ABSTRACT
We present SparkER, an ER tool that can scale practitioners’ favorite ER algorithms. SparkER has been devised to take full advantage of parallel and distributed computation as well (running on top of Apache Spark). The first SparkER version was focused on the blocking step and implements both schema-agnostic and Blast meta-blocking approaches (i.e. the state-of-the-art ones); a GUI for SparkER, to let non-expert users to use it in an unsupervised mode, was developed. The new version of SparkER to be shown in this demo, extends significantly the tool. Entity matching and Entity Clustering modules have been added. Moreover, in addition to the completely unsupervised mode of the first version, a supervised mode has been added. The user can be assisted in supervising the entire process and in injecting his knowledge in order to achieve the best result. During the demonstration, attendees will be shown how SparkER can significantly help in devising and debugging ER algorithms.

1 INTRODUCTION
Entity Resolution (ER) is the task of identifying different representations (profiles) that pertain to the same real-world entity. ER is a fundamental and expensive task for Data Integration [2]. The naive solution of ER (i.e. comparing all profiles to each others) is impracticable when the data volume increases (e.g. Big Data), thus blocking techniques are employed to cluster similar records and to limit the number of comparisons only among the profiles contained in the same block.

In a real-world scenario, to identify a blocking strategy (i.e. the blocking key) yielding high recall and precision is a hard task [4]. In particular, in the Big Data context, schema-aware techniques have two main issues: (i) schema alignment, hardly achievable with a high heterogeneity of the data; (ii) labeled data to train classification algorithms, or human intervention to select which attributes to combine. To overcome these problems, the schema-agnostic approach was introduced [10]: each profile is treated as a bag of words and schema-information is ignored. For instance, Schema-Agnostic Token Blocking considers as blocking key each token that appear in profiles, regardless of the attribute in which it appears (Figure 1(b)). However, schema-agnostic methods produce a very low precision.

1 INTRODUCTION
Entity Resolution (ER) is the task of identifying different representations (profiles) that pertain to the same real-world entity. ER is a fundamental and expensive task for Data Integration [2]. The naive solution of ER (i.e. comparing all profiles to each others) is impracticable when the data volume increases (e.g. Big Data), thus blocking techniques are employed to cluster similar records and to limit the number of comparisons only among the profiles contained in the same block.

In a real-world scenario, to identify a blocking strategy (i.e. the blocking key) yielding high recall and precision is a hard task [4]. In particular, in the Big Data context, schema-aware techniques have two main issues: (i) schema alignment, hardly achievable with a high heterogeneity of the data; (ii) labeled data to train classification algorithms, or human intervention to select which attributes to combine. To overcome these problems, the schema-agnostic approach was introduced [10]: each profile is treated as a bag of words and schema-information is ignored. For instance, Schema-Agnostic Token Blocking considers as blocking key each token that appear in profiles, regardless of the attribute in which it appears (Figure 1(b)). However, schema-agnostic methods produce a very low precision.

So, to mitigate this problem, they are typically coupled with meta-blocking [6, 10, 13]. The goal of meta-blocking is to restructure a blocking collection by removing least promising comparisons. This is achieved in the following way: profiles and comparisons are represented as nodes and edges of a graph, respectively; each node is connected to another one if the profiles co-occurs in at least one block. Then, the edges are weighted on the basis of the co-occurrence of its adjacent profiles and for each profile a threshold is computed. Finally, the graph is pruned removing the edges which have a weight lower than the threshold. A toy example is shown in Figure 1(c): each edge is weighted counting the co-occurring blocks of its adjacent profiles, and is retained if its weight is above the average. The dashed lines are the removed comparisons.

In [13] we proposed Blast, which introduces the notion of loose schema information extracted from the data and composed of: (i) attribute partitioning and (ii) attribute partition entropy (Figure 2(a)). The idea beyond attribute partitioning is that more values two attributes share, more are similar, thus similar attributes are put together in the same partition. Then, the meta-blocking takes into account the generated attributes’ partitions: the blocking key is composed by tokens concatenated to partition IDs; in this way, the token “Simonini” (Figure 2(b)) is split into two tokens, disambiguating "Simonini" as author ("Simonini_1"), and

Figure 1: Schema-agnostic (meta-)blocking process.
“Simonini” as cited author; note that “Simonini_1” do not generate any block, since it appears only in p2.

