ABSTRACT

Schema mapping generation identifies how data sets can be combined to create views that are relevant to an application. Where the data sets to be combined lack declared relationships, such as foreign keys, schema mapping generation can be considered to be in the wild. In this paper, we describe an approach to schema mapping generation in the context of open government data, in particular, the London Datastore. Mapping generation is informed by inferred profiling data about the data sets and their relationships, where the data sets are made available as csv files. We outline the mapping generation algorithm, and describe a demonstration of the approach, in which the user can: (i) specify the target to be populated by the generated mappings over a collection of sources from The London Datastore; (ii) browse the generated candidate mappings and the evidence that informed their creation; and (iii) steer the mapping generation process, to make use of preferred sources and dependable profiling results.

1 INTRODUCTION

Given a collection of source datasets, some metadata about them, and a target schema, schema mapping generation produces a collection of views that provide ways of populating the target from the sources. Mapping generation is important because the data of relevance to an application or an analysis is often not immediately available in a single, suitable, integrated form.

Most work on mapping generation has assumed that the source and the target benefit from declared constraints, for example in the form of primary and foreign keys (e.g., as in the seminal work on Clio and its descendents, as reviewed in [5]). However, with the growing availability of open data sets, and the emergence of data lakes, mapping generation over independently produced data sets, with minimal explicit metadata, is arguably even more necessary than for well-defined schemas.

We refer to mapping generation over data sets without declared relationships as in the wild. Mapping generation must, among other things, take into account relationships between data sources, and, in this paper, we assume that candidate keys and (partial) inclusion dependencies have been inferred through data profiling [1]. Then, to deploy schema mapping generation in the wild, the following are required:

(1) A way of exploring the space of candidate mappings. We use a dynamic programming algorithm to identify promising mappings, referred to as Dynamap [8].

To show (1) to (3) in practice, we demonstrate our mapping generation algorithm, and its associated user interface, in use with data from The London Datastore1, which provides hundreds of data sets providing diverse information about London.

The remainder of the paper is structured as follows. Section 2 provides some details on The London Datastore. Our mapping generation approach is reviewed in Section 3. The demonstration in Section 4 shows an example of viewing a generated mapping and understanding it based on its properties and the evidence based on which it was created. The user can steer mapping generation based on the presented information. Section 5 concludes.

2 OPEN DATA CASE STUDY: THE LONDON DATASET

Open government data is published in a collection of national, regional, city or topic-based portals, with a view to increasing transparency and informing decision making [3]. The London Datastore is a representative example of a city data repository, providing data sets across a range of topic areas, including transport, employment, housing, health and education. These datasets come from a variety of publishers, including local and national government departments, and many of the data sets use consistent, generous licenses. The London Datastore supports both search and browse interfaces, and allows data sets to be downloaded in a variety of formats.

The demonstration uses comma-separated-value file data sets, released under the UK Open Government License2. Typically files contain from a few tens of rows (e.g., there are numerous data sets that have one row for each London Borough, of which there are 33), to a few thousand rows (e.g., there are around 5000 rows in a data set of modelled household income estimates at a particular, rather fine, area granularity). There may be few (e.g., 2) to many columns in each table (e.g., there are hundreds of columns in a ward atlas table, describing different properties of an electoral ward).

3 MAPPING GENERATION IN DYNAMAP

In this section, we illustrate mapping generation in Dynamap with an example over The London Datastore.

The problem and some evidence. The problem is that of generating a set of mappings that populate a target table from a set of source tables. The target table definition provides only the names of the columns, and the source table definitions contain only column names and their associated values. Mapping generation techniques have been developed that use different types of evidence, including declared constraints [5], data examples [2] and feedback [4]. In Dynamap, the evidence used to inform mapping generation is matches between source and target attributes, and (partial) inclusion dependencies, both of which can be inferred via a web interface; our goals are to demonstrate:

- Given some source datasets, define a target and browse over the sources that are input to the system.
- Define a target and browse the available sources.
- Based on the detected profile data on the represented sources: 10 inclusion dependencies, the mapping generation system can detect that the Area/Borough profiles from tables with intermediate mappings containing two tables, etc. For example, in Figure 1, a first step could be to merge Indices of deprivation with London borough profiles by joining on Area attributes, and then, their result intermediate mapping could be merged further with the crime rates table through join on either Code or Area/Borough attributes.

