand, the triangle does not exist if at least one of edges, (u, t_i) and (v, t_i), does not exist, which corresponds to $X_i = 0$. Therefore, corresponding to each triangle $\triangle_{uvt_i}$, we can define the Bernoulli random variable X_i.

Let $p_i = p(u, t_i) \cdot p(v, t_i)$. Since X_i is a Bernoulli random variable, we know that $\mathrm{E}[X_i] = \mu_i = p_i$ and $\mathrm{Var}[X_i] = p_i(1 - p_i)$. Since $\sup_{\mathcal{G}}(e) = \sum_{i=1}^{k_e} X_i$, we have:

$$\Pr[\sup_{\mathcal{G}}(e) \geq k] = \Pr\left[\sum_{i=1}^{k_e} X_i \geq k\right]. \tag{3}$$

Bernoulli random variables X_i's are independent, but may not be identically distributed. Thus, if condition (2) is satisfied and if k_e is large enough, we can conclude that $\frac{1}{s_{k_e}} \sum_{i=1}^{k_e}(X_i - \mu_i)$ has standard normal distribution, where $s_{k_e} = \sqrt{\sum_{i=1}^{k_e} p_i(1 - p_i)}$. In order to compute the right-hand side of equation (3), we can subtract $\sum_{i=1}^{k_e} \mu_i$ from both sides of the inequality, and then divide by s_{k_e} which results in:

$$\Pr\Big[\sum_{i=1}^{k_e} X_i \geq k\Big] = \Pr\Big[\frac{1}{s_{k_e}} \sum_{i=1}^{k_e}(X_i - \mu_i) \geq \frac{1}{s_{k_e}}(k - \sum_{i=1}^{k_e} \mu_i)\Big]. \tag{4}$$

Using Lyapunov CLT and setting

$$Z = \frac{1}{s_{k_e}} \sum_{i=1}^{k_e}(X_i - \mu_i), \tag{5}$$

we can conclude that Z has standard normal distribution. Thus

$$\Pr\big[\sup(e) \geq k\big] \cong \Pr\big[Z \geq z\big], \tag{6}$$

where $z = \frac{1}{s_{k_e}}(k - \sum_{i=1}^{k_e} \mu_i)$. Using the complementary cumulative distribution function [13] of standard normal variable Z, we can simply evaluate the right-hand side of Equation (6) for each value of k. Thus, to find the η-support for an edge, we start with $k = 1$, approximate $\Pr[\sup(e) \geq k]$ using Lyapunov CLT, and find the maximum k for which the probability multiplied by $p(e)$ is above threshold η. For an edge e, the obtained value of k, which can be in range from one to k_e, is set as initial η-support for that edge. Given an edge $e = (u, v)$, time complexity of finding η-support is $O(k_e)$, where $k_e = |N(u) \cap N(v)|$. Recall that DP required $O(k_e^2)$ for this step.

In the following we show that Lyapunov's condition in Theorem 3.1 is satisfied for our problem. We set $\delta = 1$ in Equation (2) to show that this condition holds for a sequence of non-identically distributed Bernoulli random variables.

Theorem 3.2. *Given a sequence of random variables $X_i \sim$ Bernoulli(p_i), where $1 \leq i \leq n$, the Lyapunov's condition (2) for $\delta = 1$ is satisfied whenever $s_n^2 = \sum_{k=1}^{n} p_k(1 - p_k) \to \infty$.*

Accuracy of the Approximation. Using Berry–Esseen theorem [14], in the following corollary we show how to obtain an upper-bound on the maximal error while approximating the true distribution of the sum of X_i's with the normal distribution.