![Loose schema information](image1)

**Figure 2: Metablocking with loose schema information.**

**Attribute partition entropy** computes the entropy of each cluster and gives more importance to the profiles that co-occur in blocks generated from clusters with high entropy. The idea is that finding equalities inside a cluster with a high variability of the values (i.e., high entropy) has more value than finding them in a cluster with low variability (i.e., low entropy). The attribute partition entropy is used to determine the block weights: each edge of the meta-blocking graph is re-weighted according to the entropy associated to the block that generates it (i.e., the entropy of the partition from which the blocking key belongs), as shown in Figure 2(c). This affects the meta-blocking by helping to remove more superficial comparisons than those removed by the schema-agnostic blocking (the two retained red edges of Figure 1(c) are now removed).

At the end of the pruning step, the meta-blocking produces the candidate pairs, i.e., pairs of profiles related to the same entity. Then, these pairs have to be resolved, i.e., it is necessary to decide if a pair is a true match or not, this task is called entity matching. Several techniques can be applied to perform this task, e.g., resolution functions, classifiers, crowdsourcing, etc. Finally, the retained matching pairs are clustered (entity clustering) in order to group together all the profiles associated to the same entity.

Several tools were proposed to cover the full Entity Resolution stack [9, 11]. In particular, JedAI [11] is more devoted to work with semi-structured data, a schema-agnostic approach, and the entity matching phase uses only unsupervised techniques (i.e., no labeled data are required). In contrast, Magellan [9] is meant to work with structured data and a supervised approach, so the user has to align the schema, to provide matches examples to perform entity matching, and supervise each step. Moreover, JedAI covers the entity clustering step, while Magellan not.

Nevertheless, none of these tools exploits the benefits of distributed computing. Works on the meta-blocking parallelization have been proposed [5], but they are implemented using Hadoop MapReduce, that is not the best paradigm to exploit modern cluster architectures [3, 12]. SparkER is an Entity Resolution tool for Apache Spark designed to cover the full Entity Resolution stack in a big data context.

**Our approach.** The first SparkER version [14] was focused on the blocking step and implements using Apache Spark both schema-agnostic [10] and Blast [13] meta-blocking approaches (i.e., the state-of-the-art ones). The description of the algorithms that we devised for Apache Spark (and any MapReduce-like system) can be found in our technical report [15]. Also, we developed a GUI for SparkER to let non-expert users to use it in an unsupervised mode.

The new version of SparkER that will be shown in this demo, extends significantly the tool. Entity matching and entity clustering modules have been added. Moreover, in addition to the completely unsupervised mode of the first version, a supervised mode has been added. The user can be assisted in supervising the entire process and in injecting his knowledge in order to achieve the best result.

In the following Section 2, we present the main modules that compose SparkER and in Section 3 the process debugging. Finally, in Section 4 we present the demonstration for the EdBT attendees.

## 2 SPARKER

SparkER is a distributed entity resolution tool, composed by different modules designed to be parallelizable on Apache Spark. Figure 3 shows the architecture of our system. There are 3 main modules: (1) **blocker:** takes the input profiles and performs the blocking phase, providing as output the candidate pairs; (2) **entity matcher** takes the candidate pairs generated by the blocker and label them as match or no match; (3) **entity clusterer** takes the matched pairs and groups them into clusters that represents the same entity. Each of these modules can be seen as black box: each one is independent from the other.

### 2.1 Blocker

Figure 4 shows the blocker sub-modules implementing the **Loose-Schema Meta-Blocking** method described in the introduction.

**Loose Schema Generator-Attribute Partitioning:** attributes are partitioned in cluster using a Locality-sensitive Hashing (LSH) based algorithm. Initially, LSH is applied to the attributes values, in order to group them according to their similarity. These groups are overlapping, i.e., each attribute can compare in multiple clusters. Then, for each attribute only the most similar one is kept, obtaining pairs of similar attributes. Finally, the transitive closure is applied to such attributes pairs and then attributes are partitioned into nonoverlapping clusters (Figure 2(a)). All the attributes that do not appear in any cluster are put in a blob partition.
2.2 Entity Matcher and Clusterer

Regarding Entity Matching, any existing tool can be used. In the demo we will show the one implemented in Magellan [9]. The Entity Matcher produces matching pairs of similar profiles with their similarity score (similarity graph). The user can select from a wide range of similarity (or distance) scores, e.g.: Jaccard similarity, Edit Distance, CSA [1].

The Entity Clusterer receives as input the similarity graph, in which the profiles are the nodes and the matching pairs represent the edges, and partition its nodes into equivalence clusters such that every cluster contains all profiles that correspond to the same entity. Several entity clustering algorithms have been proposed in literature [8]; at the moment, we use the connected component algorithm, based on the assumption of transitivity, i.e., if $p_1$ matches with $p_2$, $p_2$ matches with $p_3$, then $p_1$ matches with $p_3$. At the end of this step, the system produces clusters of profiles: the profiles in the same cluster refer to the same real-world entity.