Annotating candidate mappings. As the search must combine pairs of intermediate mappings, we need to know the candidate keys of candidate mappings and their (partial) inclusion dependencies. These need to be derived during the search process, as it is not computationally viable to evaluate (i.e., materialize) every candidate mapping and run a profiler on it. The derived profile information is also used to compute a fitness, which represents the predicted fraction of complete rows. Formulas have been developed for propagating profiling data through unions and joins [8]. For example, in Figure 1, after joining Indices of deprivation with London borough profiles on Area, their corresponding inclusion dependencies and candidate keys are propagated such that it shows the relationship between the newly created intermediate mapping and the crime rates table. Based on this propagated profiling data, the mapping generation system can detect that the new mapping will produce Area and Code values that are overlapping with Borough and Code in crime rates, thus, it concludes that they can be joined on one of the overlapping attribute pairs.

4 DEMONSTRATION

Mapping generation in the wild will be demonstrated through hands-on experience generating and examining mappings over datasets from The London Datastore, in the context of the Data Preparer data integration and cleaning platform, a descendent of the VADA Architecture [7]. Users interact with the system via a web interface; our goals are to demonstrate: (i) how data profiling can be used to provide information about the properties of the data sets; (ii) how this evidence can be used by Dynamap to combine sources in plausible ways; (iii) how users can review the candidate mappings, and the evidence on which they are based; and (iv) how users can steer the mapping generation process, for example by excluding schema elements or profiling data that are not relevant to the result.

Figure 2 shows an example that extends the one in Figure 1 by adding to it three other sources containing data about house and population density, national insurance registrations, and statistics on the population from the local authorities. Although the demonstration will support different ways of using the system, one approach would involve the following steps.

Browse the available sources. The interface supports search and browse over the sources that are input to the system.

Define a target. The user can interactively name a target table and its attributes, or edit an existing target to add/remove attributes. The target table used throughout is that from Figure 1.

Generate mappings and view the result. Given some source tables and a target, the user can ask the system to generate a result.
which means running a matcher, a data profiler (for detecting candidate keys and partial/full inclusion dependencies), mapping generation and result display.

**View a candidate mapping.** From the result, the user can ask the system to explain how the generated mappings were produced. Each generated mapping has (i) a view that has the schema of the chosen target table and that shows how the target is populated once the mapping is executed (e.g., \(1\) in Figure 2), and (ii) a mapping explanation. Each mapping is explained through the help of a tree view where the user can understand in which order the sources were merged and which operators were used to merge them. Figure 2 shows how six sources are merged through five joins by a mapping. The root of the tree is the chosen target table and the leaves of the tree are the input sources merged by the mapping. The intermediate nodes represent the incremental build-up of the explained mapping, starting with the merge of the leaves (the sources) and reaching the target when all sources were merged or when no other merge opportunities could be identified. As mentioned in Section 3, the mappings are constructed in a bottom-up fashion, and this is shown by the tree representation, where each intermediate mapping has two corresponding nodes in the tree: (i) an operation node (e.g., \(3\) in Figure 2), and (ii) a L/R node (e.g., \(2\), \(4\), \(5\)). The operation node is used to show which was the chosen operation between the two operands, and (if present) the join condition. As explained in [8], the operations considered by Dynamap are union, (equi) join or full outer join; different combinations of profiling data lead to different operations, e.g., a candidate key whose attributes share a partial inclusion dependency can lead to a full outer join, while a full inclusion dependency can lead to a join. The L/R node shows whether the newly created intermediate mapping is the left or right operand in the next operation (if any). For example, in Figure 2, the national insurance table (\(1\)) is represented as the left operand (\(2\)) for the join operation represented in node \(3\).

**Understand a mapping.** For understanding mappings, the user can interact with the mapping explanation tree and drill down on the evidence that informed its creation. The interaction is done by clicking on the three types of nodes, i.e., leaf, L/R, and operation nodes, each revealing evidence for that merge step:

- **Leaf node.** Clicking on a leaf node leads to a snippet of the initial source that it represents. This helps the user understand the dataset information and whether it was semantically correct to merge it with the other sources in the mapping. This helps to decide whether to keep or discard a source from the search. For instance, after clicking on national insurance (\(1\)) a snippet appears (\(5\)). It can be observed from it that the source contains data about national insurance registrations, which is relevant to the chosen target that requires employment data.