Corollary 1. *For each edge e in the probabilistic graph $\mathcal{G}$ with X_i's being Bernoulli random variables defined as above in this section, where $i = 1, \ldots, k_e$, the error bound on the approximation of the right-hand side of Equation (6) to the standard normal distribution is given as follows:*

$$\sup_{x \in \mathbb{R}} \left|F_{k_e}(x) - \Phi(x)\right| \leq \frac{0.56}{\sqrt{p_1(1 - p_1) + \cdots + p_{k_e}(1 - p_{k_e})}}.$$

3.2 Peeling Algorithm (PA)

In [10], a peeling algorithm was proposed to calculate the k-truss in deterministic graphs. While the algorithm is not applicable to probabilistic graphs, its optimized array-based data structures for storing edge information of the graph are useful. Our new peeling algorithm, termed as *CLT_based-PA* algorithm, is built on the same array-based data structures but utilizes central limit theorem to compute and update support probabilities of edges which participate in more than 100 triangles.[1]

The *CLT_based-PA* algorithm consists of two main parts: **(1)** initial probabilistic support computation, and **(2)** probabilistic truss computation which involves updating probabilistic support values once an edge is removed.

In initial support computation step, the η-support of each edge e is computed using CLT and Equation (6), if k_e is greater than 100. Otherwise, DP can be used safely. The details on DP approach can be found in [5]. The initial phase can be executed in parallel, since probabilistic support of each edge can be computed independently of other edges.

After initialization, the *CLT_based-PA* algorithm runs in three steps: First, sort edges in ascending order of their η-support in the array *sortedEdge*, and store their positions in the array.

Then, remove edges with the lowest η-support. The removal of an edge $e = (u, v)$ affects the η-support of all edges that can constitute triangles with (u, v). As a result, the algorithm finds all the common neighbors w of u and v, i.e., $\triangle_{uvw}$ is a triangle containing edge (u, v).

At the third step, the η-support of (u, w) and (v, w) is updated if their η-supports are greater than e's η-support. In the updating part, if the number of remaining triangles which contain edges (u, w) and (v, w) is greater than 100, we perform update phase using CLT approach. Otherwise, we apply DP. Since the η-support has been changed, we change the position of edges (v, w) and (u, w) in *sortedEdge* array in constant time [10]. The algorithm continues until all the edges in the graph are removed. Then, the trussness of each edge is obtained by adding 2 to the final η-support.

4 EXPERIMENTS

Our implementations are in Java and the experiments are conducted on a commodity machine with Intel i7, 2.2Ghz CPU, and 12Gb RAM, running Ubuntu 14.03. The hard disk is Seagate Barracuda ST31000524AS 2TB 7200 RPM.

The statistics for the datasets are shown in Table 1. We obtained flicker, dblp, and biomine from the authors of [2], and the rest of the datasets from Laboratory of Web Algorithmics.[2] Each horizontal line in the table categorizes the datasets according to their size, small (S), medium (M), and large (L). We use the Webgraph framework [1] to store these datasets. The flickr, dblp, and biomine datasets already contained edge probability values. For the other datasets we generated probability values uniformly distributed in $[0, 1]$.

[1] This value was chosen because it was large enough to keep the approximation error obtained from Corollary 1 small.

dblp	42	14	0.1
biomine	151	33	0.1
cnr-2000	4672	13	0.1
ljournal-2008	1030	51	0.1
	1015	43	0.2
	1001	35	0.3
	980	27	0.4
	530	19	0.5

Table 3: Maximum η-support, maximum probabilistic trussness, value of the threshold η.

Table 2 represents the running times of our proposed approach, versus the running times of the state-of-the-art, which uses dynamic programming (DP) only and is referred as *DP_Pure*. The last column shows the gain of *CLT_based–PA* algorithm over *DP_Pure*. For ljournal-2008, we present the results for different values of η ranging from 0.1 to 0.5. However, for the other datasets, we only show the results for $\eta = 0.1$, and omit results for $\eta = 0.2, \ldots, 0.5$, since they are similar to those for $\eta = 0.1$ and their performance trend is similar to what we see for ljournal-2008. As can be seen, *CLT_based–PA* algorithm is significantly faster than *DP_Pure*. For instance, for biomine, which is a large dataset, the gain of our algorithm is 67 percent, making *CLT_based–PA* truss decomposition algorithm three times faster than *DP_Pure*.