3 PROCESS DEBUGGING

The tool can work in a completely unsupervised mode, i.e. the user can use a default configuration and perform the process on its data without taking care of the parameters tuning. Otherwise, the user can supervise the entire process, in order to determine which are the best parameters for its data, producing a custom configuration. Given the iterative nature of this process (e.g. the user try a configuration, if it is not satisfied changes it, and repeat the step again), it is not feasible to process the entire input data, as the user should waste too much time. Thus, it is necessary to sample the input data, reducing the size. The main problem is to take a sample that represents the original data, and also contains matching and non matching profiles. This problem was already addressed in [9], where the authors proposed to pick up some random K profiles $p^K$, then for each profile $p_i \in p^K$ pick up $k/2$ profiles that could be a match (i.e. shares a high number of token with $p_i$) and $k/2$ profiles randomly. K and k are two parameters that can be set by the user based on the time that she wants to spend (e.g. selecting more records requires a higher computation time).

Each step can be assessed using precision and recall, if a ground-truth is available; otherwise the system selects a sample of the generated profile pairs (e.g. pairs after blocking, matching pairs after matching, etc.) and shows them to the user who, on the basis of his experience evaluates whether the system is working well or not.

In the bblocker each operation (blocking, purging, filtering, and meta-blocking) can be fine tuned in order to obtain better performances, e.g. the purging/filtering are controlled through parameters that can change the aggressiveness of filters, or the meta-blocking can use different types of pruning strategies, etc. Moreover, if the Loose Schema Blocking is used, it is possible to see how the attributes are clustered together, and how to change the clustering parameters in order to obtain better clusters.

In the entity matching phase, it is possible to try different similarity techniques (e.g. Jaccard, cosine, etc.) with different thresholds.

At present no tuning activity is possible in the clustering step since the connected component algorithm used does not have any parameters. At the end of the process, the system allows to explore the generated entities and to store the obtained configuration. Then, the optimized configuration can be applied to the whole data in a batch mode, in order to obtain the final result.

4 DEMONSTRATION OVERVIEW

During the demonstration, participants will explore the features of our system on the Abt-Buy dataset\(^1\). It contains 2,000 products extracted from Abt.com and Buy.com catalogs, denoted respectively in red and blue. The dataset comes with a ground-truth that allows to analyze the performances of each SparkER step. Also, different datasets can be used\(^2\) during the demonstration.

In this demo we focus on showing the attribute partitioning unsupervised/supervised step, the use of Attribute Partition Entropy was illustrated in our previous paper [7] and the meta-blocking step including entropy.

The tool displays the attributes partitions, recall/precision, the number of blocks (blocking keys) generated, the number of candidate pairs in the blocks, and the number of false positives (i.e. the pairs that are in the ground-truth but are lost during the blocking process) obtained after blocking. Through the interface it is possible to modify the clustering threshold and other parameters (Advanced settings) which influence the algorithm in a more marginal way.

We start setting the threshold to the maximum value (1) e.g a schema-agnostic token blocking is applied and all the attributes fall in the same blob cluster (Figure 6(a)). Then the user decreases the threshold (0.3) and looks at what happens (Figure 6(b)). Two clusters are created, representing, respectively the name with the

\(^{2}\)The datasets are available at: https://sourceforge.net/projects/sparker/files/datasets/
description, and the prices of the products. However, we see how precision slightly increases but the number of candidate pairs has been reduced.

Now, the user try to modify the clusters, as apparently separating the attributes that refer to the name from those which refer to the description of products (Figure 6(c)) seems a good idea. He looks at the result and sees that unfortunately the number of false positive increases.

By the Debug button it is possible to understand where the false positives come from (Figure 6(d)). The tool shows the list of false positive pairs (i.e. pairs that are in the ground-truth but are not present after the blocking). By clicking on a pair, its profiles and shared blocking key are shown and the user can understand why this pair was lost. In the example we can see that the lost pairs match on blocking keys referring to the name and description attributes. So, partitioning descriptions and names was a wrong choice and the automatic solution proposed by the tool was better (Figure 6(b)). Moreover, it suggests that the choice of partitioning the attributes on the bases of their names (i.e. exploiting schema information) can be wrong.

Finally, Figure 6(e) shows the debugging of the meta-blocking phase, with the Entropy’s values obtained by the Entropy Extractor module. We can see a large decrease in the number of candidate pairs w.r.t. 6(b) thus proving the effectiveness of our technique.