- **L/R node.** Clicking on a L/R node shows information about each attribute of that intermediate mapping: (i) the target attribute

**Figure 2: Mapping explanation tree and associated information**
that it matches (if any), and (ii) the provenance of the distinct values in the attribute. The information about the value provenance is shown as set operations based on how the parent attributes were merged, e.g., the result of joined attributes contains the intersection of their values. This helps to understand if a match is inappropriate or if source attributes were incorrectly merged. In Figure 2, to understand how the national insurance source contributes to the target, the user needs to click on its corresponding L node (2), for which the information about the attributes appears (3) so they learn that this source contributes with both Area and NIN registration values to the target (highlighted in blue in 4). Node (3) is another example of L/R node that corresponds to the result of the join on Area between national insurance and indices of deprivation datasets (5). The attribute information for this intermediate mapping shows that its Area attribute contains the intersection of the values from Area attributes in national insurance and indices of deprivation, while the rest of the attributes are not merged.

**Operation node.** Clicking on an operation node shows the profiling data that was used to choose a certain merge operation. The information shown contains a table listing inclusion dependencies and another table for candidate keys. This helps decide whether the used profiling data is meaningful. In Figure 2, to understand how the national insurance dataset is merged with indices of deprivation, the user accesses the information about their merge by clicking on the corresponding operation node (3). This shows the profiling data that was used to decide their join on Area (6), which comprises two candidate keys on Area attributes in both sources that share one full inclusion dependency.

**Steer mapping generation.** Understanding the generated mappings can be crucial in the selection of proper mappings to populate a target. Thus, a user can understand if the chosen sources should be merged or not, or if Dynamoap was misled by any faulty matches or profiling data. After the user explores the mapping explanation and pins down any wrong decisions, they can alter through the interface the input that previously led to incorrect merges. The steering can be done through (i) adding/deleting source-to-target matches, e.g., remove those between a source attribute that represents a different concept than the one required by the target, (ii) removing misleading inclusion dependencies, e.g., remove those between semantically different source attributes that have common values, (iii) removing candidate keys on attributes which should not be keys, but were detected due to the (possibly) scarce data in the source, or (iv) removing unnecessary datasets from the search space. For example, in Figure 2, the merge opportunities that Dynamoap finds seem correct as all joined attributes are suitable pairs in terms of their meaning and value overlap. However, the snippet of the target (1) shows that many tuples have the same attribute values, for which only the Population values differ, indicating there might be an incorrect join with the source(s) that contributes to the Population attribute. By accessing the attribute information (7) corresponding to the last merge in the mapping (5) it is shown that the value provenance of Population is from the housing density source. The next step is to analyze the data in the source by clicking on the corresponding leaf node (8) for which a snippet of its extent (9) is shown. Analyzing the dataset fragment, it can be observed that the match is incorrect although the Population attribute in housing density has exactly the same name as the target, which makes it seem a correct match. The two attributes represent different types of population: in the source, the population information is per ward, not per area as required by the target. Thus, it can be concluded that the match is inaccurate. In such situations, it is not straightforward to differentiate between two (possibly close) semantic meanings, especially when the attributes contain numerical values. Learning about this incorrect match, the user steers the mapping generation process by discarding the Population match. After a new rerun of the mapping generation process with the updated input, the new resulting mappings produce sensible results in terms of aligned data per area. However, given that the housing density source does not contribute anything else to the target, it is automatically eliminated from the search space, thus, the new mappings do not involve it.

5 CONCLUSIONS

We have illustrated mapping generation in the wild with open data. Not only do we produce useful mappings, but also the system is transparent – the user can see what has been done, and steer the production of future mappings by altering and/or correcting the three types of input: inaccurate matches, misleading profiling data (candidate keys and inclusion dependencies), and unnecessary sources.

The problem of automated mapping generation might seem as an overly-engineered approach when the number of input sources is small and an expert user can hand-craft the mappings. However, the problem becomes increasingly complicated when tens or hundreds of sources are involved and they have a plethora of merge opportunities. Thus, automating mapping generation becomes an essential component for data integration. Moreover, given autonomous input sources, finding correct mappings completely automatically might become an infeasible task. This gives rise to the problem of understanding complex mappings that involve numerous, autonomous sources. Helping the user understand the mappings leads to steering the mapping generation process by providing proper input, based on which the system can make correct decisions.