CLT_based–PA produced the results in about 1.5 minutes and about 34 seconds for flickr and dblp, respectively. Although flickr is smaller than dblp in terms of the number of vertices and edges, its probabilistic maximum truss is much greater at value 47 compared to 14 in dblp. We represent the maximum probabilistic truss and maximum probabilistic support in Table 3. *These values are the same as those obtained by DP_Pure.* On biomine which is a large dataset, our proposed algorithm completed in about 43 minutes; which is quite impressive. In contrast, *DP_Pure* produced the results in more than 2 hours. The running time for ljournal-2008 increases, which is quite reasonable, because this graph has 49 million edges with probabilistic support of 1030 when $\eta = 0.1$. The same argument holds for cnr-2000 which has probabilistic support of 4672 which is significantly big. *DP_Pure wasn't able to run to completion in our machine after one day.*

Effect of η values. The running time of both algorithms increases as η becomes small. This is because as η decreases, the chance for support probabilities to pass the threshold increases, resulting in larger values of η-supports. This is particularly important in performance evaluation of *DP_Pure* algorithm– as η decreases the DP algorithm approaches its worst case time complexity, $O(k_e^2)$, for an edge e. As a result, for larger values of η, the running time of *DP_Pure* improves, but is still by far slower than *CLT_based–PA*. In terms of the effect of η on truss decomposition and support values, as can be seen in Table 3, the maximum truss and maximum initial probabilistic support decrease as η increases. As before, we report the maximum truss, and the maximum η-support for ljournal-2008 for $\eta = 0.1, \ldots, 0.5$, whereas for the other datasets we only show the values for $\eta = 0.1$.

5 CONCLUSIONS

We presented a peeling algorithm for computing truss decomposition in probabilistic graphs at web scale. Our peeling algorithm uses Lyapunov's central limit theorem to obtain the probabilistic support for an edge. Unlike the dynamic programming approach, the computation does not rely on incremental evaluation of support probabilities. In addition, it can efficiently update probabilistic support when a triangle is removed from the input graph, without the need of storing all the previously computed support probabilities. We evaluated our algorithm and showed that it is significantly faster than state-of-the-art for large datasets. For large and medium datasets our algorithm obtained approximately 50 percent gain over the proposed algorithm in the literature, completing the biomine dataset in less than one hour.

ABSTRACT

Given a network in which a undesirable rumor, disease, or contamination spreads, which set of network nodes should we *block* so as to contain that spread? Past research has proposed several methods to address this *network immunization* (NI) problem, which is to find a set of k nodes, such that the undesirable dissemination is minimized in expectation when they are blocked. As the problem is NP-hard, some algorithms utilize solely features of the network structure in a *preemptive* manner, to others that take into account the specific source of a contamination in a *data-aware* fashion. This paper presents an experimental study on NI algorithms and baselines under the independent cascade (IC) diffusion model. We employ a variety of synthetic and real-world networks with diverse graph density, degree distribution, and clustering coefficients, under realistically calculated influence probabilities. We conclude that data-aware approaches based on the construct of *dominator trees* usually perform best; however, in networks with a power-law degree distribution, preemptive approaches utilizing spectral network properties shine out by virtue of their efficiency in identifying central nodes.

1 INTRODUCTION

Real-world networks facilitate the spread of ideas, behaviors, inclinations, or diseases via *diffusion* processes [10]. Oftentimes a diffusion of malicious nature needs to be contained via countermeasures [11]. One such countermeasure is the *blocking* of a subset of network nodes. *Network Immunization* (NI) calls to find an optimal set of nodes to block so as to arrest a diffusion.

Early works on NI were motivated by epidemiology [3, 12], categorizing individuals as Susceptible $\mathbb{S}$, Infected $\mathbb{I}$, or Recovered $\mathbb{R}$. Those who are infected infect their susceptible neighbors with a transition rate β, and become recovered (hence immune) with transition rate γ. In the context of social networks [14], the *Independent Cascade* (IC) model [4] generalizes the SIR model, assigning an independent transition rate β to each edge. Kempe et al. [6] formulated the Influence Maximization (IM) problem under the IC model, where the goal is to select k seed nodes that maximize the expected diffusion spread; since then, the problem has been studied extensively [10, 14].

The NI problem is complementary to the IM problem. Certain notions are useful in both. For example, eigenvalue centrality [12] has been used to guide seed selection in IM. Similarly, Chen et al. [2] employ the first eigenvalue λ as a proxy to the objective of NI problem, scoring nodes by the eigen-drop $\Delta\lambda$ that their removal causes, leading to a succession of techniques aiming to to maximize the eigen-drop of immunized nodes [20].

We distinguish two variants on network immunization: *preemptive* immunization finds a solution before the epidemic starts; by contrast, *data-aware* immunization tailors the solution to a particular diffusion seed [19]. The state-of-the-art data-aware solution, *Data-Aware Vaccination Algorithm* (DAVA) [21] employs structures called *dominator trees*. Still, the experimental study in [21] is limited to four datasets with synthetic propagation probabilities; it is not clear how the topology of the network influences the algorithm's performance. At the same time, recent preemtive immunization methods [11, 13] significantly outperform the baselines used in [21], yet have not been compared to DAVA itself. Thus, to the best of our knowledge, no previous work has studied how data-aware and and preemptive immunization strategies fare under different graph topologies.

In this paper, we investigate the performance of state-of-the-art data-aware and preemptive NI solutions on a variety of real-world and synthetic network structures with diverse characteristics, and under realistic influence probabilities with the IC model. Our study features the *first*, to our knowledge, application of the most recent algorithm for eigen-drop maximization and a generic spectral method of activity shaping, to NI under the IC model. We demonstrate that data-aware approaches are leading in a majority of configurations, yet preemtive ones stand out under particular settings of graph density, influence probabilities, degree distribution, and clustering coefficients.

2 BACKGROUND

The classic approach to preemptive NI is the NetShield algorithm [2]. NetShield greedily selects a set of nodes S, aiming to maximize its *Shield value*:

$$Sv(S) = \sum_{i \in S} 2\lambda \mathbf{u}(i)^2 - \sum_{i,j \in S} \mathbf{A}(i,j)\mathbf{u}(i)\mathbf{u}(j)$$

where λ and $\mathbf{u}$ are the largest eigenvalue and the corresponding eigenvector of the network's adjacency matrix $\mathbf{A}$. A set S has high Sv if its elements have high eigenscore $\mathbf{u}(i)$ and are not connected to each other (zero $\mathbf{A}(i,j)$). A high eigenscore implies that their removal leads to a significant eigen-drop $\Delta\lambda$. The algorithm has a $O(n|S|^2)$ complexity, where n is the size of a network.

NetShield defines an *epidemic threshold* β' such that any edge transition probability $\beta > \beta'$ would result in a significant portion of the network being contaminated. The algorithm utilizes the fact that the *epidemic threshold* is related to the first eigenvalue of the network adjacency matrix as $\beta' = 1/\lambda$ [16]. Thus, λ expresses the *vulnerability* of the network to an epidemic. Tariq et al. [13] improved upon NetShield by approximating the eigen-drop, relying on the fact that λ can be expressed as the limit trace of the p-exponential adjacency matrix $\mathbf{A}$, which equals the number of p-sized closed walks in the graph, cw_p:

$$\lim_{p \to \inf, p \text{ even}} (trace(\mathbf{A}^p))^{1/p} = \lambda$$

$$trace(\mathbf{A}^p) = cw_p(G)$$

The proposed method greedily selects a set of nodes to block based on their contribution to closed walks, hence to network vulnerability, approximating cw_p by a submodular score function, calculated by partitioning vertices into α equal-size groups by means of a set of hash functions $i = \{1..\gamma\}$. In our experiments, we use $\alpha = 200$ and $i \in \{1..3\}$. The published version suggested using $p = 6$, yet in communication with the authors we confirmed that $p = 8$ feasibly leads to improved results; we refer to this algorithm as *Walk8*; its complexity is $O(n^2 + \gamma(n + \alpha^3) + nk^2)$.

Table 1: Default parameters for graph types

DAVA [21] accepts the seed set of a network diffusion as input and builds its NI solution around *dominator trees.* A node u *dominates* a node w w.r.t. a seed node s if all paths from s to w pass through u. A *dominator tree* is a tree where each node is dominated by its ancestors. The *benefit* of removing a node is calculated as $\gamma(v) = 1 + \sum_{u \in \text{children of } v} \gamma(u) \cdot p_{vu}$, where p_{vu} stands for the probability that influence propagates along *any* path, approximated via the *most probable* path, from v to u.

DAVA iteratively removes the node of highest benefit and reconstructs the tree. In a DAVA variant, DAVA-fast, the tree is built only once and top-k nodes are selected based on their benefit in one go. A dominator tree is built in $O(E \log N)$ [8].

NetShape [11] immunizes a network via a convex relaxation approach, maximizing the eigen-drop of the network's integrated and symmetrized *Hazard matrix*, a matrix of a continuous integrable transition rate functions $\{\beta(u, v, t)\}_{u,v \in V}$, which indicate the probability that v is influenced by u at time t after u gets infected. The first eigenvalue bounds the expected spread of an infection. We apply NetShape as a heuristic for the IC model, setting the integral of the transition rate $\beta(u, v, t)$ as equal to the influence probability between u and v, and minimize the first eigenvalue by the projected subgradient descent method in the space of possible Hazard matrices *after* immunization, while setting the effect of immunizing u on the integrated hazard matrix element as 0, if u is a seed. The complexity is $O(\frac{1}{\epsilon^2} p_{max}^2 E \ln E)$, where p_{max} is the maximum propagation probability, and ϵ is a parameter affecting a step of subgradient descent.

3 METHODOLOGY

Consider a directed graph $G = (V, E)$ with set of nodes V and set of edges E. Each edge is associated with a probability of propagation. By the *independent cascade* model, a diffusion occurs in discrete time steps. In step t_0, a *seed set* $S \subset V$ becomes *activated.* Any node v activated in step t_i attempts to activate each of its inactive neighbors in step t_{i+1}, and succeeds by the probability associated with the edge from v to that neighbor. The process terminates when there are no more newly activated nodes. The *Network Immunization* (NI) problem calls to *block* a select set of k nodes $R \subseteq V \setminus S$ so as to minimize the expected *spread* of activated nodes, by a given seed set S in a graph G.

3.1 Algorithms

We compare six solutions to the NI problem in three categories:

- **Naïve**: *Degree* selects the top-k nodes with highest degree; *Random* selects k nodes uniformly at random.
- **Preemptive**: *NetShield* [2] and *Walk8* [13],
- **Data-Aware**: *NetShape* [11] and *DAVA* [21].

On NetShape, we use the default $\epsilon = 0.2$. As exact spread computation is #P-hard, we estimate spread with any solution via 1000 Monte-Carlo IC simulations. We use the original Matlab code of Walk8. As seeds cannot be blocked, we fetch $k + |S|$ nodes to be blocked with Walk8, ensuring that at least k nodes are blocked. We implemented all other algorithms in Python[1].

3.2 Data

We use both synthetic and real data obtained as follows.

3.2.1 Synthetic Data. We generated graphs of different properties using five models. By the *Erdős-Rényi model*, each edge is present with probability p; generated graphs have a low clustering coefficient and a binomial degree distribution. We refer to this generator as **Binomial**. We render the graph directed by selecting a random direction for each edge with 50% probability.

A **Gaussian Random Partition** (GRP) [1] selects edges as with Erdős-Rényi, but with a prior grouping, where group size follows a Gaussian distribution; it uses a probability value p_{in} for edges across nodes in the same group, and p_{out} otherwise, hence varying intra-group and inter-group density.

Watts Strogatz (WS) networks model self-organizing small-world systems [17], which have small average shortest path length, and are highly clustered, hence susceptible to infectious spread. The generator employs two parameters: l indicates how many nearest neighbors each node is joined with in a ring; p is a probability of edge rewiring, which induces disorder.

Barabási-Albert (BA) networks have both high clustering coefficients (as GRP and WS graphs) and power-law degree distribution, hence are better imitations of real-world social networks. We use the algorithm of Holme and Kim [5], which extends the original Barabási-Albert model, yet use the BA label as its basis; this algorithm randomly creates m edges for each node in a graph, and for created edge with a probability p adds an edge to one of its neighbors, thus creating a triangle.

Grid graphs have each node connected to four neighbors on a lattice. With this graph type, we explore the applicability of solutions on spatial graphs such as geosocial contact networks [22].

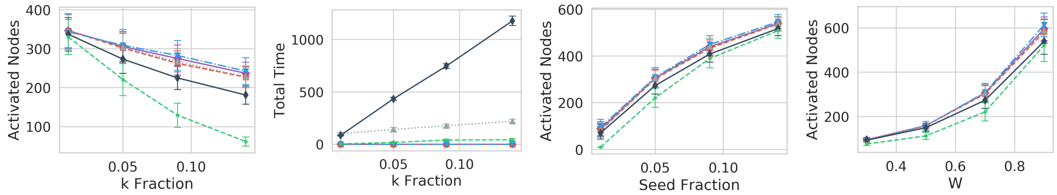

Figure 5: Experimental results on regular grids

Table 1 lists the default parameters for all models, where fractions $sf = |S|/|V|$ and $kf = k/|V|$. Figure 1 shows example graphs. All synthetic graphs have 1000 nodes, as in [16].

3.2.2 Real-World Datasets. We use 3 real-world graphs. Stanford and Gnutella, have been employed in related literature; a third, VK, provides a case of real-world propagation probabilities.

The **Stanford** data consists of pages and hyperlinks in the Stanford University website[2] [21]. The **Gnutella** peer-to-peer file sharing directed network is part of the SNAP dataset [9]. We use the biggest snapshot of 62586 nodes, with a diameter of 11 nodes and a clustering coeficient of 0.0055. It has been used in [11, 19, 21]. **vKontakte**[3] (VK) is a Russia-based social network of more than 500 million users[4]. Its public API allows to download information about public profiles, subscriptions, and posts. We fetch public posts of users to train the IC model.

3.3 Parameters

We consider **blocked node set size** k as a fraction of network size [15]. We employ *random* **seed selection** [3, 18, 21]; we pick 10 random seed sets, and show the mean and standard deviation of activated nodes. We choose **influence probabilities** uniformly at random from 0 to a maximum value W. We learn influence probabilities on the VK data using user posts as actions. We download 100 latest posts at the moment of publishing per user, resulting in 21M posts. Most posts are short, hence we can apply the same Natural Language Processing methods as for short messages. After preprocessing, we collected 536,073 non-empty messages belonging to non-isolated nodes in the VK graph, with median length of 11 words, std 187 and max 2977, leaving us with 3% of the original dataset. We define the closeness of actions by comparing the content of text messages, as in [7], to learn vector embeddings of short messages. We define term proximity as $p(w_2|w_1) = \frac{1}{|M|}\frac{c(w_1,w_2)}{c(w_1)}$, where M is a set of all posts with non-zero text content, $c(w)_m$ is the number of messages with w, and $c(w_1, w_2)$ is the number of messages with w_1 and w_2 present together. We learn stemmed term proximities and enrich the term frequency–inverse document frequency vectors of messages by increasing the probability of any words similar to words present in the message. We consider all message pairs with similarity above the median as similar. Scanning the action log to calculate the influence probability from a node u to any nove v as the ratio of successful reposts of similar messages. Filtering zero-probability edges, we select the largest component of 2.8K nodes and 40.9K edges as our VK network.

4 EXPERIMENTAL RESULTS

Here we present the results of our study. We set a timeout of 1h for all experiments for a single solver instance.

4.1 Synthetic Data

Figure 2 shows results with **Binomial** graphs. As the number of blocked nodes grows, DAVA's advantage of knowing the seeds becomes evident. Surprisingly, NetShield achieves better results than NetShape and Walk8 in this graph type. As the graph has a uniform structure, spectral-based algorithms do not perform well. This uniformity results in performance of algorithms not being dependent on the number of seeds and influence probability W. Still, as Figure 2c shows, with large W DAVA is slightly worse than preemptive approaches. DAVA assumes that the influence probability between two successive dominators in the dominator tree is equal to the probability along the shortest path. When there are many paths between two dominators, this assumption fails, hence the accuracy of the algorithm drops. We observe that NetShape is the least scalable algorithm.

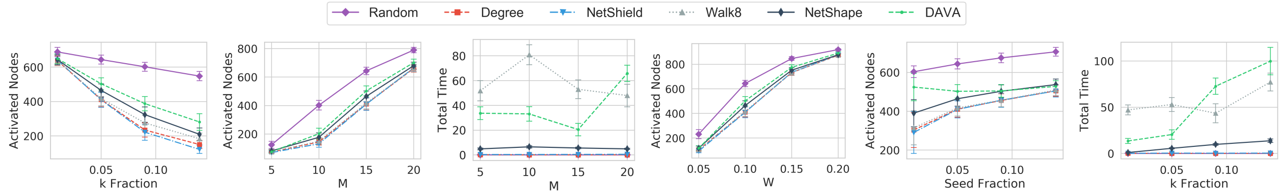

Figure 6: Experimental results on graphs generated by the Barabasi-Albert growth model

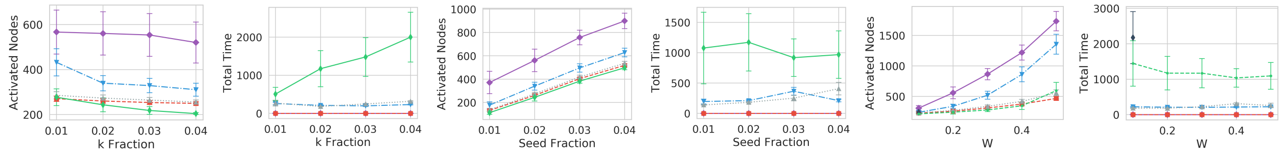

Figure 7: Experimental results on Stanford network

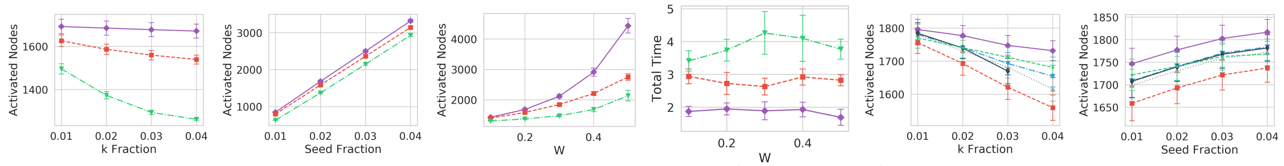

Figure 8: Experimental results on Gnutella (a-d) and VK (e-f) networks

Figure 3 shows results with **GRP** graphs. Again, the gap increases as k grows. DAVA achieves the best results on all parameters, except for the largest p_{out}. We observe that, as the inter-group probability p_{out} grows, DAVA shows slightly worse performance; in other words, as the graph forfeits its clustered structure, DAVA provides less accurate probability estimates.

Figure 4 shows results with **WS** graphs. Here, preemptive algorithms perform significantly better than DAVA, while the difference is accentuated as the number of blocked nodes k grows.

Figure 5 shows results with **Grid** graphs. All algorithms except DAVA fail to isolate seeds. NetShape outperforms other spectral approaches thanks to its data-awareness. Runtimes are similar to those in the Binomial case, with DAVA being sufficiently scalable.

Last, Figure 6 shows results with **BA** graphs; the degree heuristic and NetShield perform best. This result indicates that there are limits to the versatility of DAVA.

4.2 Real Data

Figure 7 shows results on the **Stanford** network. We employ the fast DAVA that builds a dominator tree only once so as to scale. Exploring a larger range of parameters than [21] reveals that DAVA performs similarly to the Degree heuristic, and slightly worse as W grows, due to the scale-free data topology. NetShape and Walk8 could not scale to such size. **Gnutella** has a more random topology than the Stanford network. Running on the 62K-node Gnutella snapshot, only fast-DAVA and baselines terminated within the time limit. Figure 8 shows the results, with DAVA reasserting its advantage. Our **VK** graph has high clustering coefficient and power-law degree distribution. Figure 8 shows that, on this data, DAVA is outperformed by preemptive methods. We deduce that, in real-world social networks, isolating diffusion sources is less critical than immunizing influence hubs.

5 CONCLUSIONS

We conducted an exhaustive experimental study of network immunization methods. We conclude that, while data-aware approaches stand out on networks with uniform topologies, spectral structure-based approaches are competitive on networks with power-law topologies. This result calls for further research.
